Panel Session**201 - Innovative Approaches to Increase Employment Rates for Autistic Transition Age Youth and Young Adults**

May 1st, 2025, 10:30 AM - 12:30 PM - 6B

Panel Chair: Marjorie Solomon, *Department of Psychiatry and Behavioral Sciences, UC Davis MIND Institute, Sacramento, CA***Discussant: Julie Taylor**, *Department of General Pediatrics, Vanderbilt University Medical Center, Nashville, TN*

Autistic adults' employment rates remain extremely low, posing a clinically significant problem given the benefits of employment for well-being, independence and life satisfaction in all adults. We present integrative cross-disciplinary strategies to improve employment outcomes in autistic individuals. Dr. Brianne Tomaszewski will present findings from a clinical trial of the TEACCH Autism Program, School Transition to Employment and Postsecondary Education Program (T-STEP), a community college-based transition program for autistic students that includes self-determination and executive function training, counseling and an internship. Dr. Matthew Smith will then discuss a Hybrid Type I trial of the effectiveness, feasibility, and acceptability of a virtual workplace communication training platform (WorkChat) developed with members of the autistic community and implemented in 4 post-secondary pre-employment transition services. Dr. Ben Schwartzman will discuss his study of a parent mentorship program to assist parents in connecting their adult autistic and/or intellectual disabled family members with paid employment. Finally, Dr. Marjorie Solomon will present results of a Hybrid Type 1 effectiveness trial examining employment outcomes, and feasibility and acceptability of the highly validated Individualized Placement and Support (IPS) model –which has been used extensively and successfully in the severe mental illness field –implemented in autistic adults in the community

Discussion

J. L. Taylor, *Department of General Pediatrics, Vanderbilt University Medical Center, Nashville, TN*

Introduction

201.001 Examining Moderators and Maintenance Effects of a Transition Intervention for Autistic Adolescents and Young Adults
B. Tomaszewski¹, **E. M. Lamarche**², **M. Cook**³, **C. B. Klein**⁴, **T. D. Marsh**⁵, **B. W. Kiernan**⁶, **G. M. Osborne**⁷ and **L. G. Klinger**²,
 (1)University of North Carolina at Chapel Hill, Chapel Hill, NC, (2)TEACCH Autism Program; Psychiatry, UNC TEACCH Autism Program, Chapel Hill, NC, (3)School of Medicine, University of Washington, Seattle, WA, (4)TEACCH Autism Program; Psychology & Neuroscience, TEACCH Autism Program, UNC Chapel Hill, Chapel Hill, NC, (5)TEACCH Autism Program, TEACCH Autism Program, UNC Chapel Hill, Chapel Hill, NC, (6)Department of Education and Human Development, University of Virginia, Chapel Hill, NC, (7)TEACCH Autism Program; Psychiatry, University of North Carolina, Chapel Hill, NC

Background: The TEACCH School Transition to Employment and Postsecondary Education (T-STEP) is a 12-week community college program that supports transition-aged autistic youth in pursuing their individualized goals for a successful adult life. The T-STEP has three components. For each week: (1) class focused on self-determination, executive function, professional social skills, and coping skills; (2) internship; and (3) counseling sessions focused on self-advocacy, career counseling, and disability services. In a comparative efficacy trial, students received either three components (Comprehensive T-STEP) or the counseling component (Counseling). Students in the Comprehensive T-STEP reported more significant gains in self-determination and coping skills compared to students in the Counseling group. Parents reported increases in both groups for self-determination and executive function (Tomaszewski et al., 2024).

Objectives: The objectives of the current study were to (1) examine the maintenance effects of the comprehensive T-STEP and Counseling programs at a 3-month follow-up timepoint and (2) examine moderators of the comprehensive T-STEP and Counseling groups to identify characteristics of adolescents and young adults (e.g., IQ, autism characteristics, anxiety) who benefited most from the two programs.

Methods: 110 autistic adolescents and young adults ages 16-21 ($M=18.21$, $SD=1.32$) with $IQ \geq 80$ ($M=107.72$, $SD=15.32$) were randomly assigned to complete the 12-week (Comprehensive T-STEP($N=58$) or Counseling($N=52$)). During the pre-test, an IQ test was performed(WASI-II), and caregivers completed a measure of autism characteristics(SRS-2). During the pre-test, post-test, and 3-month follow-up, autistic students completed measures of self-determination(AIR-SDS), coping skills(Coping Self-Efficacy Scale), anxiety(State-Trait Anxiety), and depression(CESD-R). Caregivers completed measures of self-determination and executive function(BRIEF). Linear mixed models examined moderators of IQ, autism characteristics, and anxiety on the outcomes for the Comprehensive T-STEP and Counseling groups and outcomes over the three- time points.

Results: Students in the Comprehensive T-STEP maintained their gains in self-determination and coping skills compared to students in the counseling group. Autism characteristics significantly moderated treatment effects between Comprehensive T-STEP and Counseling on student-reported depression, $F(2,8) = 3.22$, $p = .04$ and parent-reported executive function, $F(5,110) = 2.37$, $p = .04$. While no average treatment effects were found from pre-test to post-test, autistic students with average (T-Score=68) and high (T-Score = 77) SRS-2 scores in the Comprehensive T-STEP reported decreases in depression from pre-test to follow-up. Individuals in the Comprehensive T-STEP maintained their gains in executive function skills from the pre-test to follow-up across all SRS-2 scores. Individuals in the Counseling group maintained their gains if their SRS-2 scores were low or average but not if they were high. Moderation of anxiety and IQ on parent self-determination will be discussed. No moderators were found for student-reported self-determination or coping skills.

Conclusions: Students receiving the Comprehensive T-STEP maintained their gains in self-determination and coping skills three months after completing the program. Autism characteristics were a moderator. This analysis suggests that the Comprehensive T-STEP may work best for students with more autism characteristics, and students in the Counseling group may work best for students with less autism characteristics. Findings highlight the need for individualized approaches to interventions for autistic students.

201.002 Initial Findings from a Hybrid Type I RCT of Workchat: A Virtual Workday for Autistic Transition-Age Youth Delivered in Pre-Employment Transition Services

M. J. Smith¹, K. Sherwood², E. D. G. Williams³, B. Ross², A. Sharma⁴, D. Telfer⁵, J. Bond⁶, T. Lovelace⁷, S. Dababnah⁸, S. K. Kattari⁴, S. Magana⁹, E. Riddle¹⁰, C. Liggett¹¹, J. D. Smith¹², K. Hume¹³, T. Dawkins¹⁴, M. J. Baker-Ericzen¹⁵, S. M. Eack¹⁶, J. Burke-Miller¹⁷, J. Elkins¹⁸, L. Humm¹⁹, C. Steacy¹⁹ and S. Toda²⁰, (1)School of Social Work, University of Michigan-Ann Arbor, Ann Arbor, MI, (2)School of Social Work, University of Michigan, Ann Arbor, MI, (3)Social Work, University of Michigan, Ann Arbor, MI, (4)University of Michigan, Ann Arbor, MI, (5)Autism Self Advocate, Warren, RI, (6)Michigan Rehabilitation Services, Lansing, MI, (7)Advanced Education Research & Development Fund, Oakland, CA, (8)University of Maryland School of Social Work, Baltimore, MD, (9)Steve Hicks School of Social Work, The University of Texas at Austin, Austin, TX, (10)Waverly Community School District, Lansing, MI, (11)Autism Self Advocate, Lansing, MI, (12)Northwestern University, Chicago, IL, (13)School of Education, University of North Carolina, Chapel Hill, Chapel Hill, NC, (14)University of North Carolina at Chapel Hill, Chapel Hill, NC, (15)Administration, Rehabilitation and Post-Secondary Education, San Diego State University, San Diego, CA, (16)University of Pittsburgh School of Social Work, Pittsburgh, PA, (17)University of Illinois Chicago, Chicago, IL, (18)SIMmersion LLC, Columbia, MD, (19)SIMmersion, LLC, Columbia, MD, (20)Michigan Career and Technical Institute, Plainwell, MI

Background: Workplace conversations may be challenging for autistic transition-age youth who may use more direct communication styles or commonly experience social anxiety. Moreover, 90% of job dismissals among autistic transition-age youth have been attributed to workplace communication challenges. Notably, the field lacks evidence-based practices to support workplace conversations. Thus, our team partnered with 44 autistic youth and adults, 10 vocational counselors, and community, diversity, and scientific advisory boards to develop “WorkChat: A Virtual Workday.” WorkChat is a safe virtual space where trainees practice talking with virtual customers, coworkers, and supervisors (depicted by actors) with varying personalities and needs. WorkChat provides four levels of automated feedback to help enhance workplace conversational skill.

Objectives: To conduct a randomized controlled trial to evaluate whether WorkChat improves conversational skills, social cognitive ability, and social anxiety beyond services-as-usual (SAU).

Methods: We partnered with four post-secondary pre-employment transition services programs where staff implemented WorkChat. Autism was validated with individualized education programs or a standardized assessment. We measured outcomes via live role-plays, social cognitive assessments and self-report measures (validated among autistic people). We conducted repeated measures analysis of variance with partial eta-squared (η^2p) effect sizes to compare the group-by-time interaction among SAU with WorkChat (SAU+WorkChat) with SAU only.

Results: To date, forty-four participants (ages 18 to 26) were randomized to SAU+WorkChat or SAU only and completed pre-test and post-test assessments. The sample identified as 75% male, 21% female, 4% preferred not to answer. We found significant group-by-time interactions, characterized by large effect sizes suggesting that SAU+WorkChat, as compared to SAU, improved their emotional management ($p=.021$, $\eta^2p=.17$) and their anxiety about conversations with others ($p=.004$, $\eta^2p=.21$). WorkChat was not associated with improvements in social perception and theory-of-mind (both $p>.10$, and $\eta^2p<.04$). Role-play data were completely processed (to date) for 19 of 44 participants with SAU+WorkChat, compared to SAU, showing a significant interaction and a large effect size improvement in conversational skill with supervisors ($p=.02$, $\eta^2p=.31$), while trend-level significance and large effect sizes for conversations with customers ($p=.07$, $\eta^2p=.22$) and coworkers ($p=.06$, $\eta^2p=.22$).

Conclusions: Our preliminary results suggest WorkChat may be contributing to improvements in emotional management, social anxiety, and work-based conversational skills. Within the context of work, the need to regulate one’s emotions and anxiety during professional encounters (e.g., helping an upset customer or getting supervisor feedback) is critical to sustaining employment. Moreover, autistic transition-age youth commonly experience social anxiety and the exposure to virtual customers, coworkers, and supervisors through WorkChat could support their future comfort when having real-world conversations at work. Notably, the results must be interpreted within the context of study limitations such as small sample size and require replication.

201.003 Effects of a Parent-to-Parent Mentorship Intervention on the Competitive Integrated Employment Outcomes of Adults with Autism and/or Intellectual Disability

B. Schwartzman, Vanderbilt University, Nashville, TN

Background: The vast majority of adults with intellectual and developmental disabilities (IDD) aspire to find paid work in their communities (National Core Indicators, 2021). Yet, employment rates for adults with IDD have remained below 20% despite concerted policy, advocacy, and funding initiatives (Windsor et al., 2021). Additionally, the adult services system is fraught with fragmentation in that there are often socioeconomic disparities in which geographic areas have access to certain employment services and how programs are implemented (Shogren & Wittenburg, 2020). Due to the dearth of available services, the majority of adults with IDD continue to reside with their families as they age into older adulthood (Burke et al., 2021). Thus, it is essential to engage families in the pursuit of employment (Kamau & Timmons, 2018), as parent expectations are among the most robust predictors of future employment for individuals with IDD (Wehman et al., 2015).

