ABSTRACT

The HERMES-TP/SP mission, based on a nanosatellite constellation, has very stringent constraints of sensitivity and compactness, and requires an innovative wide energy range instrument. The instrument technology is based on the “siswich” concept, in which custom-designed, low-noise Silicon Drift Detectors are used to simultaneously detect soft X-rays and to readout the optical light produced by the interaction of higher energy photons in GAGG:Ce scintillators. To preserve the inherent excellent spectroscopic performances of SDDs, advanced readout electronics is necessary. In this paper, the HERMES detector architecture concept will be described in detail, as well as the specifically developed front-end ASICs (LYRA-FE and LYRA-BE) and integration solutions. The experimental performance of the integrated system composed by scintillator+SDD+LYRA ASIC will be discussed, demonstrating that the requirements of a wide energy range sensitivity, from 2 keV up to 2 MeV, are met in a compact instrument.

Keywords: Nanosatellites, constellation, Gamma-ray Burst, Silicon Drift Detectors, Scintillator Detectors

1. INTRODUCTION

Gamma-Ray Bursts (GRBs) are one of the most intriguing and challenging phenomena for modern science, because of their huge luminosities, up to more than 10^{52} erg/s, their redshift distribution extending from $z \sim 0.01$ up to $z > 9$. Their study is of very high interest for several fields of astrophysics, such as the physics of matter in extreme conditions, cosmology, fundamental physics and the mechanisms of gravitational wave signal production.

The *High Energy Modular Ensemble of Satellites - Technologic and Scientific Pathfinder* (HERMES-TP/SP)¹ is a new mission concept hosting compact but innovative X-ray detectors for the monitoring of cosmic high energy transients, such as Gamma Ray Bursts and the electromagnetic counterparts of Gravitational Wave events, based on a constellation of six 3U nanosatellites. The main topic of HERMES is to demonstrate that accurate location of high energy cosmic transients can be obtained using CubeSats. That means miniaturized hardware, one order of magnitude smaller costs than conventional space observatories and few years of development time. The four pillars of the HERMES project are: 1) providing a first mini-constellation for GRB localization with a total of six units, for GRB triangulation using miniaturized and distributed instrumentation, joining also to the multimessenger revolution; 2) develop miniaturized payload technology for breakthrough science; 3) contribute to the so-called Space 4.0 goals demonstrating that components off-the shelf (COTS) can be reliable for challenging missions; 4) push and prepare for final and more solid larger constellation.

The HERMES-TP project is funded by the Italian Ministry for education, university and research and the Italian Space Agency. The HERMES-SP project is funded by the European Union's Horizon 2020 Research and Innovation Programme under Grant Agreement No. 821896. The constellation should be tested in orbit in 2022. HERMES-TP/SP is intrinsically a modular experiment that can be naturally expanded to provide a global, sensitive all sky monitor for high energy transients.

2. HERMES MISSION CONCEPT

The HERMES approach differs from the conventional idea to build increasingly larger and expensive instruments. HERMES proposes to realize distributed, modular and innovative instruments composed by tens/hundreds of simple units, cheaper and with a limited development time. The current CubeSat technologies demonstrated that off-the-shelf components for space use can offer solid readiness at a limited cost. The physical dimension of a single HERMES detector need to be compliant with the nanosatellite mechanical structure; the 1U CubeSat standard is $10 \times 10 \times 10$ cm³. Therefore, the single HERMES detector is of course under-performing, having a lower effective area when compared with transient monitors currently operating. The lower costs and the innovative concept of distributed instrument demonstrate that to build an new mission with unprecedented sensitivity is actually feasible. The HERMES detector is designed to provide a sensitive area >50 cm², suggesting that with several tens/hundreds of such units a total sensitive area of the order of magnitude of ~ 1 m² can be reached. By measuring the time delay between different satellites, using cross correlation of the lightcurves detected by different satellites,² the localisation capability of the whole constellation is directly proportional to the number of components and inversely proportional to the average baseline between them. As a rough example, with a reasonable average baseline of ~ 7000 km, represented by the Earth radius, and a reasonable number for low-Earth satellites in suitable orbits (e.g. ~ 100 nanosats) simultaneously detecting a transient, a source localisation accuracy of the order of magnitude of ~ 10 arcsec² can be reached, for transients with milliseconds time scale variability.

