Abstract

This paper reports new experimental data and calibrated semi-empirical correlations concerning density and viscosity of aqueous solutions of Potassium Lysinate (LysK), a promising bio-based solvent for post-combustion CO₂ capture from flue gases, an application of relevance for industrial decarbonization. The analysis covers a LysK molality range in the solution from 2.16 m to 4.44 m, temperature intervals between 288.15 K and 358.15 K, and a CO₂ loading range of 0.3 molCO₂/molLysK – 0.98 molCO₂/molLysK. Newly collected experimental results supported the development and calibration of semiempirical correlations for density and viscosity of LysK solutions suitable to predict these thermophysical properties in the range of conditions tested. These models can predict the behaviour of the thermophysical properties investigated with high accuracy (for loaded solutions, average absolute deviation for density equal to 1.48 kg/m³ and for viscosity of 0.04 mPas) within the whole range of LysK concentration, temperature and CO₂ loading explored. Validation against literature data lying outside the calibration range shows an accuracy for density correlation $\leq 3\%$, while for viscosity model deviations are larger and vary between 1% and 15% of the measured value.

1 Introduction

Post-combustion capture (PCC) is a mature technological solution which may employ chemical solvents to separate CO₂ from flue gas streams. It is considered a benchmark CO₂ capture technology for industrial and low-carbon power production applications¹. Absorption by means of amine-based solvents has been already studied in the literature, with monoethanolamine (MEA) being widely employed at commercial scale². MEA aqueous solutions are characterized by fast CO₂ absorption rates and are available at a relatively low cost^{3,4}. However, the chemical absorption process is still affected by a non-negligible energy duty required for solvent regeneration, environmental impacts associated with amine volatility, equipment cost, corrosion and degradation issues.

Given the considerable margin of improvement in PCC, and the necessity for a fast and widespread deployment of CCS technologies, the focus of research is moving towards potentially more efficient and environmentally-compatible solvents. In recent years, amino acid salts (AAS) solutions have drawn some attention as an alternative of interest to be further investigated in the perspective of possible applications in CO₂ chemical absorption processes. Amino Acids are organic compounds characterized by the generic chemical structure NH₂-RCH-COOH, which contains a carboxyl group (-COOH), an amino functional group (-NH₂), and a side chain (R group) different for every amino acid. The amino acids salt solution is obtained by adding a strong base to an aqueous amino acid solution: the subsequent increase in pH allows the neutralization of the protonated amino group, increasing the aqueous solubility of the amino acid and enabling it to react with CO₂, with a mechanism of reaction in line with the zwitterion mechanism proposed for conventional amines⁵.

Specifically, potassium lysinate (LysK) is indicated in literature as one of the most promising amino acid solutions^{6,8,9}. At a concentration level of 43.7% mass fraction (4.21 m), LysK is expected to guarantee the same absorption capacity to that of 30% w/w MEA (benchmark solvent), and its fast kinetic when reacting with CO₂ may reduce packing requirements¹⁰ of the related absorption unit. The maximum CO₂ loading capacity and reaction kinetics of CO₂ absorption in LysK solutions, assessed through vapour-liquid equilibrium^{8,11} and bench-scale absorption tests¹⁰, seem to outperform MEA.

Despite this, there are still many open items like corrosion, thermal degradation, toxicity of relative by products and regeneration energy, which can represent a limitation to the use of AAS in CO₂ capture application via chemical absorption. Another topic of research is the formation of solid precipitate which may occur at high solvent concentration and high CO₂ loading. This phenomenon can negatively affect the CO₂ capture system by hindering the mass transfer and causing damages to the equipment. However, during the tests carried out in this and other works (Conversano et al.¹⁰), no solid precipitation has been reported. It is worth nothing that precipitation is a kinetically-controlled phenomenon, therefore the lack of observed precipitate can be a result of the duration of each experiment.

The design of a capture unit involves the definition of suitable rate-based modelling to evaluate mass and energy balance for the absorption column. Therefore, accurate correlations describing thermophysical properties like density and viscosity, are needed to carry out a suitable process design and a consistent performance evaluation of the process.

In effect, when acid gases (like CO₂) are transferred from gas to liquid (liquid to gas) across an interface that separates them, the resistance to mass transfer in each phase causes a concentration gradient in each of them. The model of "double film" of Whitman¹² is used to explain the behaviour of the absorption/desorption of acid gases in aqueous amine solutions. The mass transfer rate is proportional to liquid mass transfer coefficient, K_L (m/s) and the gradient of concentration of solute from the interface and the liquid.

$$N_A = K_L * (C_i - C) \quad \text{Eq. 1}$$

When chemical reactions occur in the bulk liquid phase, a (dimensionless) enhancement factor, E is introduced. Correlations are considered to estimate the mass transfer coefficient. The correlation is defined by $Sh = ARe^a Sc^b$. The Sherwood, Reynolds and Schmidt dimensionless numbers are calculated using Eqs. 2 to 4, respectively.

$$Sh = \frac{K_L L}{D} \quad \text{Eq. 2}$$

$$Re = \frac{\rho v L}{\mu} \quad \text{Eq. 3}$$

$$Sc = \frac{\mu}{\rho D} \quad \text{Eq. 4}$$

Where ρ is the density, μ is the dynamic viscosity, L the characteristic length (in our case the diameter of the magnetic stirrer), D the coefficient of diffusion (for CO₂ or H₂S) and v the speed.

In this context, according to Mota-Martinez¹³, the viscosity of the solvent employed in the CO₂ absorption process is one of the most relevant drivers for solvent selection. In fact, viscosity is one of the key properties affecting the interphase heat and mass transfer involved in chemical absorption, with direct consequences on the size of process units and on the performance and cost of the capture plant. Mota-Martinez¹³ calculate an increase of 5% in total annualised cost of the CO₂ capture process when increasing solvent viscosity by 20% compared with benchmark 51\$/t_{CO2} with a 30wt% MEA solution at 303 K. This is due to a significant reduction in the mass transfer of the gas in the liquid phase for two reasons: slower diffusion of the solubilised gas through the gas-liquid interface, and less favourable hydrodynamics of the liquid film, especially the mass transfer coefficient¹⁴. As a matter of fact, the benchmark correlation by Onda et al.¹⁵ on liquid mass transfer (k_L) in a randomly packed column gives a 14% decrease in mass transfer coefficient when viscosity (μ) increases by 20% ($k_L \propto \mu^{-5/6}$). Besides, higher values of viscosity are associated with higher friction factors and pressure drops, thus an increase in auxiliaries power consumption is also expected^{13,14}. In turn, high values of solvent densities are linked with a cost reduction related with the solvent circulation system (e.g. pumps and pipes)¹³.

Potassium lysinate is a relatively novel solvent, thus a limited number of studies and very few experimental data are available in the scientific literature. Thermophysical properties of LysK, such as densities, viscosities, specific heat capacity, thermal conductivity, surface tension, have been investigated by several research groups¹⁶⁻²⁰, but there is still a lack of data especially for highly concentrated solutions, loaded solutions and at high temperature levels, typical of the regeneration section. To the best of authors' knowledge, there is only one work that has determined the effect of dissolved carbon dioxide on density and viscosity of LysK solutions, so far¹⁶. Table 1 reports, in chronological order, the experimental works on aqueous LysK density and viscosity that have been published so far, specifying solvent concentration, investigated temperature range and the eventual CO₂ loading of the solvent.