Objectives: Our goal was to develop, pilot, and evaluate a parent-to-parent mentorship intervention where parents of employed adults with IDD serve as mentors for parents of unemployed adults with IDD.

Methods: After interviewing 60 parents of adults with IDD to inform the design of the intervention, we piloted our novel parent-to-parent mentorship model by pairing five parents of unemployed adults with IDD (mentees) to five parents of employed adults with IDD (mentors). We further evaluated the intervention in an RCT ($n=55$) where intervention parents ($n=25$) were paired with a mentor for 12 months, while control group parents ($n=30$) received services as usual for 12 months without being paired with a mentor. Of the 55 parents, 35% had children with ASD, 31% with ASD+ID, 21% with ID, and 13% with Down Syndrome; 74% were White, 18% Black, 5% Hispanic/Latino, and 2% Native American. Prior to being randomized, all participants received a “Roadmap to Employment” guide we created and attended four Zoom classes which covered employment best practices for adults with IDD. We collected parent-report data on employment outcomes, how prepared parents felt to navigate the employment process pre- and post-intervention, parent stress, and feedback about the intervention.

Results: Parents who were paired with a mentor (intervention group; $n = 25$) reported feeling better prepared for employment ($p < .05$), experiencing less stress ($p < .05$), and their adult children with IDD experienced improved CIE outcomes, as compared to control group parents ($n=30$). In examining employment outcomes, we conducted a chi-square test and determined that the employment rates of the intervention group (68% employed) were significantly higher than those in the comparison group (37% employed) $\chi^2(1, N = 55) = 5.4$, $p = .02$. Additionally, all participating families, both in the intervention and comparison groups, shared primarily positive feedback on their experiences participating in the project.

Conclusions: These findings indicate that the practical information and materials we provided to all families contributed to some improvement in employment preparedness and employment outcomes. Evidenced by intervention group outcomes, mentorship may provide families with an additional boost of support in connecting their family members to employment.

201.004 Enhancing Competitive Integrated Employment for Autistic Adults: Barriers, Facilitators, and the Potential of the Individualized Placement and Support (IPS) Model

J. A. Yon-Hernandez¹, M. Solomon², S. McGurk³, S. Ruder⁴, A. C. Stahmer⁵, Y. Takarae⁶, M. Smith⁷ and M. Zheng⁷, (1)Department of Psychiatry and Behavioral Sciences, University of California, Davis, M.I.N.D. Institute, UC Davis, Sacramento, CA, (2)Department of Psychiatry and Behavioral Sciences, UC Davis MIND Institute, Sacramento, CA, (3)Boston University, Boston, MA, (4)UC Davis MIND Institute, Sacramento, CA, (5)UC Davis MIND Institute, University of California at Davis MIND Institute, Sacramento, CA, (6)Department of Psychiatry and Behavioral Sciences, UC Davis, Sacramento, CA, (7)University of California Davis MIND Institute, Sacramento, CA

Background: Less than 20% of autistic individuals in the U.S. achieve Competitive Integrated Employment (CIE) (Annual Disability Statistics Compendium), yet research on supported employment services for them remains limited. The Individualized Placement and Support (IPS) model is well-established for individuals with severe mental illness (28 RCTs) (Drake & Bond, 2023). Key IPS principles include a focus on CIE, zero exclusion to employment, integrating mental and employment services, client-driven rapid job search (no internships), having the same employment specialist (ESs) handle job development (6-employer contacts/week), coaching and long-term support, and fidelity assessment at 6- and 12-months to evaluate adherence to IPS model. In the first trial (n=5) of autistic adults in a hospital setting, 100% obtained employment (McClaren et al., 2017). A follow-up community-based trial achieved 36% employment after 1 year (Noel et al., 2018).

Objectives: To test the feasibility, acceptability, and employment outcomes of IPS among California Department of Developmental Services (DDS) providers, informing the adaptation of the IPS model for autistic adults with and/or without ID.

Methods: Four community agencies participated in IPS training with ongoing weekly consultations, and site visits. Fidelity was assessed at 6- and 12-months. We enrolled 21 clients (13M, 8F), aged 20-52, (M=30, SD=19) with autism (with/without ID; n=17) or ID-only (n=4) with Verbal-IQs 59-132 (M=97, SD=19) who were 62% White, 14% Black, 10% Hispanic/Latino, and 14% Mixed Race. Employment outcomes were tracked. Focus groups with clients (n=13), caregivers (n=4), ESs (n=4), and supervisors (n=6) identified barriers and facilitators to IPS adaptation. Community-informed guidelines ensured focus group relevance. Data were analyzed using Rapid Assessment Procedures (McNall & Foster-Fishman, 2007), including thematic analysis by independent coders using Dedoose™.

Results: There was 75% agency and 100% client retention at 12-months. Eleven CIE placements were made (52% success), with 80% retaining employment for ≥6-months. At 6-months, 3 agencies had fair fidelity (1 did not meet criteria). By 12-months, 1 agency achieved good fidelity, 1 maintained fair fidelity, 1 still failed, and 1 withdrew. Common barriers to implementation included staff turnover and IPS discouragement of the use of internships (Table 1). Clients reported gaining job skills and confidence but noted some job mismatch and inadequate on-the-job supports. Parents expressed concern their children were overqualified for some job placements, although they reported learning to work effectively with ESs and helping their children self-advocate. They mentioned the utility of parent-to-parent mentorship. ESs felt IPS strengthened their relationships with consumers; they liked going out into the community to develop jobs but found the 6-contacts/week requirement challenging. ESs and supervisors highlighted inadequate training for fidelity reviews. Supervisors also cited large caseloads, combining the development and coach roles, and required duration of employment supports as barriers.

Conclusions: IPS shows potential to improve employment outcomes for autistic individuals. In adapting the model, we will be soliciting additional community input on reconsidering the use of internships, better preparing and training ESs and agencies, parent to parent mentoring, and assisting agencies in job development. Work with the Department of Rehabilitation and DDS about sustainable funding is ongoing.

Panel Session

202 - Key Factors for Data-Driven Approaches to Identifying Neuroanatomical Subgroups: Exploring Mechanisms, Validation and Clinical Relevance

May 1st, 2025, 10:30 AM - 12:30 PM - 6C

Panel Chair: Eva Loth, Department of Forensic and Neurodevelopmental Sciences, Flat 2, 116, South Hill Park, London, London, United Kingdom

Discussant: Evdokia Anagnostou, Bloorview Research Institute, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada

Current diagnostic categories in neurodevelopmental conditions are limited in predicting developmental paths, support needs, or treatment responses due to the wide clinical and biological diversity within and between conditions. This has prompted the need for identifying subgroups based on shared biological characteristics. Our panel will explore key questions for data-driven and transdiagnostic approaches to identifying and/ or validating subgroups using structural MRI. The first presentation adopts a transdiagnostic approach, examining the replicability of clustering structures in two independent cohorts of participants with autism, ADHD, OCD or neurotypical development. Next, we integrate neuroimaging and transcriptomics to examine whether brain anatomy-

based subgroups may be linked to specific molecular pathways implicated in autism aetiology by genomic investigations. The third presentation applies density-based clustering to a novel touch screen battery to identify neurocognitive subgroups in autistic and non-autistic preschoolers. Neurocognitive subgroups were then externally validated against clinical features and brain anatomy. Finally, we use deep-learning to explore whether brain-based subgrouping predicts internalising problems in neurotypical and neurodivergent young people, both cross-sectionally and longitudinally. We will close by discussing the need for benchmarks for validation and clinical relevance and consider ethical implications of bringing these subgrouping approaches into the clinic.

Introduction

E. Loth, *Department of Forensic and Neurodevelopmental Sciences, Flat 2, 116, South Hill Park, London, United Kingdom*

202.001 Replicability of Clustering Results Based on Brain Morphology

Y. Sadat-Nejad¹, M. M. Vandewouw², J. A. Brian³, J. Crosbie⁴, R. Schachar⁵, A. Iaboni⁶, E. Kelley⁷, J. Jones⁸, M. J. Taylor⁹, M. Ayub⁸, R. Nicolson¹⁰, B. Syed¹¹, S. Georgiades¹², P. Arnold¹³, J. P. Lerch¹⁴, E. Anagnostou¹⁵ and A. Kushki², (1)Autism Research Centre, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (2)Bloorview Research Institute, Autism Research Centre, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (3)Holland Bloorview Kids Rehab Hospital, Toronto, ON, Canada, (4)University of Toronto, Toronto, ON, Canada, (5)Department of Psychiatry, The Hospital for Sick Children, Toronto, ON, Canada, (6)Autism Research Centre, Bloorview Research Institute, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (7)Department of Psychology, Queen's University, Kingston, ON, Canada, (8)Department of Psychiatry, Queen's University, Kingston, ON, Canada, (9)Diagnostic & Interventional Radiology, Hospital for Sick Children, Toronto, ON, Canada, (10)Department of Psychiatry, The University of Western Ontario, London, ON, Canada, (11)Hospital for Sick Children, Toronto, ON, Canada, (12)Offord Centre for Child Studies, McMaster University, Hamilton, ON, Canada, (13)University of Calgary, Calgary, AB, Canada, (14)Wellcome Centre for Integrative Neuroimaging, University of Oxford, Oxford, ON, United Kingdom, (15)Bloorview Research Institute, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada

Background: There is significant heterogeneity within neurodevelopmental conditions and large overlap across conditions. This necessitate a shift from case-control designs to data-driven approaches that do not make a priori assumptions about groupings of individuals. As a result, clustering has gained attention for characterizing heterogeneity in neurodevelopmental conditions. Despite the success of clustering approaches, however, concerns have been raised around the replicability of clustering results.

Objectives: To examine the replicability of clustering results based measures of brain morphology in samples of neurodiverse children.

Methods: Replicability of clustering was examined using two independent datasets, namely the Province of Ontario Neurodevelopmental Disorder (POND) Network and the Healthy Brain Network (HBN). POND and HBN data were collected across various institutions in Ontario, Canada, and New York, United States, respectively. Participants were included who were 5-19 years old and had diagnoses of autism, attention deficit/hyperactivity disorder (ADHD), obsessive compulsive disorder (OCD), or were neurotypical. Measures of cortical volume, surface area, cortical thickness, and subgroup volume extracted from structural MRI data were used. Principal component analysis (PCA) and clustering were used to examine the replicability of clustering structures across the datasets. Correlations among principle components, measures of clusterability, and alignment between the four brain measures as well as male/female subsets were examined. Brain-behaviour associations were examined using univariate and multivariate approaches.

Results: 747 and 582 participants were included for POND and HBN, respectively (POND: autism n=312, ADHD n=220, OCD n=70, neurotypical n=145; HBN: autism n=60, ADHD n=445, OCD n=19, neurotypical n=58). Significant between-dataset correlations were found in 82.1% of the principal components derived from brain measures. Across datasets and brain measures a two-cluster structure was replicated. The participant composition of clusters was closely matched between cortical volume and surface area, and cortical thickness and subcortical volume. Data-driven clusters were not aligned with diagnostic labels across datasets. Brain-behaviour associations were only replicated for male subsets and subcortical volume using multivariate analysis.