A more extensive description of HERMES mission concept is given in other proceedings in this volume.²⁻⁴

3. PAYLOAD DESCRIPTION

A sketch of the HERMES payload, allocated in 1U-CubeSat ($10 \times 10 \times 10$ cm³), is shown in Figure 1. A mechanical support is placed on the instrument topside. The support is composed by two parts to hold an optical/thermal filter. The detector core is located under the mechanical support: this is a scintillator-based detector in which Silicon Drift Detectors (SDD⁵) are used to both detect soft X-rays, by direct absorption in silicon, and to simultaneously readout the scintillation light. The payload unit is expected to allocate a detector with >50 cm² sensitive area in the energy range from 2 keV up to 2 MeV, with a total power consumption <5 W and total weight of ~ 1.5 kg. The payload unit is completed by further electronic boards implementing back-end

electronics, power supply and data handling functionalities. They are allocated on the bottom of the payload unit, below the detector unit. A more extensive description of HERMES payload is given in other proceedings in this volume.⁶

Figure 1. Exploded view of the payload unit ($10 \times 10 \times 10 \text{ cm}^3$) on board the HERMES nanosatellite. From the top are shown the mechanical support composed by top and bottom parts, with optical filter (violet) in middle, the FEE board (dark green) allocating SDD matrices (light green), LYRA-FE chips on the top and LYRA-BE chips folded on the side (not shown for clarity), the GAGG:Ce crystal pixels and their housing. A mechanical rib on top is also visible, necessary to fix the whole payload to the satellite structure.

4. DETECTOR CORE ARCHITECTURE

The HERMES detector is based on the so-called “siswich” concept,^{7,8} exploiting the dual intrinsic sensitivity of silicon to both soft X-rays and scintillation light. Thus, aiming at designing a compact instrument with a very wide sensitivity band, the silicon detectors are optically coupled with inorganic scintillators. The detector is therefore composed by an array of scintillator pixels, optically insulated, read out by SDDs.

In this concept the SDDs play also the role of an independent X-ray solid state detector. When the SDD faces the sky, low energy X-rays are directly absorbed by the SDD, while higher energy X-rays and γ -rays, pass through the silicon sensor without interactions and are absorbed in the scintillator crystal. The optical scintillation photons are then collected by the same silicon sensor. Only very low noise readout devices coupled with state-of-the-art front-end electronics allow to reach a low energy scintillator threshold down to 20–30 keV. This is a key issue of this architecture, considering that around these energies the increasing sensitivity of the scintillator is able to compensate the lack of efficiency of thin silicon wafers ($450 \mu\text{m}$), so a quite flat overall sensitivity in a wide energy band for the whole integrated system is reached. This effect is clearly visible in the Figure 2 where both silicon and scintillator detection efficiency vs. photon energy are shown.

The inorganic scintillator selected for HERMES is the Cerium-doped Gadolinium-Aluminum-Gallium Garnet (GAGG:Ce).⁹ This is a very promising material with high light output ($\sim 50\,000 \text{ ph/MeV}$), a fast radiation decay time of $\sim 90 \text{ ns}$, no hygroscopicity, high density (6.63 g/cm^3) with an effective mean atomic number of 54.4, no internal radioactive background, peak light emission at 520 nm. These specifications make this material very suitable for the HERMES detector. Since GAGG:Ce is a relatively recent crystal, it has not been yet extensively investigated with respect to radiation resistance and performance after irradiation, although the published results are very encouraging.¹⁰ Further radiation tests were carried out by our collaboration, to better understand the scintillator behaviour in specific in-orbit environments to evaluate their impact on the scientific performance. A more in-depth description of in-orbit conditions and irradiation campaign results are presented in other proceedings in this volume.^{10–12} These tests confirmed the very good performance of GAGG:Ce compared