Table 1 Thermophysical properties of LysK solutions available in literature. The literature review included LysK molarity (M) [mol_{LysK}/L] and LysK molality (m) [mol_{LysK}/kg_{water}], CO₂ Loading [molCO₂/mol_{LysK}], temperature range [K].

*** @ 303.15 correspond respectively to 1.72 M, 2.35 M, 3.01 M

Therefore, additional experimental data covering an extended LysK concentration range as well as carbonated solutions are required for developing rigorous process simulations, rate-based models and techno-economic assessments, in order to better evaluate the potential of the solvent and further explore its application in CO₂ capture processes.

The objective of this work is to provide new experimental data regarding thermophysical properties of CO₂-loaded LysK solutions such as viscosity and density, covering a CO₂ loading range of around 0.3 – 1 molCO₂/molLysK, and a high LysK concentration range of 2.16 m – 4.44 m (where m is the molality in mol_{LysK}/kg_{H₂O}) referred to as a range of interest in previous studies¹⁰. Moreover, this article also aims at proposing and calibrating new semi-empirical correlations for density and viscosity, based on the new data collected.

The work is organized as follows: section 0 outlines the experimental campaigns, starting with the summary on rationale and motivations of the tests performed, a description of the experimental facility employed and the procedure for preparing LysK solutions. Section 3 presents the numerical results obtained during the experiments. Section 4 is dedicated to modelling and numerical data processing, including an overview on the models used to correlate experimental density and viscosity and the regression analysis. In section 5 the results obtained are discussed in terms of physical behaviour and dependencies of the measured quantities; the accuracy of the models developed is analysed and a comparison with literature data and the benchmark solvent is provided. Section 6 contains the main conclusions, possible improvements, and future perspectives to advance the state of the art of amino acid salts for CO₂ chemical absorption.

2 Material and methods

2.1 Solution preparation

The salts of amino acids are formed by adding an equimolar amount of a strong base to the amino acid under investigation. In this case, potassium hydroxide (KOH 85% purity) is added to a solution of deionised water and L-lysine (98% purity) to form potassium lysinate solutions. Water was purified by a Millipore system with a 0.22 µm membrane. A list of the chemicals used in this work is provided in Table 2.

To reach the target potassium lysinate concentration in water, weight measurements have been performed using an electronic analytical balance (Mettler-Toledo XS205) with an accuracy of 0.1 mg.

The aspects that affect the uncertainty of LysK concentration in the aqueous solution include the accuracy of the instrument (type-B uncertainty), the standard error of the mean linked to the repeatability of the weight measurements (type-A uncertainty) and the uncertainty related to the purity if the chemicals used. A detailed analysis of the uncertainty determination is provided in the Supporting Information (SI) file.

The CO₂-loaded solutions are obtained using a variable volume press under vacuum where the unloaded solution is introduced after being degassed. Afterwards, the desired amount of CO₂ is injected in the press from a separate vessel of known volume with constantly monitored pressure and temperature conditions via a pressure transducer ($u_B(P) = 3$ mbar) and a platinum probe ($u_B(T) = 0.02$ K). The initial and final densities of CO₂ in the intermediate vessel are then determined using the equation of state provided by Span and Wagner²¹ within the REFPROP database²² (Version 10.0), given initial and final pressure and temperature conditions. The number of moles of carbon dioxide loaded into the press can be calculated by measuring the density variation inside the CO₂ vessel:

$$n_{CO_2} = V_{vessel} * (\rho_1 - \rho_2) * \frac{1}{M_{CO_2}} \quad \text{Eq. 5}$$

The values of CO₂ densities (ρ_1, ρ_2), in kg/m³ depend on vessel pressure and temperature, while V_{vessel} and M_{CO_2} indicate, respectively, the volume of the vessel (m³) and the molecular weight of carbon dioxide (kg/mol). To completely dissolve CO₂ in the amino acid solution and to guarantee monophasic liquid phase, the two components are compressed inside the press using an external gas bottle with pressurized nitrogen at a pressure greater than the bubble pressure of CO₂ (0.5 Mpa for several hours).

Uncertainty on the number of moles of CO₂ can be derived by applying the formula of the combined uncertainty to Eq. 5, knowing the accuracy of the equation of state by Span and Wagner provided in their work²¹. As described in the SI file, the combination of the uncertainty on LysK concentration and on the number of moles of CO₂ dissolved gives the final uncertainty value on the CO₂ loading of the solution.

Table 2: List of the chemicals used in this work along with the vendor, molecular weight (M), purity and molecular structure.

Chemical	Abbreviation	CAS number	Source	M [g/mol]	Purity ^a [% w/w]	Chemical structure

2.2 Summary of the experimental campaigns

The LysK concentration level in the aqueous solutions investigated in this work ranges from 2.16 m to 4.44 m. In total, five different LysK molality concentrations in aqueous solutions have been tested during the experimental campaigns, and their values are listed in Table 3 together with the corresponding uncertainties.

The procedure used to estimate the uncertainty on LysK concentration is explained in paragraph 1 of the Supporting Information (SI) file.

Table 3: Concentration level (molality $\text{mol}_{\text{LysK}}/\text{kg}_{\text{water}}$) of the LysK solutions tested in this work and the standard uncertainty value $u(w)$.

LysK concentration level [$\text{mol}_{\text{LysK}}/\text{kg}_{\text{water}}$]	2.16	2.93	3.65	4.21	4.44
Standard uncertainty on LysK concentration in solution $u(w)$ [$\text{mol}_{\text{LysK}}/\text{kg}_{\text{water}}$]	0.10	0.10	0.13	0.13	0.11

An overview of the experimental campaigns carried out is reported in Table 4. For all the five different LysK concentrations, thermophysical properties of the unloaded solution have been studied. For what concerns CO_2 -loaded solutions, the experiments focused on a LysK mass fraction of 43.7% (4.21 m), indicated in literature as a promising concentration level to obtain the same absorption capacity as the benchmark solvent 30% MEA¹⁰. The explored temperature and loading ranges reflect the conditions envisaged during the capture processes (avoiding the region in which solid precipitation may occur), in the absorber². Therefore, CO_2 loading varies between 0.3 and around 0.9 $\text{molCO}_2/\text{molLysK}$.

Table 4: Summary of the experimental campaigns carried out on thermophysical properties of LysK solutions (concentration level expressed in molality m)

	LysK molality values investigated [m]: 2.16 – 2.93 – 3.65 – 4.21 – 4.44		LysK molality value investigated: 4.21 m	
	Density Measurements	Viscosity Measurements	Density Measurements	Viscosity Measurements
CO_2 Loading range [$\text{molCO}_2/\text{molLysK}$]	0	0	0.29 - 0.98	0.33 - 0.81
Temperature range [K]	288.15 - 343.15	293.15 - 343.15	293.15 - 358.15	293.15 - 343.15

2.3 Density measurements

The Anton Paar DSA 5000 M density meter is used to determine densities of LysK solutions. The working principle of the densimeter is based on the oscillating U-shaped tube method²³. Once the sampled liquid is introduced in the measurement cell, the U-tube is vibrated at its characteristic frequency, while optical pickups observe its changes which depend on the density of the solution. The latter is determined via the following mathematical model²⁴:

$$\rho = K_A * Q^2 * f_1 - K_B * f_2 \quad \text{Eq. 6}$$

Where ρ is the density in gcm^{-3} , K_A and K_B are specific constants of the instrument, Q is the quotient of the period of oscillation of the U-tube divided by the period of oscillation of the reference oscillator, f_1 and f_2 are correction terms for temperature, viscosity and non-linearity.