Conclusions: Our results supported the replicability of data structures and clustering results across two independent datasets for individual measures of brain morphology; however, clustering results did not replicate across all brain measures.

202.002 Parsing Autism Heterogeneity: Transcriptomic Subgrouping of Imaging-Derived Phenotypes in Autism

J. Leyhausen^{1,2}, C. Gurr¹, L. Berg^{1,2}, H. Seelemeyer^{1,2}, B. Hermila^{2,3}, T. Schäfer⁴, A. Chiocchetti¹, C. M. Pretzsch⁵, E. Loth⁶, B. Oakley⁷, J. K. Buitelaar⁸, C. Beckmann⁸, T. Background:

Neurodevelopmental conditions, such as autism, are highly heterogeneous both at the causative and phenotypic level. Parsing heterogeneity is therefore vital for uncovering underlying mechanisms that could inform the development of targeted, i.e., personalized support. While the neuroanatomy of autism is highly diverse across individuals, imaging transcriptomics studies suggests that imaging-derived phenotypes (IDPs) in autism may be linked to specific molecular mechanisms and pathways that have been implicated in autism aetiology by genomic investigations. There is thus now an opportunity to subgroup autism both on the neuroanatomical and transcriptomic level, and so to provide biologically informed subgroups that converge onto distinct molecular aetiologies.

Objectives:

Our study aims to subgroup individuals on the autism spectrum to identify subgroups that converge at both mechanistic and phenotypic level.

Methods:

We employed an imaging transcriptomics approach to link individual neuroanatomical imaging-derived phenotypes (IDPs) in autism to gene expression signatures by means of the Allen Human Brain Atlas. Data was provided by the EU-AIMS Longitudinal European Autism Project, one of the largest multicentered case-control cohorts on autism worldwide. The total sample consisted of N=279 individuals with autism and N=359 non-autistic participants aged 6-30 years (both males and females). Inclusion of autistic participants required an existing diagnosis of autism according to DSM-IV/V or ICD-10 criteria. Autistic participants with co-occurring psychiatric conditions, except psychosis and bipolar disorder, and on regular medication were included. Individuals were subdivided using clustering techniques based on similarities in their IDP-associated transcriptomic profiles, and subsequently linked to clinical and neuroanatomical measures, i.e., cortical thickness.

Results:

We identified three robust subgroups of individuals with autism, each characterized by similar IDP-related transcriptomic signatures. These subgroups aligned with distinct clinical phenotypes, whereby individuals with the strongest transcriptomic associations were the least affected on the level of symptomatology. The subgroups also differed on the level of neuroanatomy, i.e., cortical thickness differed between subgroups in the frontal and cingulate cortex. The gene sets most characteristic for each subgroup were significantly enriched for genes previously implicated in autism aetiology by genetic and transcriptomic investigations, many of which regulate typical brain development.

Conclusions:

Individuals with autism can be stratified based on the transcriptomic signatures associated with their neuroanatomical fingerprints, revealing subgroups that also align with distinct clinical phenotypes. Our study thus provides a novel analytical framework for linking neurodevelopmental and clinical diversity in autism to underlying molecular mechanisms, thus providing the foundations for the future development of personalized support strategies.

202.003 Density-Based Robust Clustering Identifies a Distinct Neurocognitive Profile in a Subgroup of Autistic Preschoolers Linked to ADHD Features and Neuroanatomical Differences

J. Koziel¹, A. Goodwin², J. K. Buitelaar³, T. Falck-Ytter⁴, R. Delorme⁵, H. Roeyers⁶, T. Charman⁷, M. J. Brammer⁸, C. Ecker⁹ and E. Loth¹⁰, (1)Institute of Psychiatry, Psychology & Neuroscience, King's College London, UK, London, United Kingdom, (2)Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (3)Department of Cognitive Neuroscience, Donders Institute for Brain, Cognition and Behaviour, Radboud University Nijmegen Medical Center, Nijmegen, NETHERLANDS, (4)Development and Neurodiversity Lab, Department of Psychology, Uppsala University, Uppsala, Sweden, (5)Excellence centre for Autism and Neurodevelopmental disorders, Paris, France, (6)Department of Experimental-Clinical and Health Psychology, Ghent University, Ghent, Belgium, (7)Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, UNITED KINGDOM, (8)Centre for Neuroimaging, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (9)Department of Child and Adolescent Psychiatry, University Hospital, Goethe University, Frankfurt am Main, Germany, (10)Department of Forensic and Neurodevelopmental Sciences, Flat 2, 116, South Hill Park, London, London, United Kingdom

Background:

Autism frequently co-occurs with Attention Deficit Hyperactivity Disorder (ADHD), which significantly impacts developmental outcomes, quality of life, and adaptive functioning (1,2). However, early and reliable markers of ADHD traits in autistic individuals have not yet been identified. While differences in neurocognitive domains such as executive functioning (EF) and reward processing have been reported separately in some autistic children and children with ADHD (4,5), these domains are typically studied in isolation. Furthermore, research was limited mostly to middle childhood and adolescence. It is essential to assess whether parsing variability in composite neurocognitive profiles can help to identify clinically and neuroanatomically distinct subgroups of autistic preschool children.

Objectives:

To identify cross-domain neurocognitive profiles using a clustering approach and to validate neurocognitive subgroups against clinical features, and brain anatomy in the EF and reward networks.

Methods:

This study utilised data from a well-characterised cohort of 98 autistic and 142 typically developing preschoolers aged 34-54 months who participated in the Preschool Brain Imaging and Behaviour Project. A sub-sample of 80 children also provided structural MRI data. Primary and secondary dependent variables were derived from a touchscreen battery that included inhibitory control, sustained attention and reward learning tasks. We entered these in-model variables into a density-based clustering algorithm and subsequently, we compared the emergent subgroups on clinical features, including the ADHD Rating Scale–Preschool Version, Social Responsiveness Scale-2, Strengths and Difficulties Questionnaire and Sensory Experiences Questionnaire, as well as on neuroanatomical features, mainly surface area and cortical thickness.

Results:

We identified four distinct subgroups, with two subgroups enriched for neurodivergence (Subgroup 1 & 3). Subgroup 1 exhibited difficulties across all neurocognitive domains (inhibitory control, sustained attention, reward learning) and had significantly elevated ADHD traits despite typical IQ (see Figure 1A-C). Subgroup 3 showed intermediate ADHD traits, struggled with task completion, and had low IQ. Both subgroups also demonstrated higher levels of social difficulties ($\eta^2=0.11$) and behavioral problems ($\eta^2=0.09$) compared to Subgroups 2 and 4, which exhibited typical neurocognitive performance and low ADHD traits (for subgroup characterization details, see Table 1). Neuroanatomical comparisons revealed widespread surface area differences across frontal and parietal regions (see Figure 1), with additional orbitofrontal cortex alterations in both Subgroup 1 and 3.

Conclusions:

Our findings indicated that brain-based neurocognitive subtypes, derived from a scalable tool, could be used to parse clinical heterogeneity in autistic and non-autistic preschoolers. Children who exhibited high ADHD traits may manifest either cognitive challenges in EF and reward processing, or more pervasive cognitive difficulties accompanied by low IQ. Impairments in these neurocognitive domains were linked to greater social difficulties, behavioral problems, and have distinct neuroanatomical correlates. Identifying unique profiles that aligned with behavioral symptoms at age 3 could allow clinicians to predict the likelihood of ADHD in autism and facilitate early personalized interventions, such as targeted cognitive training. Future longitudinal analysis will assess whether these profiles have predictive value for identifying autistic preschoolers who will develop ADHD.

**202.004 Predicting Internalizing Problems from Measures of Brain Structure: A Deep Learning Study**

M. M. Vandewouw¹, B. Syed², E. Kelley³, J. Jones⁴, M. Ayub⁴, P. Arnold⁵, J. Crosbie⁶, A. Iaboni⁷, R. Schachar⁸, M. J. Taylor⁹, J. P. Lerch¹⁰, E. Anagnostou¹¹ and A. Kushki¹, (1)Bloorview Research Institute, Autism Research Centre, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (2)Hospital for Sick Children, Toronto, ON, Canada, (3)Department of Psychology, Queen's University, Kingston, ON, Canada, (4)Department of Psychiatry, Queen's University, Kingston, ON, Canada, (5)University of Calgary, Calgary, AB, Canada, (6)University of Toronto, Toronto, ON, Canada, (7)Autism Research Centre, Bloorview Research Institute, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (8)Department of Psychiatry, The Hospital for Sick Children, Toronto, ON, Canada, (9)Diagnostic & Interventional Radiology, Hospital for Sick Children, Toronto, ON, Canada, (10)Wellcome Centre for Integrative Neuroimaging, University of Oxford, Oxford, ON, United Kingdom, (11)Bloorview Research Institute, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada

Background: Children and youth experiencing internalizing problems, such as anxiety and depression, often experience adverse outcomes. Although we have identified certain risk factors for internalizing problems, such as neurodiversity, the neurobiological markers are not well understood. Studies investigating the potential of brain structure to predict internalizing problems in neurodiverse youth have yielded inconsistent results, largely due to methods that may not fully capture the complex and multi-dimensional associations between neurobiology and mental health.

Objectives: This study aimed to predict both cross-sectional ($N=14,523$) and worsening trajectories ($N=10,540$) of internalizing problems in neurotypical and neurodivergent youth using deep learning.

Methods: Data were sourced from four datasets: (1) the Adolescent Brain Cognitive Development study, (2) the Healthy Brain Network, (3) the Human Connectome Project Development study, and (4) the Province of Ontario Neurodevelopmental network. Structural brain data were extracted from magnetic resonance images, and internalizing problems were measured using the Child Behaviour Checklist. Deep learning models were tuned, trained, and tested using a stratified cross-validation scheme. In one model, clinically significant internalizing problems were predicted cross-sectionally, and in another model, worsening trajectories of internalizing problems were predicted longitudinally (approximately two years later). Performance was evaluated using the area under the receiving operating characteristic curve (AUC).

Results: The cross-sectional model showed strong performance ($AUC = 0.80$ [95% CI: 0.71, 0.88]). Predicting worsening trajectories in the general population yielded sub-optimal results ($AUC=0.66$ [0.65, 0.67]). However, acceptable performance was reached in a small, external test set consisting primarily of neurodiverse children and youth ($AUC=0.80$ [0.78, 0.81]), as well as across all participants with a neurodevelopmental condition ($AUC=0.73$ [0.70, 0.76]).

Conclusions: This work demonstrates the potential of precision health approaches to mental health, where outcomes are predicted using an individual's neurobiology, especially for neurodiverse children and youth.

Panel Session

203 - Expanding Research Opportunities for Individuals with Profound Autism

May 1st, 2025, 10:30 AM - 12:30 PM - 6A

Panel Chair: Alison Singer, Autism Science Foundation, New York, NY

The Lancet Commission first defined “profound autism” in 2021 and stated that the new term was critical to distinguish people with high dependency needs from the more verbally and intellectually able population of people with autism. The Lancet described those with “profound autism” as having IQ under 50, being nonverbal or minimally verbal, being at least 8 years old, and requiring 24/7 supervision to maintain safety. The commission expressed hope that the introduction of the term “profound autism” would spur research to prioritize the needs of this vulnerable and underserved population. Since that time, many labs have conducted and published research on profound autism. Many of these groups have revised, added to, or removed elements from the Lancet definition, making it challenging to compare study results or link datasets. The purpose of this panel is to review options for a global consensus research definition of profound autism and invite attendees to discuss the pros and cons of various options.