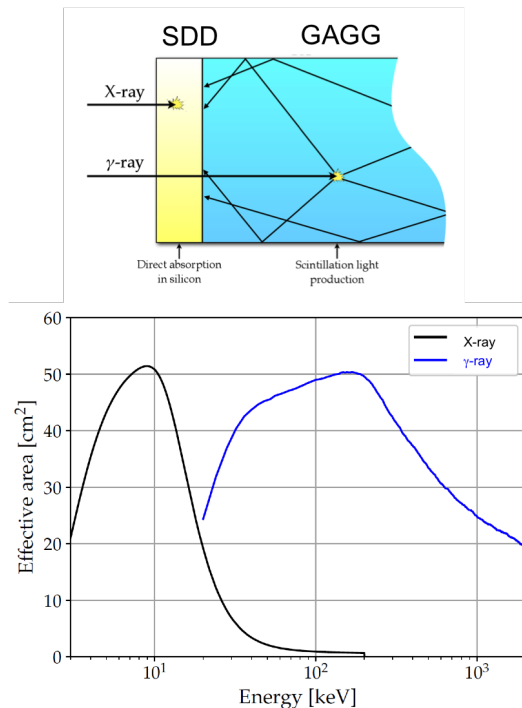

Figure 2. *Top*: the working principle of a *siswich* detection system. The SDD, directly facing the sky, is coupled with a GAGG:Ce scintillator crystal. The low energy radiation (below ~ 30 keV) interacts in the SDD. Photons with higher energy cross the SDD and interact in the scintillator. The light output is collected by SDD. *Bottom*: efficiency vs. photon energy for the direct detection in the SDD (black curve) and through light conversion in the GAGG:Ce (Blue curve).

to other scintillator materials largely used in the recent years in space-borne experiments for γ -ray astronomy (e.g. BGO or CsI).

5. THE HERMES SILICON DRIFT DETECTORS

The SDD development builds on the state-of-the-art results achieved within the framework of the Italian ReDSOX collaboration*, with the combined design and manufacturing technology coming by a strong synergy between INFN-Trieste and Fondazione Bruno Kessler (FBK, Trento), in which both INFN and FBK co-fund the production of ReDSOX Silicon sensors. Thanks to several projects funded by ASI, INAF and INFN a large amount of work was done in past years to consolidate the design of SDDs, as well as the production process, for different applications, for both on-ground and space-based experiments.^{13–19} The current state of the consolidated design/process concerns, for example, pitch and distance of the drift cathodes, low power consumption of sensors, extremely low dark current, high detection efficiency (both for ionizing radiation and optical photons), enhanced efficiency on the sensor edges, optimized charge collection efficiency. The SDDs are the base elements around which the overall P/L is designed. The HERMES SDD design is shown in Figure 3. Nominal thickness of the SDD arrays is $450 \mu\text{m}$, with a certified standard deviation of $2.88 \mu\text{m}$ (by manufacturer). The SDD is organized in a 2×5 array. Guard rings surround the SDD matrix, allowing for a correct electric field termination. The guard ring area is passive, thus the overall geometric area of the SDD device is $39.6 \times 14.5 \text{ mm}^2$, while the sensitive area of each SDD cell is $6.05 \times 7.44 \text{ mm}^2$. A single crystal ($\sim 12.1 \times 6.94 \text{ mm}^2$ and 15.0 mm thick) is coupled with two SDD channels on the *p*-side. On this side to avoid optical cross-talk coming from different crystals, a metal implant strip 0.5 mm wide is present between adjoining couple of cells (Figure 3 right panel). With this configuration a signal from a single isolated SDD channel will be considered to be originated by the

*<http://redsox.iasfbo.inaf.it>

direct absorption of an X-ray in silicon, while a trigger (with comparable amplitude) from the two SDD channels coupled to the same crystal will be considered as a γ -ray event given the expected uniform illumination on both SDD cells by the scintillation light.