Temperature is controlled by two Pt 100 thermometers and Peltier elements, with an accuracy guaranteed by the manufacturer of 0.01 K and a maximum temperature level of 343.15 K.

For CO_2 -loaded solutions, Nitrogen at 0.5 MPa is used as pressurising agent to move the piston of the variable-volume press and make the loaded solution flow inside the measurement cell of the densimeter. A scheme describing the connection between the cell containing the CO_2 loaded solvent and the measurement cell of the densimeter is graphically represented in Figure 1.

A new version of the Anton Paar DSA 5000 M, able to measure up to 363.15 K, but featuring the same accuracy, operating principle and configuration as the previous one, is employed for this purpose.

The density measurements of unloaded LysK solutions were performed in three different cycles to check their repeatability.

As a result, the uncertainty u is determined with Eq. 7:

$$u = \sqrt{\left(\frac{u_{RB}}{\sqrt{3}}\right)^2 + \left(\frac{s}{\sqrt{N}}\right)^2} \quad \text{Eq. 7}$$

Where u_{RB} is the accuracy of the densimeter (type-B uncertainty), s is the standard error of the mean (type-A uncertainty) of the three different measurement cycles (N).

2.4 Viscosity measurements for unloaded LysK solutions

The viscosity measurements have been carried out using an Anton Paar LOVIS 2000 ME viscometer. It is a modular instrument to be coupled with a densimeter; in this case it is coupled with the Anton Paar DSA 5000 M density and sound velocity meter. The solution sample under testing is filled into a glass capillary (diameter of 1.59 mm) which is introduced into a temperature controlled capillary block. This block can be inclined at a variable predefined angle according to the calibration performed. The capillary had already been calibrated with appropriate standard fluids²⁵.

The LOVIS 2000 ME viscometer is based on the falling ball method: by measuring the falling time of a steel ball in the capillary tube filled with the sample fluid and inclined at different angles, it automatically provides the viscosity value for the specified temperature level. The equation governing this principle (i.e. the calibration curve of the instrument) is the following²⁵:

$$\mu = K_1 * (\rho_K - \rho_S) * t_1 \quad \text{Eq. 8}$$

where μ is the dynamic viscosity of the sample solution in mPas; K_1 is the calibration constant of the measuring system; ρ_K is the ball (steel) density in gcm⁻³; ρ_S is the sample density in gcm⁻³, measured by the instrument, and t_1 is the rolling time in seconds²⁵. The DSA 5000 M density meter and LOVIS 2000 ME viscometer are not equipped with pressure transducer. In consequence, the value of atmospheric pressure is given by GE Druck DPI 142, Precision Barometric Indicator with an accuracy of $u(P) = 0.035$ kPa.

The same procedure used to evaluate the experimental uncertainty on the density values, is also employed for the viscosity measurements of LysK unloaded solution. The full calculations are reported in the SI file paragraph 4.

2.5 Viscosity measurements for CO₂ loaded LysK solutions

The instrument used for the viscosity measurement of potassium lysinate loaded solutions is the Flucon QVis 01/L²⁶. It is a vibrating quartz viscometer that transduces the viscosity of the surrounding fluid into the resonance frequency of an oscillating quartz sensor. The torsional oscillation is caused by the creation of an electrical field: the oscillation of the sensor produces a high frequency shearing (approx. 56kHz) of the measuring sample. The dampening of the system is mainly influenced by the viscosity of the liquid sample. A scheme of the experimental test bench is reported in Figure 2. The quartz sensor is inserted in a cell, of around 20 mL volume, immersed in an isothermal water bath with temperature control ± 0.1 K. A platinum probe and a pressure transducer allow for the measurement of pressure and temperature conditions of the fluid inside the cell. The CO₂-loaded solution is introduced in the measurement cell by means of a press, pushed by nitrogen at 0.5 MPa. The circuit is completed with a vacuum pump which provides the necessary vacuum conditions inside the cell before starting the measurements.

The Flucon QVis viscometer consists in a torsional quartz vibrator (TQV) that, when is immersed in a viscous medium, is able to measure the visco-elastic properties from the resonance frequency of the oscillating

sensor. According to Laesecke et al.²⁷, a purely torsional stress will produce purely shearing deformation in the fluid without any other displacement normally to the surface, thus, only the viscous-elastic effects have an influence on the oscillating frequency.

The working principle of a TQV is based on the equation derived by Webeler²⁷, and it gives the product between the dynamic viscosity and the density of the liquid sample:

$$\mu[\text{Pas}] * \rho[\text{kgm}^{-3}] = \left(\frac{m}{S}\right)^2 * (\pi f) * \left(\frac{\Delta f}{f} - \frac{\Delta f_0}{f_0}\right)^2 \quad \text{Eq. 9}$$

Where m is the mass of the quartz crystal (kg), S is the surface area exposed to the viscous medium (m^2), f is the resonance frequency under test conditions (Hz), Δf is the associated bandwidth of the resonance curve under test conditions (Hz), f_0 and Δf_0 are, respectively, the resonance frequency and its associated bandwidth in vacuum conditions (Hz).

Therefore, from the values of resonance frequency measured by the instrument it is possible to predict the viscosity of the solution sample under test conditions, by means of a suitable empirical correlation. This logarithmic relationship, reported in Eq. 10, is derived from the model of TQVs reported in Eq. 9, to which a term describing temperature influence is introduced, together with the density factor from Eq. 9, and with two terms expressing the relationship with frequency f . The frequency dependence is described by a linear and sixth power polynomial contribution, chosen for their statistical representativeness. Other factors, such as Δf , m or S could not be included in the model because they are not available from the instrument datasheet, nor they could be directly measured. This approach is required since the liquid viscosity not only depends on the resonance frequency but also on the density of the solution. As a result, the following empirical correlation, more practical than Eq. 9, is used as calibration curve for the TQV viscometer:

$$\mu(f, T, \rho) \rightarrow \ln(\mu/\text{mPas}) = A + \frac{B}{T} + C * f + D * f^6 + E/\rho \quad \text{Eq. 10}$$

Where μ is the viscosity in mPas, T is the temperature in Kelvin, f is the resonance frequency (Hz) of the vibrating quartz cell and ρ is the density in gcm^{-3} , \ln represents the natural logarithm.

The model includes numerical coefficients ($A - B - C - D - E$) which are fitted using the viscosity data measured with the falling ball viscometer related to unloaded LysK solutions (presented in 2.4): the resonance frequency is measured for unloaded solutions (4.44 m, 4.21 m, 2.16 m, 2.14 m LysK molality) under the same conditions reported in Table 4 (left column) and, via linear regression against the experimental viscosity, the values of the model parameters ($A - B - C - D - E$) which minimise the deviation between the model and the data are obtained; these values are reported in Table 5 with the standard deviations.

The pressure transducers have been calibrated against a PACE 5000 Modular Pressure Calibrator (GE Sensing France). The accuracy of the pressure transducer is ± 0.0002 MPa. The viscometer cell temperature is measured by one four-wire Pt100 Platinum Resistance Thermometer probe calibrated against a reference four-wire PT-25 Platinum Resistance Thermometer probe (PT-100). The 25 Ω reference platinum resistance thermometer (TINSLEY Precision Instruments) was calibrated by the Laboratoire National d'Essais (Paris) based on the 1990 International Temperature Scale (ITS 90). The results accuracy for temperature is not higher than ± 0.03 K.