Introduction

A. T. Singer, Autism Science Foundation, New York, NY

203.001 Developing a Consensus-Based Global Research Definition of Profound Autism

C. Lord¹, **H. Tager-Flusberg**², **M. Siegel**³, **A. Halladay**⁴, **J. Ursitti**⁵ and **A. T. Singer**⁴, (1)UCLA Semel Institute for Neuroscience and Human Behavior, Los Angeles, CA, (2)Psychological and Brain Sciences, Boston University, Boston, MA, (3)Boston Childrens Hospital, Boston, MA, (4)Autism Science Foundation, New York, NY, (5)Profound Autism Alliance, Boston, MA

Background: The Lancet Commission on Autism first defined “Profound Autism” in 2021 as an administrative term to describe people with autism who had IQ under 50, who were nonverbal or minimally verbal, were at least 8 years old, and who required 24/7 supervision to maintain safety. The Commission stated that the term “profound autism” was critical to distinguish people who have high dependency needs from the more verbally and intellectually able population of people with autism. The Commission expressed “hope that [the introduction of “profound autism”] will spur both the clinical and research global communities to prioritize the needs of this vulnerable and underserved group.” Since that time, multiple research groups have conducted and published research on profound autism and others have expressed interest in doing so. Many of these groups have revised, added to, or removed elements of the Lancet definition. Because these research groups used different definitions of profound autism, it has been challenging to compare study results and share or link datasets, and has led to confusion as to the research definition of “profound autism.”

Objectives: A global “Delphi Consensus Process” was initiated to achieve consensus on a research definition of profound autism. The Delphi technique is a well-established approach to answering a research question through the identification of a consensus view across subject experts. This process was led by an independent consulting firm that has extensive experience conducting Delphi processes in the healthcare community.

Methods: A survey was developed covering 8 topics, consisting of 32 statements which would be tested for agreement/disagreement with a diverse group of autism researchers, clinicians, autistic persons and family members. 137 surveys were distributed via email and 76 responses were received across 5 geographic regions. The consensus threshold set by the independent consulting firm was 75% agreement.

Results: Of the 32 statements, consensus was achieved on 20. Areas of greatest consensus were around language, adaptive functioning, co-morbid diagnoses (including intense/dangerous behaviors) and the need for continuous support. For example, 92% of respondents agreed that people with profound autism exhibit periods of intense and dangerous behaviors; 95% of respondents agreed that a person with profound autism cannot consistently verbally communicate healthcare needs to caregivers or providers (e.g., express pain); 97% agreed that a person with profound autism requires adult support to meet their basic needs, e.g., food preparation, dressing, and bathing adequately; and 97% agreed that a person with profound autism requires an adult available to them 24/7 to maintain safety. There was less consensus about the IQ component of the profound autism definition. Requiring an IQ less than 50 achieved the highest consensus (68%). Inter-group differences were notable, particularly around IQ, with autistic persons and family members reaching consensus that IQ under 50 should be a part of the research definition, but clinicians and researchers disagreeing.

Conclusions: Based on these findings, a new working research definition of “profound autism” is proposed. Next steps include inviting the broad research community at INSAR to discuss and comment on the new definition.

203.002 Profound Autism: Parsing the Relative Contributions of IQ, Communication and Adaptive Behavior

M. Siegel¹ and **K. A. Pedersen**², (1)Boston Childrens Hospital, Boston, MA, (2)Center for Clinical and Translational Science, MaineHealth, Portland, ME

Background: Autism spectrum disorder (ASD) encompasses a wide range of symptoms. However, limited research focuses on those with profound autism (PA). The definition of PA, initially set by the Lancet Commission highlights the need for adult support but did not provide guidance on measurement of potentially defining domains like adaptive functioning, IQ, and verbal ability. Recent studies have focused on operationalizing PA through IQ and spoken language criteria, as when the CDC reported 26.7% of youth with ASD in a community sample met the PA criteria.

Objectives: This study aims to assess the relative contributions of adaptive functioning, IQ, and verbal ability in determining profound autism, using a sample from the Autism Inpatient Collection (AIC).

Methods: We analyzed data from the AIC, which includes 1,512 children and adolescents diagnosed with ASD using the Autism Diagnostic Observation Schedule-2 (ADOS-2) and DSM-5 criteria. The AIC is a multi-site study of youth with ASD hospitalized in psychiatric units due to significant emotional and behavioral challenges. Caregivers completed the Vineland Adaptive Behavior Scale-3 (VABS-3) upon admission, and participants were given the Leiter test of non-verbal intelligence. Verbal ability was identified per the appropriate ADOS-2 module. Profound autism was defined as having a Leiter non-verbal IQ score below 55, being minimally or non-verbal (ADOS module 1 or 2) or needing extensive support for daily adaptive functioning (VABS-3 $\leq$ 70). A logistic regression model was used to assess the contributions of Leiter IQ, VABS-3, and ADOS module as predictors of profound autism. The results are presented as odds ratios (OR) with 95% confidence intervals (CI).

Results: In the AIC sample, 72.2% of participants met the criteria for profound autism, significantly higher than the 26.7% reported by the CDC (Table 1). The logistic regression model explained a substantial portion of the variance in profound autism (Cox & Snell $R^2 = 0.497$; Nagelkerke $R^2 = 0.946$), indicating a good model fit. Leiter non-verbal IQ was a significant predictor of profound autism ($B = -0.089$, $SE = 0.041$, Wald $\chi^2 = 4.714$, $p = 0.030$). VABS-3 scores were a significant predictor ($B = -1.654$, $SE = 0.382$, Wald $\chi^2 = 18.744$, $p < 0.001$). For each unit increase in adaptive functioning, the odds of profound autism decreased by 81% ($OR = 0.191$, 95% CI: 0.091–0.405). In terms of IQ, the odds of profound autism decreased by 8.5% for each point increase in the Leiter ($OR = 0.915$, 95% CI: 0.844–0.991). ADOS module did not significantly predict profound autism status ($B = -57.876$, $SE = 1742.544$, Wald $\chi^2 = 0.001$, $p = 0.974$).

Conclusions: The findings underscore the critical role of adaptive functioning in predicting profound autism, followed by non-verbal IQ. Verbal ability contributed minimally to the prediction of profound autism. These results suggest that adaptive functioning and cognitive abilities are key factors in distinguishing profound from non-profound autism, which may guide more tailored interventions and precise measurement. A refined approach to defining PA could improve data comparability across studies and enhance interventions for this high-needs population.

203.003 Determinants of Participation/Attrition of People with Profound Autism in Research Studies

C. W. Nordahl, B. Heath, M. Solomon and D. G. Amaral, Department of Psychiatry and Behavioral Sciences, UC Davis MIND Institute, Sacramento, CA

Background:

Autistic individuals with co-occurring intellectual disability (ID), especially those with profound autism, are often under-represented in research studies. This is particularly problematic in neuroimaging studies of autism that often exclude individuals with lower intellectual abilities. In 2017, Jack and Pelphrey found that out of 47,400 autistic individuals in the National Database for Autism Research, only 11% had IQs < 85. Since 2006, we have conducted an inclusive longitudinal neuroimaging and behavioral study of autistic children enrolled at 2-3 years and followed for four time points through middle childhood (9-11 years). There are no restrictions based on intellectual ability, and the cohort represents the entire spectrum of abilities.

Objectives:

To assess behavioral and demographic variables associated with attrition/retention of families in the Autism Phenome Project. We also examine rates of scanning success in autistic children with ID (IQ < 70) and in children with profound autism (IQ < 50).

Methods:

We examined the rate of attrition in the autistic cohort from the time of enrollment (T1) at 2-4 years of age to the fourth longitudinal time point (T4) at 9-11 years (coinciding with when profound autism is identified; >8 years). To determine whether participant characteristics at baseline were associated with attrition, we compared scores from children who returned versus those who did not on T1 assessments of developmental ability (MSEL), autism symptom severity (ADOS CSS), adaptive functioning (VABS), externalizing behaviors (CBCL), and self-injurious behaviors (RBS). We also compared groups on several demographic factors at T1: maternal and paternal age, family income, and parental education. Additionally, we examined MRI scanning success rates in autistic children with intellectual disability, including those with profound autism.

Results:

At T1, 186 autistic children were enrolled and eligible to return for the T4 assessment ~7 years later. At T4, 118 (63%) returned and 68 (37%) did not. Comparison of scores of returners versus those lost to follow-up revealed no cognitive or behavioral differences at 3 years of age. Maternal age was the only demographic variable that distinguished autistic children who stayed in the study from those who did not. Mothers of children lost to follow-up were younger than returners (mean age 30.1 vs 32.2 years). Groups did not differ on paternal age, family income or educational level. Despite attrition, the cohort remained representative of the full spectrum of intellectual abilities at T4; 40% have IQs < 70 and 24% have IQs in the range of profound autism (<50). Regarding success of MRI scanning, of the scans attempted in children with IQs < 70 (n = 35), 77% were successful; this includes 15 children with profound autism.

Conclusions:

Our results suggest that there are no systematic differences in behavioral characteristics of autistic children at age 3 that predict retention or attrition in a longitudinal study. Moreover, representation of participants at the longitudinal visit includes a significant proportion with profound autism, suggesting that with adequate support there is no reason to exclude these children from research studies, even studies that involve neuroimaging as part of the protocol.

203.004 Patient-Centered Outcome Measures in Dup15q Syndrome and Profound Autism

S. Jeste and C. DiStefano, Children's Hospital Los Angeles, Los Angeles, CA

Background: Even as therapeutics for genetic forms of profound autism and intellectual disability show promise in preclinical studies, many phase 2 and 3 clinical trials have failed. One major obstacle to trial success is the identification of evidence-based, patient-centered clinical endpoints that are sensitive to meaningful change and reflect the needs of families. Our team has worked closely with industry and advocacy partners to bolster clinical trial readiness in Dup15q syndrome, a genetic condition associated with hypotonia, intellectual disability, and profound autism (Distefano et al, 2020; Saravanapandian et al, 2020). Here, we report the design of patient-centered outcome measures for future trials in this syndrome, first through the start of a Disease Concept Model (DCM) and then a syndrome specific Clinical Global Impression (CGI) severity scale. A disease concept model (DCM) is a framework that assesses the lived experience of individuals and their families. DCMs are based on qualitative interviews and capture the relationship between symptoms, concerns, and impact on daily life, and they can be used to generate trial endpoints. The CGI is a widely used clinician rating of severity of symptoms that is used as an outcome measure for trials in autism.

Objectives: (1) To develop a DCM of Dup15q syndrome to guide the choice of standardized outcome measures. (2) To develop a CGI that focused on specific clinical challenges in Dup15q syndrome.

Methods: For the DCM, in partnership with the Dup15q Alliance and an outside firm, we conducted caregiver interviews that were transcribed and coded using a HIPAA compliant qualitative data analysis computer software. Categories included symptoms and the impact of the symptoms on caregivers and individuals with dup15q syndrome. For the CGI, relevant domains were identified based on the DCM. For each domain, anchor descriptions were written to describe levels of symptomology (five ratings from “very mild” to “very severe”). A previously published CGI on Angelman syndrome was used as a template for the anchors, with modifications based on clinical expert opinion on the features of dup15q syndrome (Kolvezon et al, 2021). Vignettes were written by expert clinicians to train the providers on the use of the CGI for a trial.