Figure 3. SDD design. Left: *p*-side, right: *n*-side

6. THE HERMES READOUT ASIC: LYRA

The potentially high energy resolution of SDDs can be reached only with highly custom and advanced front-end electronics requiring a preamplifier in close proximity to the anode.²⁰ Being the HERMES detector constituted by 120 channels distributed over a total geometrical area $<100\text{ cm}^2$, a special architecture for the readout electronics is so required. A low-noise, low-power Application Specific Integrated Circuit (ASIC) named LYRA has been conceived and designed for this task. The heritage for the LYRA ASICs comes from the VEGA project,^{21,22} that was developed by Politecnico of Milano and University of Pavia for the readout of SDDs within the ReDSOX Collaboration during the LOFT Phase-A study (ESA M3 Cosmic Vision program), although a specific and renewed design is necessary to comply with the different SDD characteristics and the unique system architecture in HERMES. Each LYRA chipset is divided into 30 Front-End ASIC (LYRA-FE) and 1 Back-End multichannel ASIC (LYRA-BE) for a total of 120 LYRA-FE and 4 LYRA-BE circuits. The LYRA-FE chips include the charge sensitive amplifier (CSA), first shaping stage and a current-mode line driver. Each LYRA-BE channel is used to read and process the output of a single LYRA-FE, completing the spectroscopic chain with mixed-signal architecture.²³

6.1 LYRA-FE

The LYRA-FE die is $0.9\times 0.6\text{ mm}^2$ and includes a complete back-up channel for offline replacement. Due to its compact dimensions the LYRA-FEs can be placed very close to the SDD anodes, in order to minimize the stray capacitance of the detector-preamplifier connection, improving the overall electronic noise performance. A total of 120 LYRA-FE chips are used to readout all the SDD channels in the HERMES detector. The LYRA-FEs transmit their analog output signals to the LYRA-BE ASIC in current-mode in order to inhibit the destructive inter-channel crosstalk that the classical voltage-mode signal transmission would cause. The LYRA-FE chip is shown in Figure 5.

6.2 LYRA-BE

In the HERMES configuration, the LYRA-BE chips ($\sim 6.5\times 2.5\text{ mm}^2$ die), shown in Figure 5, can be placed out of the detection plane, where the SDD matrices and LYRA-FE chips are accommodated on a central rigid part. Two additional wings, where LYRA-BE are accommodated, are connected to the central part by means of embedded flex cables, which allow also avoiding the additional space required by connectors, offering the possibility to “fold” the wings at right angle with respect to the detection plane, on the external side of the payload unit, maximizing the detector effective area. A total of 4 LYRA-BE chips are used for the whole payload. Each LYRA-BE has 30 operating channels in HERMES configuration, i.e. connected to LYRA-FE chips, and the individual LYRA-BEs are operated in parallel increasing also the redundancy of the system. In detail a LYRA BE ASIC embeds 32 channels due to the presence of 2 back-up channels. Each channel is made up of a current-mode signal receiver, a second shaping stage, a discriminator, a peak stretcher circuit and a control logic. In addition the LYRA BE chip