Once the relationship between the resonance frequency of the quartz crystal and the viscosity of the liquid is established, it is then possible to measure the resonance frequency of a CO_2 loaded LysK solution and to convert it into the corresponding value of viscosity via this correlation. The density of CO_2 -loaded solutions is evaluated with a suitable empirical correlation, previously calibrated on volumetric measurements made available by the Anton Paar densimeter (see Section 4 for more details).

The accuracy of the calibrated model of the TQV (i.e., Eq. 10), expressed as the capability to reproduce the experimental data obtained from the falling ball viscometer is highlighted in the parity plot in Figure 3 (reporting the matching between the experimental data and the model results) and in SI paragraph 3. As it is displayed in Figure 3 and Figure S1 (plot of residual), once the resonance frequency of the quartz sensor, the temperature of the system and the density of the solution are known, the model can provide accurate results. For the entire range of frequencies tested, the maximum absolute value reached by the residual function, defined as the absolute deviation between the experimental viscosity and the calculated one, is 0.06 mPas (for experimental results ranging from 0.96 to 7.60 mPas).

Table S1 in SI paragraph 3 summarises the numerical values of the quantities (density and viscosities) and parameters (frequency) used to calibrate the coefficients of Eq. 10, and, for each test condition, it compares the values of experimental viscosity (from the falling ball viscometer) vs the ones calculated with the calibrated model.

Since the viscosity values for CO₂ loaded LysK solution are derived from a semi empirical correlation that reproduces a calibration curve of the quartz viscometer, the sources of uncertainty will be of different nature. They include: (i) the accuracy of the calibration performed (deviation between experimental data and model results), (ii) the intrinsic uncertainty of the experimental values used for the calibration and (iii) the uncertainty linked to the standard deviation of the model parameters of Eq. 10. A more detailed analysis on the uncertainty determination is given in SI paragraph 4.

Table 5: Values of the model coefficients used for the calibration of the Flucon QVis quartz viscometer.

	A	B [K]	C [Hz ⁻¹]	Dx10 ⁷ [Hz ⁻⁶]	E
Values	14.54	1228.76	-0.28	7.17	-17.07

3 Experimental results

In this section, the numerical values of densities and viscosities obtained during the experimental campaigns are presented, both for unloaded and for CO₂ loaded LysK solutions, and they are associated to the corresponding uncertainty values (u).

3.1 Density and viscosity of unloaded LysK solutions – Experimental data

The measured thermophysical properties of unloaded LysK solution are reported in Table 6 and Table 7. These data refer to three different measurement cycles of densities and viscosities inside the temperature range of 288.15 – 343.15 K (with a 5 K step), and for the five values of LysK concentration in the solutions indicated in paragraph 2.2. The uncertainty on the experimental data is calculated as a combination of a type A and a type B uncertainty (see paragraph 5 of the SI file for more information).

3.2 Density and viscosity of CO₂ loaded LysK solutions – Experimental data

Experimental data of density and viscosity for the loaded solutions are reported in Table 8 and Table 9 for each value of temperature tested and at the various CO₂ content in the solution reached. Density measurements of CO₂ loaded solutions were only performed once, so statistical dispersion is simply attributable to instrument accuracy (type B uncertainty). Uncertainty on viscosity is calculated with the formula for the combined standard uncertainty reported in ²⁸, which combines the uncertainty related with the falling ball viscometer, the one coming from the frequency – viscosity calibration and the standard deviations of the model parameters. The uncertainty on the CO₂ loading achieved is equal to 0.05 molCO₂/molLysK and it is the same for all the loadings obtained. It is determined following the procedure explained in paragraph 3 of the SI file.

Table 6: Experimental measurements for density of unloaded LysK solutions (concentration level expressed in molality m) \pm the corresponding calculated uncertainty values ($u(\rho)$) at the five different LysK concentration levels in the temperature range $T = (288.15$ to $343.15)$ K at 0.1013 MPa. $u(T)$ and $u(P)$ represent respectively the standard uncertainty on the temperature and pressure at which the measurements have been carried out.

Experimental densities of unloaded LysK solutions [gcm ⁻³] and combined standard uncertainty [gcm ⁻³]					
Temperature [K]	LysK molality in the aqueous solution (m)				
	2.16 m	2.93 m	3.65 m	4.21 m	4.44 m

4 Modelling approaches

4.1 Density of unloaded LysK solutions

To propose a suitable correlation to interpolate the density of unloaded LysK solutions as a function of temperature and concentration, the modified form of the empirical equation by Graber [30] is employed. It is an empirical correlation that has been already applied with good accuracy to other amino acid salts solutions, like α -aminobutyric acid, α -alanine, L-phenylalanine, serine^{29–32}. The equation is the following:

$$\rho[\text{gcm}^{-3}] = \exp(A_1 + A_2 * T^{0.5} + A_3 * w_{\%}^{0.5}) + A_4 + A_5 * w_{\%}^{0.5} \quad \text{Eq. 11}$$

Where ρ is the density, T is the absolute temperature [K], $w_{\%}$ is the mass fraction (% w/w) of LysK and A_j ($j = 1$ to 5) are the correlation parameters. The latter have been obtained by fitting the experimental data (60 points) with the equation above using the linear least square regression of the function lsqcurvefit in MATLAB® (version R2020b). They are listed in Table 10 with the corresponding standard deviation. The procedure to determine the standard deviation of the model parameters is explained in paragraph 4 of the SI file. In addition, the table reports statistical parameters which can give an indication on the performance of the model in reproducing the experimental data.

Table 10: Model parameters for the Graber equation with their relative standard deviations and relative statistical errors of the correlation. R^2 is the coefficient of the determination, ARD is the average relative deviation ($\frac{1}{N} * \sum_{i=1}^N \left| \frac{\rho_{exp} - \rho_{calc}}{\rho_{exp}} \right|$) and AAD is the average absolute deviation ($\frac{1}{N} * \sum_{i=1}^N |\rho_{exp} - \rho_{calc}|$).

	A₁	A₂	A₃ x10²	A₄	A₅x10²	R²	0.9993

Std. Deviation	0.52	0.03	1.33	0.01	0.05	AAD [gcm-3]	0.00054

4.2 Viscosity of unloaded LysK solutions

The Modified Vogel-Tamman-Fulcher (VTF) equation has been applied for a large number of amino acid salts solutions^{29–32} to model the viscosity of unloaded solutions as a function of temperature and AAS concentration. The model can be considered as an Arrhenius type asymptotic exponential function, where a second order temperature-dependent term is added to account for the characteristic behaviour of ionic systems³²:

$$\mu[mPas] = \exp\left(A_0 + \frac{A_1}{T} + \frac{A_2}{T^2}\right) \quad \text{Eq. 12}$$

As it is reported in the abovementioned works^{29–32}, the A_j parameters are assumed to be concentration-dependent. This approach has demonstrated higher accuracy in viscosity interpolation for different concentration values of the tested potassium lysinate solutions. As a result, the modified VTF equation becomes:

$$\ln(\mu/mPas) = (b_1 + b_2 w_{\%} + b_3 w_{\%}^2) + \frac{(b_4 + b_5 w_{\%} + b_6 w_{\%}^2)}{T} + \frac{(b_7 + b_8 w_{\%} + b_9 w_{\%}^2)}{T^2} \quad \text{Eq. 13}$$

Where $w_{\%}$ is the mass fraction of the amino acid salt. The parameters indicated as b_4 and b_9 showed little statistical representativeness in terms of model accuracy and performances. Thus, Eq. 13 can be simplified, as reported in Eq. 14:

$$\ln(\mu/mPas) = (b_1 + b_2 * w_{\%} + b_3 * w_{\%}^2) + \frac{(b_4 * w_{\%} + b_5 * w_{\%}^2)}{T} + \frac{(b_6 + b_7 * w_{\%})}{T^2} \quad \text{Eq. 14}$$

The model parameters are obtained from linear least square regression in MATLAB® (version R2020b) against the experimental data (60 points), using the lsqcurvefit function. The model parameters are reported in Table 11 together with their standard deviations.