Results: The initial DCM, based at this point on caregiver interviews, identified key developmental domains as therapeutic targets, including motor skills, cognition, language, and social skills. Other areas of importance included neurological, psychiatric, and medical. The CGI included ratings for the following areas, in descending order of concern: seizures, expressive communication, fine and gross motor skills, cognition, self-care, social interactions, maladaptive behaviors, sleep problems. A severity rating was based on a holistic evaluation of these items.

Conclusions: FDA and industry partners are deeply invested in developing more patient centered outcome measures for trials, especially in profound autism where standardized measures are limited in their ability to identify meaningful change. The DCM and CGI in dup15q syndrome will continue to be developed and will be used in ongoing and future clinical trials for this condition and can be modified for other genetic neurodevelopmental disorders.

Panel Session

204 - Integrating Research on Autism and Psychosis: Phenomenology, Social Cognition and Brain Measures across Both Spectra

May 1st, 2025, 10:30 AM - 12:30 PM - 611-614

Panel Chair: Tim Ziermans, *Department of Psychology, University of Amsterdam, Amsterdam, Noord-Holland, Netherlands*

Discussant: Noah Sasson, *University of Texas at Dallas, Richardson, TX*

Overlapping symptoms across the autism and schizophrenia spectra have long been recognized. However, limited research has examined the cognitive and neural underpinnings of this shared phenomenology, which could help inform targeted treatment innovations. In this symposium, we present findings from three types of study populations (general, high-risk, and clinical) using three different measurement approaches (phenomenology, cognitive performance, and neuroimaging). Specifically, the symposium will address: 1. The reliability of measuring autistic traits in general population samples characterized by low or high schizotypy; 2. The impact of autistic and psychotic features on anomalous self-experience in help-seeking individuals at risk for psychosis; 3. Comparison of neurocognitive and social cognitive performance in individuals diagnosed with autism or a schizophrenia spectrum disorder; 4. Different applications of resting-state fMRI to investigate links between brain activity, social cognition, and clinical symptoms and diagnoses. Taken together, these studies confirm the need to move beyond diagnosis-based analyses, highlighting that transdiagnostic research in clinical and non-clinical populations is essential for identifying subgroups within and across both spectra that may share more homogeneous underlying etiologies and show more targeted treatment responses.

Introduction

T. Ziermans, *Netherlands*

204.001 A Measurement Invariance Analysis of Autistic Traits in Individuals with Typical Range and High Schizotypal Traits
M. Pelton¹, **K. Chisholm**², **T. C. Ford**³ and **S. J. Wood**⁴, (1)University of Cambridge, Cambridge, Cambridgeshire, United Kingdom, (2)University of Sussex, Brighton, East Sussex, United Kingdom, (3)Cognitive Neuroscience Unit, Deakin University, Melbourne, VIC, Australia, (4)Orygen, Melbourne, VIC, Australia

Background: People with high autistic traits who develop psychosis experience worse outcomes than those with typical range autistic traits, including more severe psychotic symptoms, more frequent suicidality, lower quality of life, and reduced role functioning. The Autism Spectrum Quotient (Baron-Cohen et al., 2001) is widely used to assess autistic traits in psychosis services, however, it is yet to be validated in individuals with psychosis.

Objectives: We explored whether the measurement properties of the Autism Spectrum Quotient Short form (AQ-S; Hoeskstra et al., 2011) were equivalent in a general population sample of individuals with high and typical-range schizotypal traits. Schizotypal traits are sub-clinical personality traits reflecting psychotic experiences. Individuals with high schizotypal traits are more likely to experience schizotypal personality disorder and brief psychotic episodes.

Methods: 1713 participants aged 18 to 40 years (mean 26.4, 25% male) were recruited from the general population via social media and at an Australian University. Participants completed the AQ-S and the Schizotypal Personality Questionnaire (SPQ; Raine, 1991). High schizotypy was defined as the top 10% of SPQ scores (SPQ > 164/296, n=564). We undertook measurement invariance analysis, using multi-group structural equation modelling. Increasing parameters (thresholds, factor loadings and intercepts) were constrained equal across groups and models tested for significant degradation of fit.

Results: As shown in Table 1, the high schizotypy group were more likely than the typical range schizotypy group to be male (n=168, 29% vs n=263, 23%), have a history of psychiatric intervention (n=230, 41% vs n=358, 32%) and medication (n=156, 27% vs n=236, 21%), and reported higher scores on the SPQ (mean=187.31 (SD=19.36) vs 128.26 (SD=21.42)) and the AQ-S (mean=70.66(SD=7.92) vs 48.85 (SD=8.82)). Single group analysis confirmed that the model fit well in male and female gender groups and random samples. As shown in Table 2, the configural model showed reasonable fit to the data ($\chi^2=3428.625$ (df=688, CFI=.921, TLI=.914, RMSEA=.068). Constraining thresholds and factor loadings equally across groups resulted in no significant degradation of fit, meaning criteria for metric invariance was met. Constraining intercepts equal resulted in significant degradation of fit ($\Delta CFI=0.023$) meaning assumption of scalar invariance was not met. Constraining intercepts in 'imagination' ($\Delta CFI=0.01$) and 'switching' ($\Delta CFI=0.012$) subscales led to significant degradation of model fit.

Conclusions: The AQ-S demonstrated configural and metric invariance across groups meaning the same constructs can be measured in people with high and typical schizotypy. The AQ-S demonstrated scalar invariance in the social, routine and patterns and factors subscales suggesting these factors can be accurately measured and compared between groups. The imagination and switching factors were non-invariant suggesting bias in the measurement of these factors, which could indicate differences in baseline levels of imagination and switching difficulties in those with high compared to typical schizotypy. Overall, results suggest the AQ-S does not accurately measure autistic traits in those exhibiting a high degree of schizotypy. Future research should work in partnership with autistic people to develop accurate measures of schizotypal traits and should extend these findings in a sample of autistic people experiencing psychosis.

204.002 What Is the Impact of Autism Traits and Psychotic Symptoms on Anomalous Self-Experiences?
S. J. Wood, Orygen, Melbourne, VIC, Australia

Background: There are historical and theoretical indications of a difference in subjective experience between autism spectrum disorder (ASD) and the schizophrenia spectrum. While diagnostically independent, these conditions can co-occur in the same individual at both the trait and diagnostic levels, but the impact of such co-occurrence on subjective experience is unknown. The diametric model suggests that the two conditions represent the extremes of a unidimensional continuum of cognition and behaviour, which would imply that anomalous self-experiences would be attenuated in individuals with mixed symptom expressions.

Objectives: To test the combined effects of autism traits and psychotic-like experiences on anomalous self-experiences in a two groups of young people help-seeking for mental health problems, and a healthy comparison group.

Methods: A total of 150 participants were recruited, made up of people meeting clinical high-risk criteria for psychosis (CHR; n=84), people help-seeking for mental health problems without meeting high-risk criteria (Clinical Control; n=43), and those without mental health problems (Healthy; n=23). Clinical groups were recruited from several *headspace* clinics in Melbourne, Australia, which are clinical services designed for young people with mild to moderate mental health problems. Positive psychotic symptoms were assessed using the positive subscale of the Brief Psychiatric Rating Scale (BPRS), and autistic traits were assessed with the Autism Quotient (AQ). The presence or absence of self-disorders was assessed with the Examination of Anomalous Self-Experience (EASE) scale.

Results: Comparison of the groups for AQ, EASE, and BPRS positive scales revealed that the CHR group had the highest scores on all three measures, although they did not significantly differ from the Clinical Control group on AQ scores. Least-squares regression analyses were conducted in which EASE score was estimated with the Z standardized scores of the BPRS positive and AQ total scores, and their interaction. This produced a significant model ($F(3,148)=19.8$, $p<0.001$) where EASE scores were predicted by both BPRS positive ($\beta=0.42$, $t=5.84$, $p<0.001$) and AQ totals ($\beta=0.24$, $t=3.31$, $p<0.001$). The interaction term was negative, suggesting that when both BPRS positive and AQ scores were increased, EASE scores were smaller. However, this did not reach significance ($\beta=-0.13$, $t=-1.78$, $p=0.077$).

Conclusions: Anomalous self-experiences are positively associated with both positive psychotic symptoms and autistic traits. Although non-significant, there was tentative evidence that these self-experiences were attenuated in young people with equal expressions of positive psychotic and autistic features. This would be consistent with recent evidence for the diametric model of co-occurrence for schizophrenia and autism. Understanding why this occurs and its impact on clinical outcomes would assist in developing new intervention options for autistic people with psychotic disorders.

204.003 Comparative Analysis of Social and Neurocognitive Performance across Autism and Schizophrenia Spectrum Disorders and Related Neurobiology

A. Rashidi¹, S. Bagheri², L. Oliver², I. Moxon-Emre³, T. Tan², J. C. Yu², R. Pan², M. T. Secara², P. Desarkar⁴, M. C. Lai⁵, P. Szatmari⁶, E. W. Dickie⁷, A. Malhotra⁸, R. Buchanan⁹, A. Voineskos⁷, C. Hawco⁷ and **S. H. Ameis¹⁰**, (1)250 college st, Centre for Addiction of Mental Health, Toronto, ON, Canada, (2)Centre for Addiction of Mental Health, Toronto, ON, Canada, (3)The Centre for Addiction and mental health, Toronto, ON, Canada, (4)Department of Psychiatry, University of Toronto, Toronto, ON, Canada, (5)Campbell Family Mental Health Research Institute, Centre for Addiction and Mental Health, Toronto, ON, Canada, (6)Centre for Addiction and Mental Health, The Hospital for Sick Children, Toronto, ON, Canada, (7)The Centre for Addiction and Mental Health, Toronto, ON, Canada, (8)Northwell Health, New York, NY, (9)University of Maryland School of Medicine, Catonsville, MD, (10)Child and Youth Mental Health, The Centre for Addiction and Mental Health, Toronto, ON, Canada

Background:

Impacted social and neuro- cognitive performance has been reported across Autism and Schizophrenia Spectrum Disorders (SSDs).

Objectives: In the upcoming INSAR meeting, data will be presented comparing social and neuro-cognitive performance across a large sample, including autistic youth/young adults, individuals with SSDs, and typically developing controls (TDCs). Associations between social cognition, neurocognition and social functioning will be presented across groups. In addition, published data from our group examining neural correlates of social cognition across our transdiagnostic sample, using resting state brain activity, will be described.

Methods:

Participants were recruited from two National Institute of Mental Health funded studies (N=585; autism N=100, SSDs N=276, TDCs N=209; aged 16-55 years; 61% male assigned at birth). Participants completed social cognitive tasks, ranging from lower-level (e.g., emotion processing) to higher-level (e.g., theory of mind/mental state inference), the MATRICS Consensus Cognitive Battery, and a social functioning scale. Social and neurocognitive data across groups were compared using non-parametric methods, adjusting for age and sex, and relationships between social cognition with neurocognition and functioning were examined using within-group correlations. Permutation analysis of linear models was employed to investigate the relationship of fractional amplitude of low frequency fluctuation (fALFF) --a measure of resting-state spontaneous local brain activity-- with diagnostic group, higher and lower-level social cognition, in a subsample (autism N=68, SSDs N=242, TDC N=185) of the parent studies.