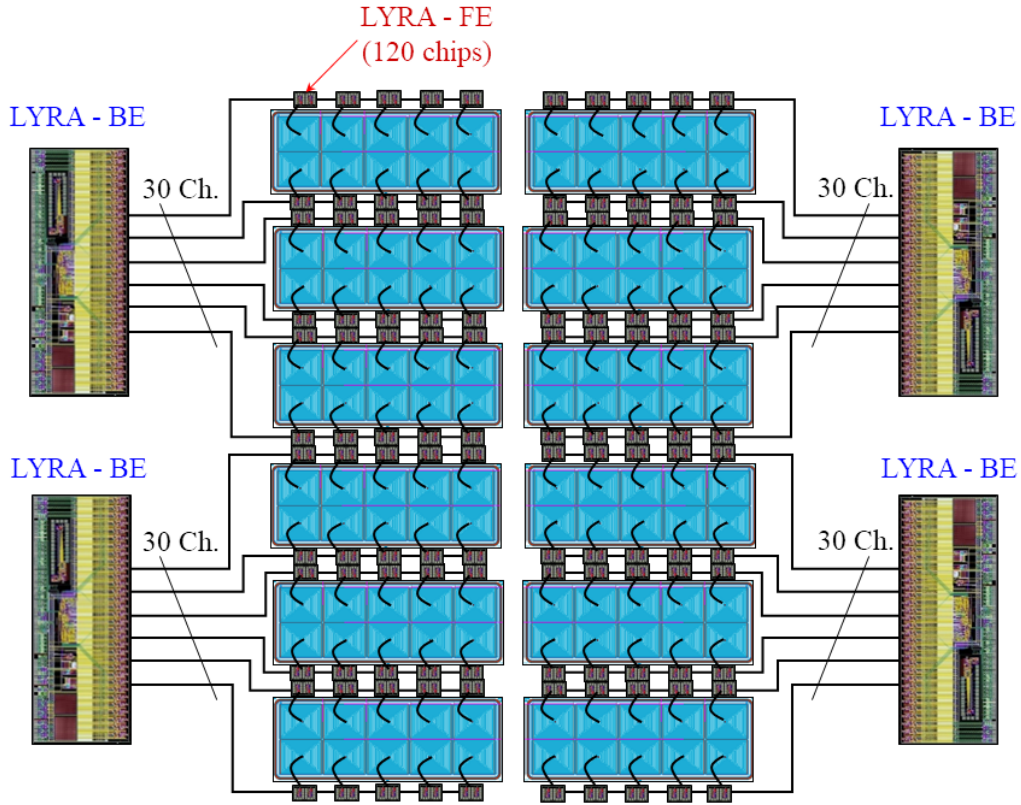

Figure 4. Architecture of the LYRA chipset with 120 LYRA-FE connected to 120 anodes of the SDD and 4 LYRA-BE.

includes a configuration register and an output multiplexer followed by an analog buffer to drive the input load on-board FPGA. Through the multiplexer all the analog outputs of each SDD (in shaper and in stretcher mode) can be read-out as well as the event detection triggers. The threshold for the discriminator can be programmed in two steps through the configuration serial register: a coarse value for all channel and a fine one for each pixel. For debug purpose all the pixels can be disabled by suitable configuration bits if required.

Figure 5. Microscope view of the LYRA-FE (left) and LYRA-BE (right) ASICs integrated on the FEE breadboard.