Table 11: Values and standard deviations of the modified VTF parameters. Additional statistical errors of the correlation are reported in the table: R^2 is the coefficient of the determination, ARD is the average relative deviation ($\frac{1}{N} * \sum_{i=1}^N \left| \frac{\mu_{exp} - \mu_{calc}}{\mu_{exp}} \right|$) and AAD is the average absolute deviation ($\frac{1}{N} * \sum_{i=1}^N |\mu_{exp} - \mu_{calc}|$).

4.3 Correlation for density of CO₂-loaded LysK solutions

Experimental densities of the CO₂-loaded solutions have been correlated with the following equation:

$$\rho[gcm^{-3}] = K_0 + K_1 * \alpha_{CO_2} + K_2 * (\alpha_{CO_2})^2 + K_3 * T \quad \text{Eq. 15}$$

Where K_0 , K_1 , K_2 are the model parameters (Table 12), α_{CO_2} is the CO₂ loading in molCO₂/molLysK and T is the temperature [K].

The correlation was first proposed by Shen et al.¹⁶, and in the present paper we have modified it introducing a second order CO₂ loading dependent term that has been shown to improve the accuracy of the model and to better correlate experimental data. An equation able to model the density of CO₂ loaded solutions for a wide range of loadings and temperatures is necessary also to calculate the viscosity from the correlation developed between the resonance frequency of the quartz viscometer and the viscosity of the solution under investigation, as outlined in paragraph 2.5. Thanks to this correlation, it is possible to calculate, with reasonable accuracy, the density of LysK solutions at CO₂ loading values different from the ones tested experimentally, as in the case of the samples used to calculate the viscosity of CO₂ loaded solutions.

Table 12: Values and standard deviations of the parameter used to correlate the density of CO₂ loaded LysK solutions. Additional statistical errors of the correlation are reported in the table: R² is the coefficient of the determination, ARD is the average relative deviation ($\frac{1}{N} * \sum_{i=1}^N \left| \frac{\rho_{exp} - \rho_{calc}}{\rho_{exp}} \right|$) and AAD is the average absolute deviation ($\frac{1}{N} * \sum_{i=1}^N |\rho_{exp} - \rho_{calc}|$).

4.4 Correlation for viscosity of CO₂-loaded LysK solutions

A similar correlation is applied to the viscosity values for CO₂ loaded LysK solutions, and it is presented below in Eq.16. It is a modification of the correlation proposed by Shen in the already mentioned work¹⁶, since an additional quadratic term describing the dependence of viscosity on CO₂ loading has been added to improve the fitting, with the same approach used for density. The temperature-dependent term of the viscosity model is a derivation of the Arrhenius equation. This model will be helpful for predicting the viscosity in the CO₂ loading and temperature ranges tested.

$$\ln(\mu/mPas) = a + \frac{b}{T} + c * \alpha_{CO_2} + d * (\alpha_{CO_2})^2 \quad \text{Eq. 16}$$

Table 13: Values and standard deviations of the parameter used to correlate the viscosity of CO₂ loaded LysK solutions. Additional statistical errors of the correlation are reported in the table: R² is the coefficient of the determination, ARD is the average relative deviation ($\frac{1}{N} * \sum_{i=1}^N \left| \frac{\mu_{exp} - \mu_{calc}}{\mu_{exp}} \right|$) and AAD is the average absolute deviation ($\frac{1}{N} * \sum_{i=1}^N |\mu_{exp} - \mu_{calc}|$).

5 Discussion

In the context of experimental research on thermodynamic and physical properties for pure substances or mixtures, it is always a good practice to compare the results obtained with the literature values when available. The measurements carried out in this work on unloaded LysK solutions have been compared with the literature data taken from the works of Bian et al.¹⁸ and Suleman et al.²⁰, and the results are plotted in Figure 4 and Figure 5. The diagrams reflect the fact that there exist still significant deviations between the data reported. However, when comparing solution with an equal LysK concentration (3.65 mol_{LysK}/kg_{water}) the maximum relative percentage error calculated is 1.16% for density and 14.5% for viscosity, therefore providing indications of a good accordance between the sets of data.

Figure 4: Comparison of experimental data on density at 303.15 K of LysK solution at various molality concentrations (□ this work, Δ Bian et al.¹⁸, ○ Suleman et al.²⁰).

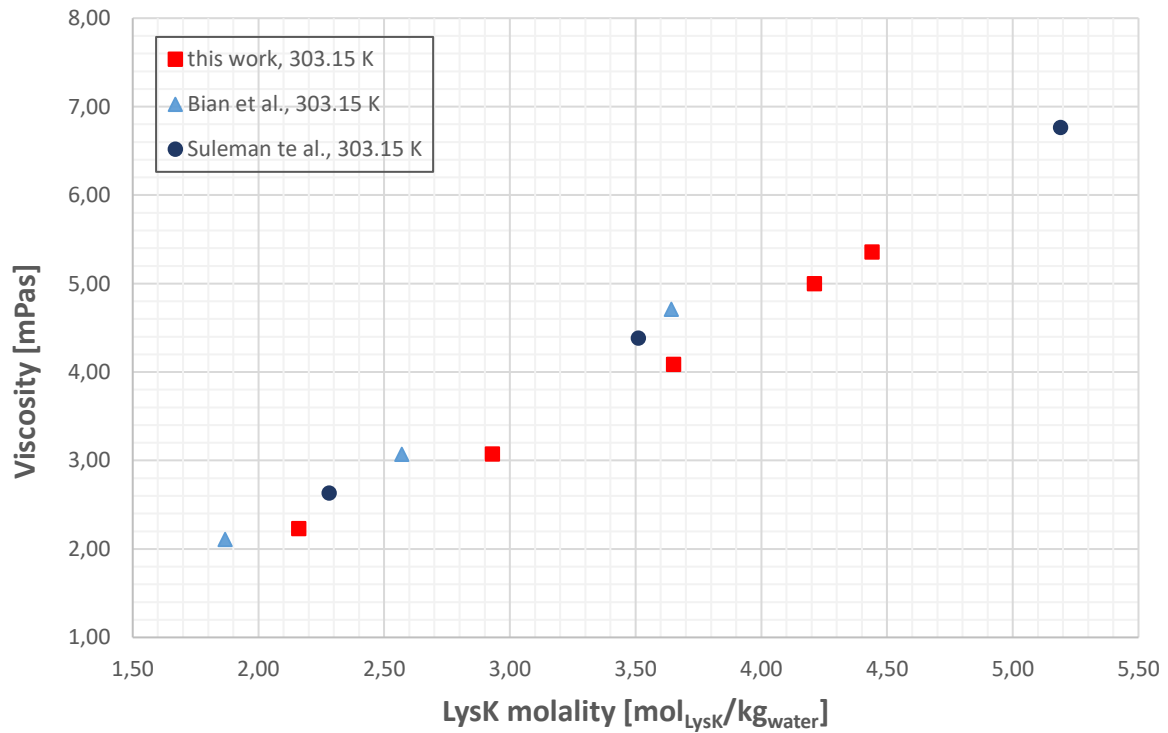

Figure 5: Comparison of experimental data on density at 303.15 K of LysK solution at various molality concentrations (□ this work, Δ Bian et al.¹⁸, ○ Suleman et al.²⁰).