Results:

Autistic and SSDs groups performed worse than TDCs on lower- and higher-level social cognitive tasks, with few differences between clinical groups. Both autism and SSDs had lower neurocognitive scores than TDCs, where SSDs demonstrated more pronounced deficits in processing speed, working memory, verbal learning, and visual learning. Across groups, positive associations between social cognitive tasks and neurocognition were found across groups, but only self-reported measures of empathy showed consistent correlations with social functioning. Lower fALFF in the visual and higher fALFF in frontal regions were found in both autism and SSDs compared to TDCs. Positive associations between fALFF and higher level social cognition was found across the whole sample.

Conclusions:

This work compares both social cognition and neurocognition in a large autism/SSDs transdiagnostic sample. Findings confirmed that relative to controls, autistic participants and those with SSDs show similar performance on lower- and higher-level social cognitive tasks, while neurocognition was less impacted in autism versus SSDs. While both autistic and SSD groups featured significant differences in social cognition compared to TDCs, and overlap in differences in fALFF-measured resting-state brain activity, brain-behaviour findings suggested similar patterns of associations between regional resting-state brain activity and high-level social cognitive performance were present across autism, SSDs and TDCs. Our findings provide further support for transdiagnostic research into mechanisms underlying social cognition, and suggest some common neurobiological patterns associated with high-level social cognition across our heterogeneous transdiagnostic sample.

204.004 The Value of Excitation/Inhibition Ratio in Classifying Autism and Schizophrenia

M. Assaf¹, L. Uscatescu², C. Hyatt¹, J. Dunn³, M. Kronbichler⁴, V. Calhoun⁵, S. Corbera⁶, K. A. Pelphrey⁷, B. Pittman⁸ and G. Pearlson¹, (1)Olin Neuropsychiatry Research Center, Institute of Living, Hartford, CT, (2)Olin Neuropsychiatry Research Center, Hartford Hospital/Institute of Living/Olin Neuropsychiatry Research Center, Hartford, CT, (3)Interpretable AI, Cambridge, MA, (4)University of Salzburg, Salzburg, Austria, (5)Tri-institutional Center for Translational Research in Neuroimaging and Data Science (TReNDS) Georgia State University, Georgia Institute of Technology, Emory University, Atlanta, GA, (6)Department of Psychological Science, Central Connecticut State University, New Britain, CT, (7)Department of Neurology, University of Virginia School of Medicine, Charlottesville, VA, (8)Psychiatry, Yale School of Medicine, New Haven, CT

Background: Although autism spectrum disorder (ASD) and schizophrenia (SZ) have traditionally been considered as separate diagnoses, phenotypic overlap can hinder differential diagnosis. Overlap in underlying neural mechanisms have been suggested, including in excitation/inhibition (E/I) ratio imbalance. However, the extent of shared or differential E/I differences and their relationship to specific diagnosis is not well understood.

Objectives: We aimed to 1) directly compare in the E/I ratio between ASD, SZ and typically developed (TD) matched individuals and evaluate its viability to dissociate between ASD and SZ; 2) verify the results in an independent dataset; and 3) assess E/I ratio classification accuracy as a standalone measure and in combination with phenotypic measures.

Methods: We computed the Hurst exponent (H), an indicator of the E/I ratio, from the time courses of 53 predefined brain areas derived from resting state fMRI scans of two datasets: 1) An exploratory dataset that consisted of 519 TD, 200 ASD and 355 SZ available from publicly available imaging data repositories (e.g. ABIDE, BSIP), and 2) a replication dataset of 55 TD, 30 ASD and 39 SZ collected locally under unified protocol including symptomatic and social and non-social cognitive assessments. We first used a random forest classifier (RF) on the exploratory dataset to identify the ten H contributing the most to classify SZ and ASD. Next, we combined these H values with phenotypic information collected in the replication dataset and used RF to compare the classification performance using five models: (a) H only; (b) Positive and Negative Syndrome Scale (PANSS) and the Autism Diagnostic Observation Schedule (ADOS) only; (c) PANSS, ADOS, Bermond-Vorst Alexithymia Questionnaire (BVAQ), Empathy Quotient (EQ), and IQ; (d) H, PANSS and ADOS; (e) H, PANSS, ADOS, BVAQ, EQ and IQ.

Results: Classification parameters for the two datasets and all models are depicted in the attached figure. The classification performance using H only (model a) in the exploratory dataset was high (AUC = 84%). In the replication dataset this model yielded lower, yet acceptable performance (AUC = 72%). However, accuracy increased in this dataset in the models that include phenotypic data (models b to e), with the highest classification performance achieved when combining H with PANSS, ADOS, BVAQ, EQ and IQ (i.e., model e; AUC = 83%). For all models, sensitivity for classifying SZ correctly was higher than specificity, indicating a better classification of SZ compared to ASD.

Overall, the E/I ratio of the precentral gyrus, inferior occipital gyrus, lingual gyrus, and precuneus were the most important neural features contributing to the classification across the models. Phenotypically, the most important features were IQ, ADOS and PANSS positive and negative scores.

Conclusions: These results demonstrate that E/I ratio has a good discriminatory power between SZ and ASD as a standalone measure. Importantly, it augmented the discriminative effect of traditional phenotypic measures, illustrating the potential added value of E/I in differentiating ASD and SZ.

Panel Session

205 - Assessing Quality of Educational Settings for Autistic Students in Four Countries

May 1st, 2025, 10:30 AM - 12:30 PM - 608-609

Panel Chair: Samuel Odom, *Frank Porter Graham Child Development Institute, University of North Carolina at Chapel Hill, San Diego, CA*

To build the strengths of autistic children and youth, educators in many countries establish school-based programs to address the unique learning needs of their students. However, the power of such programs to effect positive outcomes for autistic students is a function of the quality of the educational environment and instructional/intervention features of such programs. In the past decade, there has been substantial progress in assessing the quality of educational programs for autistic students, with this work being conducted across countries and cultural contexts. The purpose of this panel presentation is to present research from four countries (Poland, Sweden, Spain, and the United States) addressing different dimensions of assessment of educational program quality for autistic students. Presenters will identify a variety of questions addressed about assessment of educational contexts and cultural adaptations they have made to common measures of quality.

Introduction

S. L. Odom, *Frank Porter Graham Child Development Institute, University of North Carolina at Chapel Hill, Chapel Hill, NC*

205.001 Improving Program Quality for Autistic Students in Swedish Primary School Classrooms: Outcomes from an Apers-Based Intervention

K. Wenneborg¹, **H. Bejn  ²**, **S. Bolte³** and **L. Roll-Pettersson⁴**, (1)*Stockholm University, Stockholm, Stockholm, Sweden*, (2)*Stockholm University, Stockholm, Sweden*, (3)*Center for Neurodevelopmental Disorders at Karolinska Institutet (KIND), Department of Women's and Children's Health, Karolinska Institutet, Stockholm, Sweden*, (4)*Department of Special Education, Stockholm University, Nyk  ping, Sweden*

Background: The increasing number of children diagnosed with autism in Sweden has highlighted the need for high-quality learning environments. However, research indicates that many educators lack sufficient knowledge of autism, evidence-based practices (EBPs), and inclusive learning environments. The Autism Program Environment Rating Scale (APERS), developed in the U.S., has been successfully used to improve program quality in educational settings in the U.S. and Swedish preschools. Yet, no comprehensive tool is currently available to evaluate autism program quality in Swedish primary schools. Collaborative research with schools using APERS could create sustainable change in the learning environment.

Objectives: This presentation aims to describe the process of translating, adapting, validating, and using the APERS to improve autism program quality in Swedish primary school classrooms. It also aims to share results from the research project, with a focus on the scale's cultural fit, social validity, and use in Swedish primary schools.

Methods: First, we culturally adapted and validated a Swedish primary school version of the APERS. Second, we piloted this version in 10 primary classrooms over one semester, assessing its feasibility and effects on autism program quality through an intervention that included APERS assessment, feedback, in-service training, action plan development, and coaching on implementing EBPs. Third, we conducted a quasi-experimental study with improved autism program quality as primary outcome. It involved four primary schools and 24 classrooms, divided into experimental and control groups, including 25 children (ages 6 to 9 years; 4 girls) with an autism diagnosis or related challenges across two cohorts and two school years. Additionally, coaches and teachers rated the intervention's social validity.

Results: The adapted scale demonstrated strong cross-cultural content validity for assessing autism program quality in Swedish primary schools, requiring substantial adaptations to fit the Swedish context. The pilot study showed significant improvements in the learning environment post-intervention (assessed by APERS). Insights from the pilot led to further modifications of the instrument and intervention and informed the design of the subsequent quasi-experimental study. In this study, autism program quality improved significantly in the experimental group compared to the control group ($F = 31.19$; $p = 0.001$; $\eta^2 = 0.59$). Significant within-group changes were observed in the domains of Learning Environment ($t [11] = -3.47$; $p = 0.005$), Assessment and Individual Education Plan ($t [11] = -4.48$; $p = 0.001$), Personal Independence ($t [11] = -4.17$; $p = 0.002$), and Teaming ($t [11] = -4.29$; $p = 0.001$) for the experimental group. Social validity assessment indicated moderate to high social validity, with coaches scoring higher than teachers.

Conclusions: The adaptation of the APERS to the Swedish primary school context demonstrated strong cross-cultural validity for assessing autism program quality. Findings from both the pilot and quasi-experimental studies suggest the APERS-based intervention is feasible and has the potential to significantly improve the learning environment's quality for autistic learners in Swedish primary schools. The intervention demonstrated high social validity and was well-received by both teachers and coaches.

205.002 Long-Term Evaluation of the National Professional Development Center on ASD (NPDC) Model in Therapeutic Preschools for Children with Autism in Poland

A. Waligórska¹, M. Waligórski², K. Kuncewicz-Sosnowska², M. Andrzejewska² and M. Rupińska², (1)The Maria Grzegorzewska University, Warsaw, (2)The SOTIS Autism Therapy Center, Warsaw, Poland

Background: The NPDC model of evidence-based (EB) educational practice for autism was developed in the US and has been implemented internationally. Poland, sharing similar educational regulations with the US but lacking a strong EBP tradition, presents an appropriate context for studying cross-cultural implementation. This study extends previous research by examining the long-term effects of NPDC model implementation in Polish therapeutic preschools. Formative assessment, as an element of EB models relates both to professional development of team members and to supporting fidelity of EBP implementation. However, especially in novel cultures, there is a tendency for overestimation of self- vs external evaluation of EBP implementation (Hu et al., 2014, McNeill, 2019). This study, conducted 3 years post implementation of the NPDC model in Polish therapeutic preschools aimed at: (a) a comparison of external and self-evaluation of quality of educational practice for students with autism, (b) an analysis of factors influencing the quality of services, related to model implementation.

Objectives: The APERS-PE (Autism Program Environment Rating Scale-Preschool/Elementary), a measure created by the NPDC, was used to compare the external and self-evaluation of quality of educational intervention for children with autism. The analysis involved potential factors influencing the evaluation.

Methods: Participants were 73 teachers and therapists working in 24 preschool groups 3 years after the conclusion of the NPDC model implementation (the model and its evaluation requirements were sustained post-implementation). The repeated measures analysis compared self- and external APERS evaluation of the team members, taking into account potential aspects of impact to the implementation fidelity (i.e. experience of working with EBPs, preschool status of implementation the NPDC model, attitude of preschool supervisor towards the measure, professional background of team members).