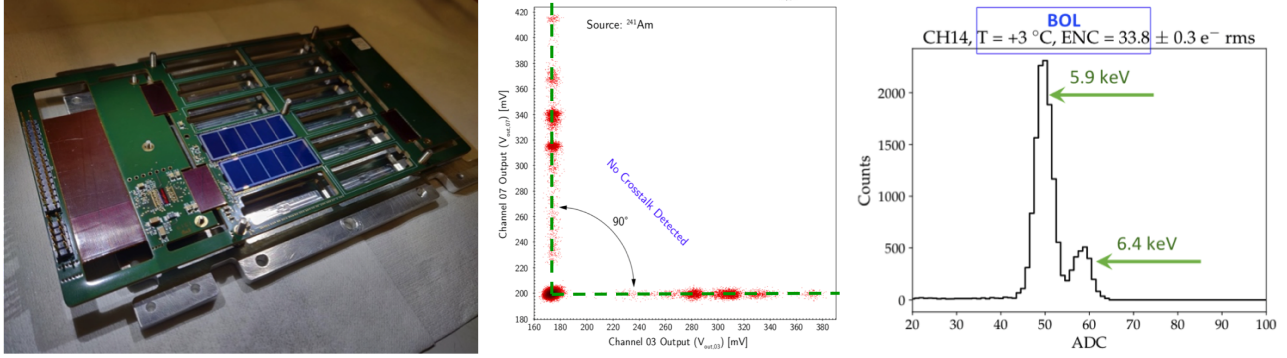

Figure 6. HERMES FEE breadboard (left), measured channel cross-talk (center) and energy spectrum acquired with a ⁵⁵Fe radioisotope (right).

7. BREADBOARD FOR CROSS-TALK AND PRELIMINARY PERFORMANCE MEASUREMENTS

A FEE breadboard has been designed and manufactured to consolidate the PCB design verifying the system requirements in terms of performances. The rigid-flex technology used to cope with the strong space constraints imposed by the S/C, as well as the architecture of the readout electronics with two different ASIC exploiting current-based interfaces, represent the main innovative points of the final FEE PCB. An electrical characterization was therefore carried out to verify the absence of channel cross-talk that could degrade the energy resolution and the event discrimination performance.

Thanks to the modular design of the HERMES detector, the PCB layout of the test breadboard has been limited to the routing of a single quadrant (40 LYRA-FE dies) integrating 2 SDD detectors for a total of 20 SDD cells (Figure 6, left). The channel cross-talk that could be introduced by the reduced distance of PCB traces carrying the LYRA-FE output analog signals has been characterized in INAF/OAS laboratories, in order to verify the PCB layout and to confirm current-based interface between the LYRA-FE analog outputs and the LYRA-BE analog inputs. Central panel of Figure 6 shows the scatter plot of the non-correlated (²⁴¹Am radioactive source) on two channels with adjacent copper traces in the PCB. The absence of systematic correlations of the two signals (shown as a perfect orthogonality between the signals generated by the two channels) demonstrates the negligibility of the cross-talk contribution to the system performance. Right panel of Figure 6 shows instead a ⁵⁵Fe spectrum acquired with the integrated breadboard in the INAF/OAS climatic chamber at a detector temperature of +3 °C. The energy resolution at the 5.9 keV peak is 311 eV FWHM. A detailed description of simulation and experimental results can be found in [23,24](#)

8. THE DEMONSTRATION MODEL: THE FIRST INTEGRATED COMPLETE HERMES DETECTOR

Due to the required readiness level and the reduced development time, in the development plan of HERMES project the conventional model philosophy was customised, introducing what we called *Payload Demonstration Model* (DM). This represents the first completely integrated non-flight HERMES payload, to be dedicated to validate the integration procedure, and to functional and preliminary performance tests, including verification/qualification tests. The DM is described more in detail in other proceedings in this volume.⁶ The HERMES payload integration workflow is summarised in the Figure 7, where the whole integrated FEE PCB is shown on the left, the crystal box with the individual wrapped crystals in the middle and whole integrated Detector Assembly on the right.

Although the P/L DM is a non-flight element, it has been integrated with a representative set of flight-like components, following the finalized AIT/V procedures. The whole integrated Detector Assembly is composed by:

- Mechanical assembly;

Figure 7. HERMES Detector Assembly workflow. The whole integrated FEE PCB (left) includes 120 LYRA-FEs, 12 SDD matrix and 4 LYRA-BEs; the crystal box (middle) contains 60 wrapped GAGG:Ce crystals, optical pads are also visible; whole integrated Detector Assembly (right) include a dummy optical filter, which is also visible.