The experimental data obtained in this work have been used to calibrate the models presented in paragraph 4. These correlations are able to reproduce the behaviour of density and viscosity of LysK solutions as a function of the AAS concentration, temperature and CO₂ loading. As expected, both thermophysical

properties have the same trend: they decrease by increasing the temperature of the system, while they increase with the AAS concentration and the CO₂ loading in solution.

For unloaded solutions in particular, the temperature of the system and the solvent composition seems to affect in a similar way the value of density: from two hypothetical absorber and regenerator temperatures (linearly extrapolated) and from least concentrated to most concentrated solution, the density variation is around 0.05 gcm⁻³. Viscosity of unloaded solutions exhibit a more complex behaviour: while for low values of LysK molalities moderate variations of viscosity are registered with temperature changes, for highly concentrated solution viscosity tends to increase significantly, and not linearly, below 310-320 K, with a behavior similar to amine-based solvents³³.

Density of loaded solutions varies of 40 kg/m³ between 293 K and 358 K, regardless of the CO₂ content; this last factor causes an increase in the density value of 7% from the unloaded solution to a 0.98 molCO₂/molLysK loaded solution. The CO₂ loading in the LysK solvent displayed a strong impact on the viscosity trend: even moderate CO₂ levels (0.33 molCO₂/molLysK) result in viscosity values 2.5 times higher than the unloaded solution on average, while for high CO₂ concentration the average increase is almost 4 times higher. It is worth remarking that as the solution absorbs CO₂, its ionic strength increases significantly, leading to strong molecular interactions and this can explain the impeding of transport properties such as viscosity.

The authors would like to point out that during the experimental campaigns neither of the tested solution has formed a solid precipitate, even at the lowest temperature (288 K), highest loading (0.98) and solvent concentration considered (4.44 m).

For what concerns the modelling part of the work, the values of average absolute deviation (AAD) are 0.00054 gcm⁻³ for density and 0.0148 mPas for viscosity of unloaded solutions. The correlations developed for the CO₂ loaded solutions can reproduce the density and the viscosity with an AAD of 0.00148 gcm⁻³ and 0.04 mPas, respectively. As can be noticed from Figure 6, Figure 7, Figure 8 and Figure 9, models provide a good fitting of the experimental data, thus demonstrating the reliability of the thermophysical properties correlations adopted in the range of interest.

Figure 6: Experimental density (dots) and model predictions (lines) of unloaded LysK solutions at 2.16 m (○), 2.93 m (◻), 3.65 m (Δ), 4.21 m (◻), 4.44 m (◊) LysK molality from 288.15 K to 343.15 K.

Figure 7: Experimental density (dots) of CO₂ loaded LysK solutions at 4.21 m and model predictions (lines) from 293.15 K to 358.15 K. The 4 different CO₂ loadings are 0.29 (○), 0.49 (◻), 0.78 (Δ), 0.98 (◻) mol CO₂/mol LysK; it is reported also the density of the unloaded solution at 43.7% w/w (◊).

Figure 8: Experimental viscosity (dots) and model predictions (lines) of unloaded LysK solutions at 2.16 m (○), 2.93 m (■), 3.65 m (Δ), 4.21 m (□), 4.44 m (◇) LysK molality from 288.15 K to 343.15 K.

Figure 9: Experimental viscosity (dots) of CO₂ loaded LysK solutions at 4.21 m and model predictions (lines) from 293.15 K to 343.15 K. The 3 different CO₂ loadings are 0.33 (□), 0.54 (Δ) and 0.81 (■) mol CO₂/mol LysK; it is reported also the viscosity of the unloaded solution at 43.7% w/w (○).

To further extend and verify the applicability of these models for predictive purposes, outside their calibration range, validation against literature data presented in the work of Suleman et al.²⁰ is conducted. Experimental data-set reported by Suleman involve density and viscosity measurements of unloaded LysK solutions of 2.28 m, 3.51 m and 5.19 m, temperature range $T = (303.15 \text{ to } 343.15) \text{ K}$. The results are presented in the parity plots below (Figure 10 and Figure 11) where the values calculated by the models are plotted against the literature values. For density, the agreement between the model and literature data is very good, with discrepancies lower than 3% of the measured value. For viscosity, deviations increase, but the great majority of the points are included within $\pm 10\%$ relative error range, hence indicating a good applicability of these equations also in the case of LysK concentration values outside the calibration range of the models.

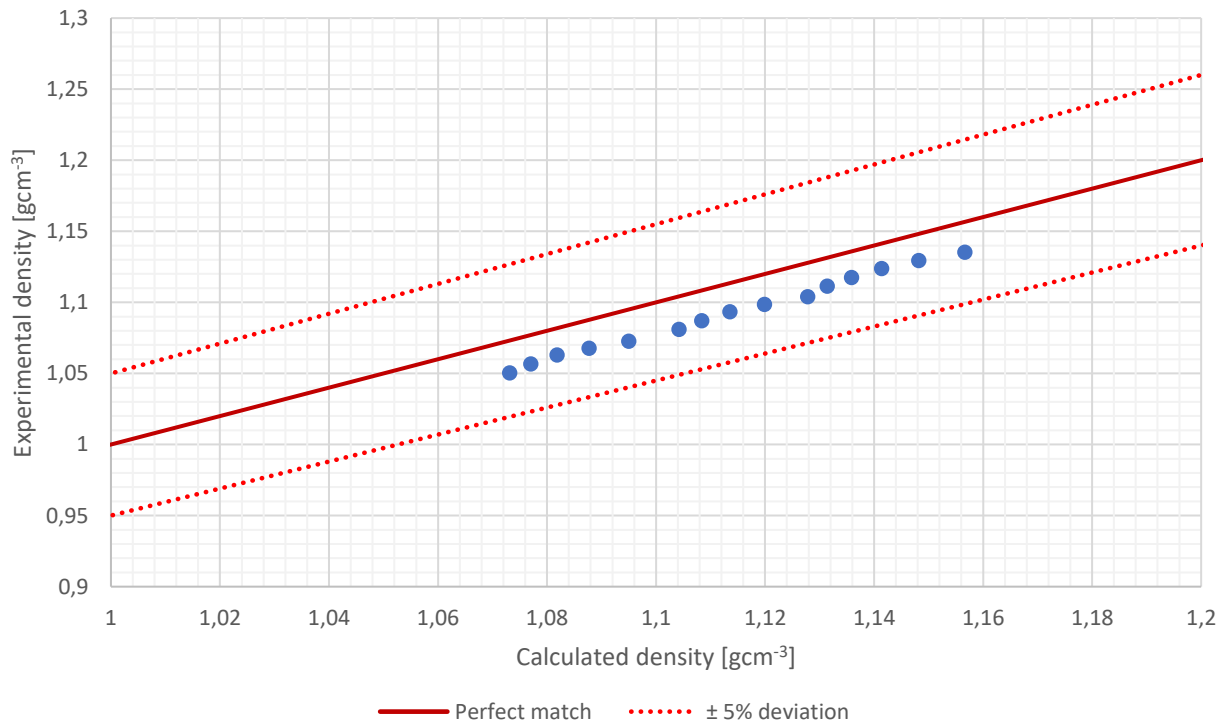

Figure 10: Parity plot of the density values calculated by the model developed and the actual literature values provided in Suleman et al.[24]. The results are plotted against $\pm 10\%$ of error deviation from the perfect match.