Results: Parallel to the previous, mid-implementation study, results indicated consistence of self- and external evaluation using APERS-PE. Both evaluation types indicated a high intervention quality (at the 80% of the maximum score). The analysis of variance demonstrated significance of duration of employment in the preschool using EB model ($F(1,72) = 7.43$, $p = 0.01$, $\eta^2 = 0.1$) and status of the implementation process (completed vs in progress; $F(1,72) = 7.85$, $p = 0.01$, $\eta^2 = 0.1$) for the overall intervention quality and for specific domains of the APERS-PE. Importantly, the observed interaction of these factors ($F(1,72) = 7.75$, $p = 0.01$, $\eta^2 = 0.1$), indicated that completion of the NPDC implementation in preschool related to high intervention quality in both experienced and new team members.

Conclusions: The results replicate previous findings of consistency between external and self-evaluation of intervention quality embedded in the NPDC model implementation. Similarly to the pilot study, the team members' experience of working in the establishment introducing EBP related to higher external and self-evaluation. Completion of the NPDC model implementation process by an establishment was also positively related to intervention quality in all team members, irrespective of their experience. The results support the notion that introducing the complex EB model in the novel cultural context such as Poland is feasible, and the effects are consistent several years after its sustained implementation.

205.003 Piloting of Apers Use to Measure Quality of Education Programs for Autistic Students in Spain

C. C. Gándara¹, **M. Martínez²**, **E. López³**, **O. Lizasoain⁴**, **L. Gámbrá⁴** and **A. Arellano⁴**, (1)Education, University of Navarra, Pamplona, Pamplona, Spain, (2)Psychology, University of Navarra, Pamplona, Spain, Spain, (3)Centro Huarte de San Juan, Pamplona, Spain, Spain, (4)Education, University of Navarra, Pamplona, Spain

Background: Measuring the quality of educational programs for students with autism is essential for enhancing educational strategies and ensuring accountability. In Spain, there are no validated, comprehensive tools to assess the quality of education for students with autism. The Autism Program Environment Rating Scale (APERS; Odom et al., 2023) is an instrument designed to evaluate critical areas for guaranteeing access to quality education for autistic students, whether in general education or self-contained settings.

Objectives: This study aims to evaluate the feasibility and application of both versions of the APERS (Pre-school/Elementary and Middle/High School; APERS-PE and APERS-MH) within the Spanish educational context.

Methods: Seventeen self-contained classrooms in Spain were assessed. The study was conducted at a special education center where the students (110 in total) are 6-22 years of age and have a diagnosis of developmental disability with high need for support; around 50% of the students are autistic. The participants of the sample (focus students) have a diagnosis of autism and intellectual (IDD). A bilingual research team member, certified in APERS-PE and APERS-MH, scored the instrument in four Preschool/Elementary (PE) and thirteen Middle/Highschool (MH) classrooms. Additionally, the Evidence-Based Classroom Observation Tool (EBP COT; Carnahan et al., 2018), a 27-item checklist overlapping in some domains with APERS, was completed for each classroom. Another researcher simultaneously conducted classroom observations, documentation reviews, and interviews with families and teachers, scoring 50% of classrooms to calculate intraclass correlation. Observations covered 24 hours over two months, spanning environments such as physical education, multisensory therapy (Snoezelen), physiotherapy, animal-assisted activities, speech therapy, social skills training, cooking, and laundry. Transitions between activities were also observed. Interviews were conducted on-site or via telephone with 17 main teachers, 14 family members, two speech-language pathologists (SLPs), one physiotherapist, and one administrator. The documentation reviewed included 34 individualized education plans (IEPs), 4 "My Plan" profiles, 4 "Get to Know Me" profiles, and 7 behavior records. Satisfaction surveys were completed by 34 school staff (teachers, SLPs, teacher aides, and specialists) and 56 family members through Google Forms.

Results: For APERS-PE, all domains scored above 3 (on a 1-5 Likert scale, where 3 indicates satisfactory implementation), with a mean of 3.7 (SD=1.04). APERS-MH scores averaged 3.65 (SD=1.19), though "Transition to Adulthood" scored low, likely due to infrastructure and cultural differences. APERS showed good internal consistency, with a Cronbach's alpha of 0.80. The consistency across domains was robust. APERS proved viable in Spain, and we discuss its comparison to EBP COT based on evaluation objectives, and also the utility of satisfaction scales in quality assessments.

Conclusions: APERS is a viable and valuable tool for assessing the quality of education for students with autism in Spain. Validation of this instrument would greatly benefit the Spanish educational system.

205.004 Measuring Program Quality By an External Assessor or Self-Evaluation

A. Sam¹, S. L. Odom² and B. Tomaszewski³, (1)Frank Porter Graham Child Development Institute, Carrboro, NC, (2)Frank Porter Graham Child Development Institute, University of North Carolina at Chapel Hill, San Diego, CA, (3)University of North Carolina at Chapel Hill, Chapel Hill, NC

Background: The Autism Program Environment Rating Scale Preschool Elementary Version (APERS-PE; Odom, Sam, Cox, 2024) was designed to measure the quality of preschool and elementary programs for autistic students. The full APERS assessment consists of 62 items that measure 10 domains (learning environments, positive learning climate, assessment and IEP development, curriculum and instruction, communication, social competence, personal independence and competence, interfering behavior, family involvement and teaming. A trained assessor gathers information through observations, record reviews and interview to score the measure. The APERS has a supplemental self-assessment which a teacher can use to reflect about their own practice. The APERS self-assessment consists of 32 items across the same 10 domains. The full APERS has been evaluated as a reliable and valid tool to measure program quality (Odom et al., 2018; Odom et al., 2022). However, limited research has explored the APERS self-assessment and its correlation to the full APERS.

Objectives: This study aims to explore the correlation between the full APERS-PE and the APERS self-assessment in elementary programs that serve students with autism.

Methods: Data are drawn from a larger randomized control trial. Seventeen teachers participated in this portion of the study. All teachers provided special education services for autistic elementary students in a separate, resource, or general education setting. For completing self-assessment, the teachers were provided a paper copy of the self-assessment. Teachers rated each of the 32 items as one of three responses: “This is a challenge in our program” (score of 1); “This element is consistently in place, but we still have some work to do.” (score of 3), or “This is a real strength of our program” (score of 5). A trained APERS assessor observed in the program for at least three hours, reviewed records (including IEPs and BIPs), and conducted interviews with team members and families. The assessor then scored each item of the full APERS on a scale from 1 (challenge) to 5 (strength). Descriptive statistics and correlations were used to examine the data.

Results: The full APERS total mean score was 2.90 (SD=0.66) with programs rating higher in domains of family involvement (M=3.56, SD=0.66), positive learning climate (M=3.37, SD=0.82), and teaming (M=3.25, SD=0.70). Programs were rated lower in the domains of social competence (M=2.32, SD=0.67), interfering behaviors (M=2.46, SD=0.90), and communication (M=2.62, SD=0.91). The self-assessment mean score was 3.67 (SD=0.27) with teachers rating higher domains of teaming (M = 4.63, SD = 0.62), positive learning climate (M=4.59, SD=0.42), and learning environments (M = 3.99, SD = 0.51). Teachers rated themselves lower in the domains of social competence (M=2.63, SD =1.03), interfering behavior (M=3.26, SD=1.01) and assessment and IEP development (M=3.37, SD=0.97). Based on pooled one-tail t test teaming $t(16)=0.461$, $p=0.032$; interfering behavior $t(16)=0.545$, $p=0.024$, and IEP and assessment $t(16)=-0.622$, $p=0.004$ were correlated.

Conclusions: While the APERS self-assessment was not correlated across all domains with the full APERS, the self-assessment did yield similar patterns based on descriptive statistics. The self-assessment could be used for formative information to facilitate development of plans for program improvement.

Panel Session

206 - Enhancing Equity and Access to Autism Services through Primary Care Integration

May 1st, 2025, 10:30 AM - 12:30 PM - 606-607

Panel Chair: Serene Habayeb, *Children's National Hospital, Washington, DC*

Discussant: Annie Inge, *Center for Autism (CASD), Center for Autism Spectrum Disorders, Children's National, Washington, DC*

Given the growing prevalence of Autism Spectrum Disorder (“autism”), and the continued shortage of autism specialists, recent guidelines from the American Academy of Pediatrics emphasize the need to build the capacity of pediatric primary care systems to support children with autism (Hyman et al., 2020; Jimenez et al., 2017). The focus of this panel will be to highlight innovative projects aimed at decentralizing autism services by embedding care within primary care settings, with a focus on improving equity and access. Studies will highlight the importance of embedding autism services in primary care settings by highlighting populations with high resource needs that have historically been underserved. Projects will also highlight innovative training and consultation models, including tele-consultation models for remote communities, to support providers in primary care to extend the reach of diagnostic services, and in turn, decrease reliance on overloaded specialty centers. Panelists will highlight innovative community engaged methodology used to ensure the scalability and sustainability of these integrated primary care models. Overall, this panel will highlight the value of place-based care to improve equitable access to autism care.

Introduction

S. Habayeb, *Center for Autism Spectrum Disorders, Children's National, Washington, DC*

206.001 Exploring the Childhood Opportunity Index in Autism Diagnostic Clinics in Primary and Specialty Care Settings

R. Iqbal¹, **A. B. Ratto**², **A. Inge**³, **L. Godoy**⁴, **E. Eisenman**⁴, **V. Fuentes**⁴, **S. Godovich**⁴, **M. Lauer**⁴, **T. Abu-Ramadan**⁵, **C. Lucke**⁴, **A. Taylor**⁴, **R. Williams**⁶, **X. Marshall**⁴ and **S. Habayeb**², (1)Georgetown University School of Medicine, Washington, DC, (2)Center for Autism Spectrum Disorders, Children's National, Washington, DC, (3)Center for Autism (CASD), Center for Autism Spectrum Disorders, Children's National, Washington, DC, (4)Children's National Hospital, Washington, DC, (5)University of Wyoming, Laramie, WY, (6)Child Health Advocacy Institute, Children's National Hospital, Washington, DC

Background: Although specialty autism centers typically serve a socioeconomically diverse population across a large catchment area, there continue to be significant racial and health inequities in access to autism diagnosis and care for children from very low-resourced neighborhoods, often due to geography and insurance barriers. One option to address these inequities is embedding evaluations in primary care settings which serve neighborhoods with low levels of resources, such as the Autism in Primary Care (APC) Program at Children's National Hospital in Washington, DC. APC is staffed by psychologists within community-based primary care clinics primarily serving patients with public insurance. No research to date has examined the sociodemographic characteristics of children diagnosed in specialty autism centers compared to primary care centers. Understanding differences in the families served in each clinic type can better elucidate social drivers of health (SDOH) that may impact access to autism care for low-resource populations and evaluate the benefit of services embedded in primary care.

Objectives: To evaluate differences in ethnoracial identity and socioeconomic status of children diagnosed with autism in urban primary care settings compared to specialty autism clinics, using the Childhood Opportunity Index (COI; a validated multidimensional index of neighborhood opportunities, ranging from 1-100, serving as an indicator SDOH).

Methods: The sample consisted of children under age six who received a primary diagnosis of autism between 2019-2023 at Children's National, either through primary care, APC ($N = 310$; $M_{\text{age\_months}} = 38.43 \pm 13.31$) or a specialty autism center, Center for Autism Spectrum Disorders (CASD; $N = 212$; $M_{\text{age\_months}} = 50.37 \pm 13.62$). Chi-squared analyses examined ethnoracial differences between the groups. The metropolitan area-normed COI was used to characterize SDOH. Linear regression analyses were conducted to determine whether clinic setting (APC versus CASD) predicted COI scores while controlling for race and age.