- Optical filter;
- FEE board equipped with:
 - 4 LYRA-BE ASICs (one per DA quadrant);
 - 120 LYRA-FE ASICs (30 per quadrant);
 - 12 SDD arrays (4 in-spec + 8 dummy, mechanically representative);
- 60 GAGG:Ce crystals;
- Fully representative optical coupling and crystal preload pads;
- Tungsten shields;

Because of the mechanical fragility of the quite thin SDDs ($450\ \mu\text{m}$) combined with soft optical coupling pads between crystals and SDD matrix and the PCB support for Silicon sensor only on the surrounding perimeter, an additional frame (ABS+Kovar) is glued on the p -side of SDD for mechanical strenghtening. The frame geometry is also optimised to minimize potential optical cross-talk between contiguous crystals. This frame (white) is clearly visible in the Figure 7, left. Here the reinforced SDD are glued on the bottom side of FEE PCB (in the Figure 7 left, the FEE PCB is up side down), facing the frame side towards scintillators. For the optical coupling a soft silicone pad (one per crystal) is used. To facilitate the coupling of 60 crystals and 12 SDD matrices, wrapped scintillator crystals are arranged in the so called crystal box (Figure 7, center). This box is optimised to precisely couple crystals and controlling also the compression against Silicon sensors. Completing the integration of Detector Assembly is the mechanical structure on the top of FEE PCB, a two-component frame designed to fix FEE PCB in a "sandwich" configuration towards the crystal box. The top mechanical structure is able also to accommodate an optical filter. A dummy optical filter is visible in the Figure 7 right.

9. DETECTOR ASSEMBLY: PRELIMINARY PERFORMANCE EVALUATION

In order to assess the X-rays and γ -rays detection capabilities and preliminary performance, the integrated Detector Assembly (DA) has been characterized with radioactive sources at the IAPS Rome facility. The DA has been powered by means of unfiltered laboratory power supplies connected, through an adapter board, directly to the LYRA-BE and LYRA-FE ASIC and to the SDD bias network. The LYRA-BE ASICs command and communication tasks have been managed through a custom Test Equipment including a commercial multi-channel fast ADC (CAEN DT5740) for data acquisition. The Detector Assembly has been characterized with X-ray sources at the IAPS laboratories. A series of energy spectra have been acquired at $+26\ ^\circ\text{C}$ and $+5\ ^\circ\text{C}$ by illuminating the detector with ^{55}Fe (Mn K_α at 5.9 keV, Mn K_β at 6.49 keV) and ^{109}Cd (Ag K_α at 22.1 keV, Ag K_β at 24.9 keV). In Figure 8 we show an example of the collected X-ray spectra: on the left a raw spectrum, i.e. without any selection between X-rays and γ -rays, acquired stimulating the detector simultaneously with ^{55}Fe and ^{109}Cd sources at $26\ ^\circ\text{C}$, while on the right panel a ^{55}Fe spectrum is shown.

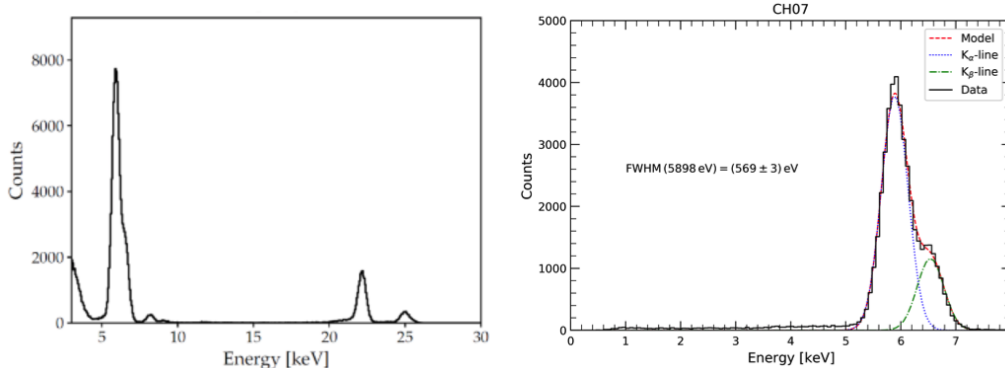

Figure 8. Left: ^{55}Fe and ^{109}Cd spectrum acquired on one detector channel at a temperature of $(26 \pm 1)^\circ\text{C}$. Right: ^{55}Fe spectrum acquired at $T = 26 \pm 1^\circ\text{C}$, where the Mn K_α and Mn K_β best-fit was used to estimate the overall noise.