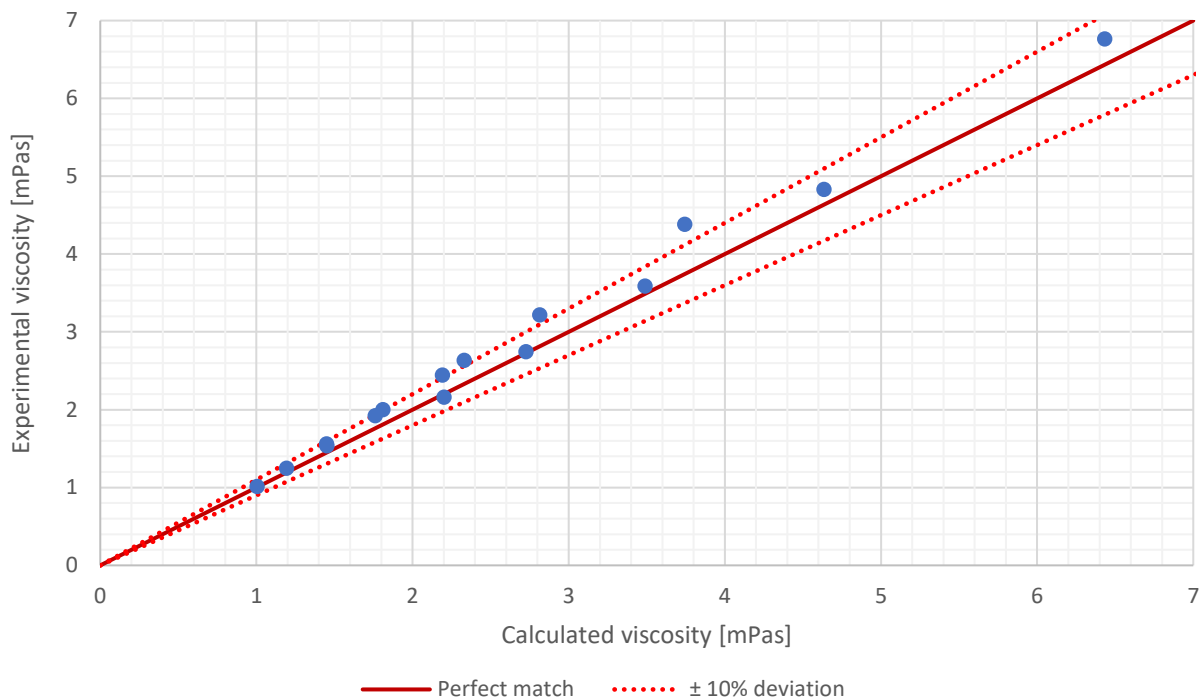

Figure 11: Parity plot of the viscosity values calculated by the model developed and the actual literature values provided in Suleman et al.[24]. The results are plotted against $\pm 10\%$ of error deviation from the perfect match.

In the context of research and development of new chemical solvents such as LysK aqueous solutions, besides assessing the kinetics and thermodynamics performance of the solvent (VLE data, maximum CO₂ loading, kinetics rate, capacity, etc.), a comparison between density and viscosity is recommended in order to establish if the new solvent (e.g. LysK) might be a viable and superior alternative to the benchmark (30% w/w MEA). The plots of Figure 12 and Figure 13 show, respectively, the behaviour of density and viscosity with temperature at different CO₂ loadings for aqueous 30% w/w (or 7 m) MEA³⁴, and for 43.7% w/w (or 4.21 m) LysK solutions tested in this work. Even for lower molality concentration, due to the larger molecular weight and high ionic strength of even unloaded mixtures, LysK solutions are characterized by higher values of density and viscosity compared to MEA solutions. In the temperature and CO₂ loading range investigated in this work, the density of 43.7% w/w LysK is between 7 and 13% higher compared to the density of MEA under the same conditions.

The effect of CO₂ loading on density is more significant for the amine solution, where the percentage increase, when loading raises from 0 to 0.5 molCO₂/molLysK, is up to 10%, whereas the same parameter for LysK solvents increases by 4%.

The viscosity of LysK solution is strongly affected by the CO₂ content, and this phenomenon is even more significant for LysK compared to MEA: at 0.5 molCO₂/molLysK the maximum viscosity (i.e. the one measured at 293 K) is 4 times higher than the one of the unloaded solution, whereas for MEA solutions the corresponding relative increase is close to 1.5 times.

The typical range of MEA dynamic viscosity envisaged within a CO₂ absorber (CO₂ loading up to 0.5 and temperatures between 303 K and 343 K) is between 0.9 and 3.2 mPas, while the range measured for LysK under the same conditions is between 1.9 and 18 mPas. As a result, LysK dynamic viscosity under loaded conditions can be up to 6 times larger than the one of MEA.

In a CO₂ absorption process, a larger viscosity leads to reduced mass and heat transfer between the gas and liquid phase (e.g correlation by Onda et al.¹⁵ and Chilton and Colburn³⁵). Moreover, a higher viscosity leads to larger pressure drops and solvent circulation pumps auxiliary consumption. In any case, since other solvent properties may play a counteracting role compared to the one here described for viscosity (e.g. improved

kinetics, lower vapor pressure), comprehensive techno-economic studies are needed to fully evaluate the solvent performance, as well as to address its competitiveness against the benchmark. Moreover, other criteria can lead to the selection of LysK over MEA as a CO₂ capture solvent, such as lower toxicity and volatility, thermal degradation properties, etc.

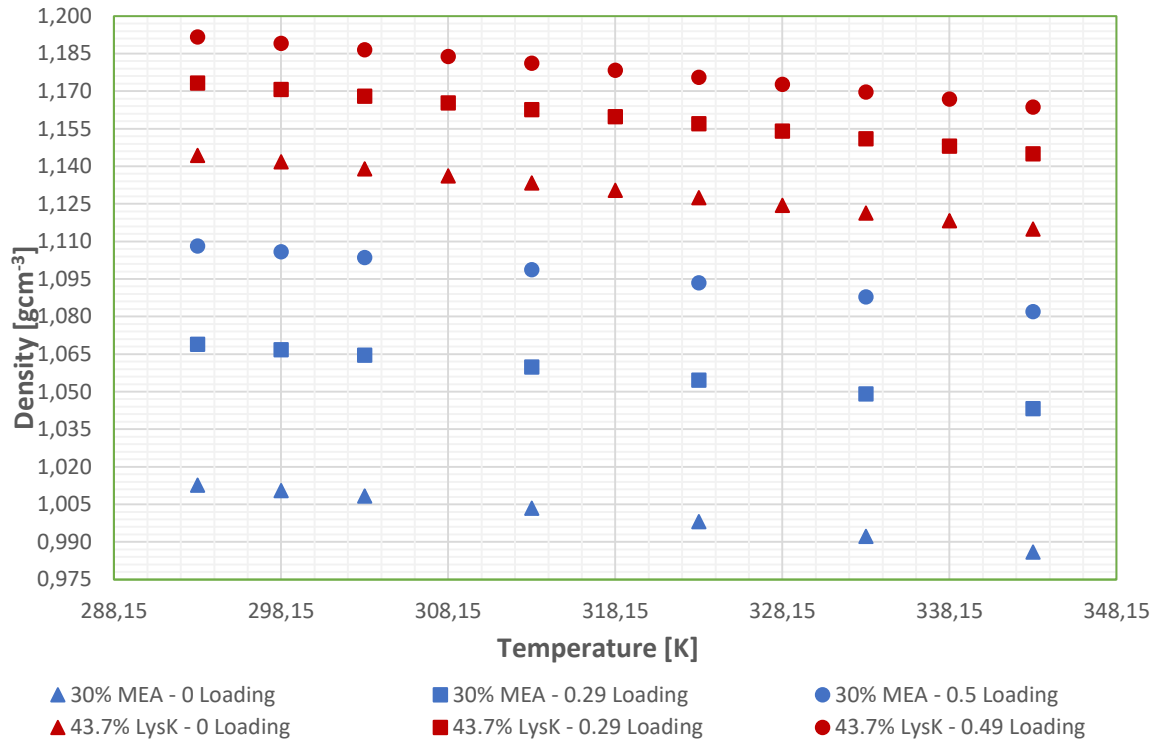

Figure 12: Experimental density of CO₂ loaded 7 m MEA³⁴(blue) and 4.21 m LysK (red) solutions at similar CO₂ concentration levels: 0(Δ) – 0.29(\square) – 0.5(\circ) molCO₂/molLysK.

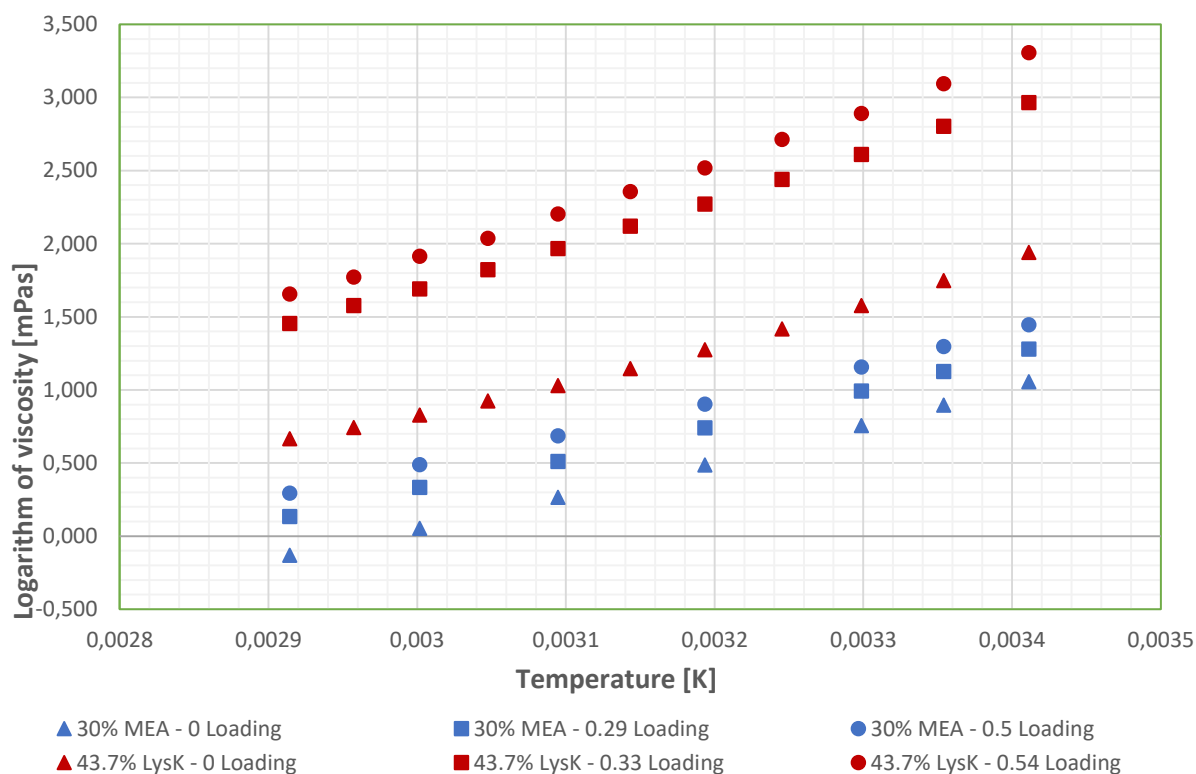

Figure 13: Experimental viscosity of CO₂ loaded 7 m MEA³⁴(blue) and 4.21 m LysK (red) solutions at similar CO₂ concentration levels: 0(Δ) – 0.29(\square) – 0.5(\circ) molCO₂/molLysK.

6 Conclusions

This work presents a new set of experimental data and related empirical correlations of densities and viscosities of aqueous LysK solutions, in a concentration range from 2.16 m to 4.44 m, a temperature range $T = (288.15 \text{ to } 358.15) \text{ K}$ and CO₂ loadings from 0.3 molCO₂/molLysK to 0.98 molCO₂/molLysK. The main contributions to the existing literature are the experimental values, and newly formulated models, for density and viscosity of CO₂ loaded LysK solutions at a concentration level of 4.21 m. In fact, such high LysK concentration level has never been investigated for carbonated solutions, in view of CO₂ capture applications. The uncertainty achieved on the experimental points is below 10% for most of the data obtained and in accordance with the values reported in literature for similar works^{16,18,19}.

The empirical models developed in this work reproduce the values of density and viscosity at different LysK concentration levels and temperatures for what concerns the unloaded solutions, and at different temperatures and CO₂ loadings for the CO₂ loaded solutions. These correlations fit the new experimental data presented in this study with an AAD equal to 0.00054 gcm⁻³ and 0.00148 gcm⁻³ for density of unloaded and loaded solutions respectively, while for the viscosity the reported AAD values are 0.0148 mPas and 0.04 mPas respectively for the unloaded solutions and for the CO₂ loaded ones. Furthermore, the proposed models have been verified against experimental data available in literature²⁰, reporting the density and viscosity of LysK aqueous solutions at 2.28 m, 3.51 m, 5.19 m LysK molality concentrations and temperature range $T = (303.15 \text{ to } 343.15) \text{ K}$.

7 Supporting Information

The Supporting Information file contains the results of the quartz viscometer calibration (figures and tables). It also presents the procedures applied for the calculation of the experimental standard and combined uncertainty and the statistical analysis on modelling results.

8 Acknowledgment

The activities have been carried out with the support of the Erasmus+ programme of the European Union. The authors would also like to thank the Mines ParisTech University for the support and the Centre of Thermodynamics of Processes for the laboratory facility.