The characterization of the integrated DA included the comparison between the leakage current measurement for all SDD cells and the final noise performances estimated by ^{55}Fe spectra. Using the I_{leak} values, measured for each SDD cell, and the noise values estimated by X-rays spectra, we verified the I_{leak} -ENC relationship obtained for the SDD+LYRA system by means of simulations. Figure 9 shows the measured I_{leak} -ENC values for each channel (black circles), superimposed to the simulated system performance for the two selectable peaking times (red and blue areas, $\tau_{\text{peak}}=1.6 \mu\text{s}$ and $2.3 \mu\text{s}$ respectively). Although a set-up induced noise excess ($\sim 10 e^-$ r.m.s) is evident for low detector leakage currents, for $I_{\text{leak}} > 90 \text{ pA}$ the experimental data match the expected system performance. Noise performance with a flight-representative set-up will be assessed after the electrical integration of the power-supply unit (PSU) PCB with the DA. Using the current temporary set-up, an average value $< 0.8 \text{ keV}$ for X-rays low energy threshold was calculated on a total of 40 characterized SDD channels.

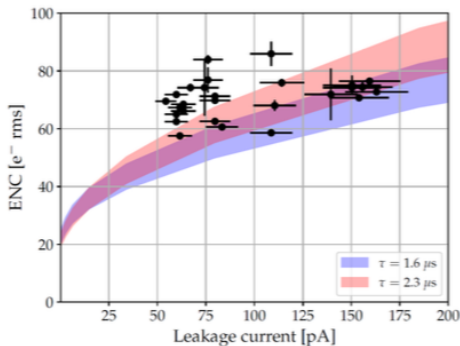

Figure 9. Measured I_{leak} -ENC values (black circles) at $T = 26 \pm 1^\circ\text{C}$ superimposed to the simulated system performance. See text for more details.

A ^{137}Cs radioactive source (γ -ray at 662 keV) has been used to characterize the γ -ray detection capabilities and the scintillation light output response. A series of energy spectra have been acquired at $+26^\circ\text{C}$ and $+5^\circ\text{C}$ in order also to evaluate the increase in the light output with decreasing temperature. An average value of $\sim 12.2 e^-/\text{keV}$ was measured at 26°C , when a signal from a single SDD cell is acquired, while an average increment of 11.8% in the light output is observed at a temperature of $+5^\circ\text{C}$, demonstrating a full agreement with both design expectation and requirements as well as literature results. A typical ^{137}Cs spectrum acquired during the HERMES Detector Assembly characterization is shown in Figure 10.

10. CONCLUSIONS

The experimental activities described in this paper, concerning the integration of the HERMES Detector Assembly, were carried out to successfully conclude, in these last weeks (end of November 2020), the Critical Design

Figure 10. Typical ^{137}Cs spectrum acquired on a single detector channel at a temperature of $T = 26 \pm 1$ °C, used to estimate γ -ray detection capabilities and performance.

Review milestone. In this scenario, the experimental measurements described in the previous sections were used to demonstrate the satisfaction of requirements for both beginning-of-life, corresponding roughly to the measurements at +5 °C, and end-of-life conditions, corresponding to the +26 °C measurements, given the worsening of performance induced on the silicon sensor due to radiation damage during in-orbit life.

As an outcome of these activities, the HERMES wide energy range compact detector, sensitive from 2 keV up to 2 MeV, is now ready for all the necessary forthcoming steps of the System Assembly, Integration and Test of its Flight versions, in the Phase D of the project.