Results: There were significant differences in the ethnoracial breakdown of the groups, $X^2(6, N = 522) = 178.52, p < .001$. Children served through APC were predominantly Black (88.7%) and children diagnosed through CASD were more racially diverse (Black 35.9%; Latine 24.1%; and White 19.8%). 79.8% ($n = 170$) of the APC sample and 20.3% ($n = 43$) of the CASD sample resided in "Very Low" opportunity neighborhoods ($< 20^{\text{th}}$ COI percentile). Regression analyses revealed that, controlling for age and race, compared to children receiving autism diagnostic services in APC, those receiving services at CASD had an estimated 21-point higher COI ($\beta = 21.43$; $p < 0.001$).

Conclusions: The results of this study suggest that traditional autism clinics, although serving an ethnoracially diverse population from a wide geographical area including rural and exurban areas, may still be missing children from very-low resourced neighborhoods. Findings speak to the importance of place-based care and embedding services in primary care clinics to ensure equity in access to diagnostic services. Doing so can address significant health disparities in access to autism care and inform critical policy work to reduce health inequities. Future planned analyses will examine whether COI score predicts autism symptom severity and behavioral characteristics in children seen at both clinics.

206.002 Using Synchronous and Asynchronous Teleconsultation to Increase Access to Autism Evaluations in Primary Care Settings
J. Hine¹, T. E. Foster¹, K. Carlson², C. Stone³, A. K. Spitler², R. Coleman⁴, Z. Warren³, L. Bahrami⁵ and H. Miller⁶, (1)Division of Developmental Medicine, Vanderbilt University Medical Center / VKC TRIAD, Nashville, TN, (2)Vanderbilt University Medical Center, Nashville, TN, (3)Vanderbilt University Medical Center - Treatment and Research Institute for Autism Spectrum Disorder, Nashville, TN, (4)Department of Pediatrics, Vanderbilt University of Medical Center, Nashville, TN, (5)Division of Pediatrics, Vanderbilt University Medical Center, Nashville, TN, (6)Division of General Pediatrics, Vanderbilt UMC, Nashville, TN

Background: Factors such as limited availability of autism specialists and long wait times for diagnostic confirmation support the need for increased timeliness of action-steps within primary care settings. Using embedded specialists and teleconsultation procedures to support diagnoses in primary care settings significantly decreases service delays, reflects high levels of parent/provider satisfaction, and fosters additional opportunities for primary care provider (PCP) training and family support.

Objectives: We examined the use of synchronous and asynchronous specialist teleconsultation to improve access to diagnostic assessment within a network of primary care clinics. The objective was to sustain low wait times, an early age of diagnosis, and provider/family satisfaction across clinics that varied in geography, patient volume/demographics, and autism-specific PCP training experience.

Methods: We extended our streamlined diagnostic model across a network of primary care clinics using synchronous and asynchronous teleconsultation procedures. Children under 48 months were referred from six primary care clinics affiliated with our medical center. Families either received a) a clinic-to-clinic (C2C) or direct-to-home (D2H) tele-diagnostic assessment lead by a psychologist or b) an e-consultation procedure through which a psychologist confirmed a diagnosis via a recorded evaluation submitted by a trained PCP. All families that were seen through teleconsultation procedures were eligible for expedited in-person assessment as necessary. Using data from our in-person hub clinic as a comparator, we compared 1) patient demographics, 2) age at diagnosis, 3) evaluation type, 4) wait times, 5) need for in-person follow up, and 6) provider/family satisfaction with the assessment across types/settings. Data were extracted from our electronic health record (EHR) as well as via REDCap surveys.

Results: Data were extracted for the last 12 months of service during which 80 synchronous teleconsultations and 49 e-consultations were completed across satellite clinics. These data were compared to the same 12 months of our in-person clinic in which we have embedded diagnosticians providing streamlined evaluations (113 in-person visits). Data suggests that the teleconsultation model was successful, as shown by sustained low wait times (median days to evaluation C2C/D2H = 90, e-consult = 35, vs. in-person = 103) and sustained early age of diagnosis (median years for teleconsultation clinics = 2.6). The number of teleconsultation visits that necessitated in-person follow up was low overall (24%), but reasons for follow-up varied (i.e., family/provider preference as opposed to lack of diagnostic certainty). Teleconsultation clinics served a diverse patient population (65% racially/ethnically/linguistically diverse, 70% public insurance). Family/provider feedback showed high rates of satisfaction with teleconsultation model overall, with specific areas for improvement identified.

Conclusions: Extending our diagnostic program via two types of teleconsultation resulted in sustained improvements in accessibility, provider certainty, wait times, age of diagnosis, and provider/family satisfaction. Further, extension clinics served a racially/ethnically/linguistically diverse population and helped minimize common barriers to care (e.g., access to tertiary care, rural locations, lack of autism-specific training for PCPs). Discussion will include specific comparisons across visit types, review of feedback from providers and families, and plans to further address disparities via more longitudinal primary care support.

206.003 Bridging the Gap: Expanding Autism Evaluations in Primary Care

T. Snider¹, R. Lyren¹, A. Moore¹, K. G. Stephenson¹ and B. Mackinaw-Koons², (1)Nationwide Children's Hospital, Columbus, OH, (2)The Ohio State University, Columbus, OH

Background: The prevalence of autism spectrum disorders has increased over the past decade with a current reported prevalence of 1 in 36 children identified with ASD (CDC ADDM, 2023). Long wait lists for autism evaluations nationally have resulted in delays to diagnosis, which subsequently results in delays to accessing early intervention and treatment services (Hightshow et al., 2023). The frequency of recommended well-child checks and developmental surveillance recommended by the American Academy of Pediatrics makes the pediatric primary care center (PCC) a critical and valuable setting to aid in early identification of children with suspected autism. The evidence supporting integration of behavioral health providers in primary care further creates an opportunity to promote early identification of developmental delays including access to targeted autism evaluations resulting in shorter wait times and earlier age of diagnosis.

Objectives: The Integrated Primary Care Autism Spectrum Disorder (IPC ASD) evaluation pathway was developed in collaboration with our academic medical center's (AMC) primary care network, developmental and behavior pediatrics, and our AMC's affiliated autism center. The Autism Learning Health Network's diagnostic algorithm was utilized as a framework with the goals of decreasing the time families wait from first concern to diagnosis and improving timely access to evidence-based care and critical early intervention services. The work focused particularly on families who identify as racial or ethnic minorities.

Methods: Baseline data on autism evaluation completion rates and wait times from referral to diagnosis in the AMC's autism center was gathered. After determining root causes as barriers for completing evaluations, the primary intervention was development of the IPC ASD evaluation pathway. The IPC ASD pathway was developed in 2020 with the goals of decreasing the time families wait from first concern to diagnosis and improving completion rates of evaluation, particularly for underserved populations. Key drivers adopted include clinic staff education, collaboration with providers in the AMC's autism center, creation of EMR strategies to support implementation, and strategies to support patient and family experiences.

Results: From November 2020 through October 2023, the IPC ASD evaluation pathway received 671 appropriate referrals. The IPC ASD pathway completion rate was 81.5%. In comparison, the completion rate for the evaluation pathway in our AMC's affiliated autism center (traditional pathway) from 2019-2022 was 63.5%. The median days from referral for IPC ASD evaluation to feedback was 38 days (SD 62.4) compared to 138 days in the traditional pathway. The average age of diagnosis for patients evaluated through the IPC ASD pathway was 35.3 months. Review of patient demographics reveal that patients who identify as racially and ethnically diverse are more likely to complete the IPC ASD pathway compared to the traditional pathway.

Conclusions: By creating a new level of service for targeted autism evaluations in the pediatric primary centers, our PCN and Behavioral Health system was able to improve access to care for patients and families in need of an autism evaluation resulting in decreased wait time and earlier age of diagnosis, particularly for families who encounter barriers navigating complex health systems.

206.004 Primary Care Autism Diagnosis: Enhancing Quality and Scalability of Training through Human-Centered Design

R. McNally Keehn¹, B. Cockrum², A. Kiser², A. Harishchandrar², A. Paxton¹, T. Ryan-Lengacher³ and S. Wiehe³, (1)Pediatrics, Indiana University School of Medicine, Indianapolis, IN, (2)Indiana Clinical and Translational Sciences Institute Patient Engagement Core, Indiana University School of Medicine, Indianapolis, IN, (3)Indiana University School of Medicine, Indianapolis, IN

Background: Autism prevalence has increased by nearly 400% in the past 20 years, but the systems in place to support diagnosis have not kept pace. Primary care autism diagnosis is one solution to address this public health crisis. There is mounting evidence that primary care autism diagnosis is feasible, accurate, reduces evaluation wait time, and allows for streamlined access to community interventions. Despite this potential, widespread uptake of autism diagnosis within primary care has been limited by implementation challenges, including the time and resource intensive nature of training primary care physicians and clinicians (PCP).

Objectives: To revise an evidence-based training program for community PCPs to reach independent competency in the diagnostic evaluation of young children at increased likelihood for autism using a human-centered design approach. Specifically, our goal was 1) to identify strengths and challenges with the training program to drive refinements, and 2) to explore strategies to enhance training quality and scalability.

Methods: *Accelerating the Diagnosis of Autism with Primary care Training (ADAPT)* is a training program to prepare PCPs to develop independent competency in evaluating young children ages 14-48 months for autism. ADAPT includes didactic education, case-based observation, and case-based practicum with practice-based coaching delivered by an expert diagnostic specialist. An interdisciplinary team of human-centered design research experts led two virtual 2-hour sessions, applying participatory design techniques to co-create solutions with PCPs (session 1: N=9; session 2: N=6) who previously participated in the ADAPT training program. A variety of evidence-based co-design methods, including experience mapping, generative activities, and prototype development, were utilized. Qualitative analysis methods (i.e., affinity grouping and data visualization) were used to identify themes and subthemes across the data from each session. Themes from session 1 guided changes to a revised ADAPT prototype that was presented to PCPs in session 2.

Results: In the first co-design session, primary themes regarding ADAPT strengths emerged across the domains of training format (e.g., flexible synchronous or asynchronous options; expert trainer support), content (e.g., practical and comprehensive), and technology (use of learning management platform). Key weaknesses or threats to sustainability included need for greater transparency regarding training processes, non-reimbursable time spent on training, specific gaps in content areas, and need for greater usability of the training platform. In the follow-up session, PCPs reported that ADAPT prototype enhancements including development of a pre-training orientation video, added content on differential diagnosis of autism, and guidance on practical logistics of evaluation (i.e., billing and coding guidelines) improved the training experience. Additional areas for training enhancements, including the need for individualized training based upon PCP experience, were identified.

Conclusions: Human-centered design is an efficient and impactful method for co-creating solutions with end-users to solve critical healthcare challenges. PCP end-users provided key insights to enhance quality and scalability of an evidence-based primary care autism diagnosis training program. Preparing PCPs to deliver autism diagnostic evaluations within community settings has the high potential to ameliorate autism diagnostic delays and disparities.

Oral Session -

301 - New Findings from Early Intervention Randomized Controlled Trials

May 1st, 2025, 2:00 PM - 3:00 PM - 6B

Moderator: Tony Charman, *Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, UNITED KINGDOM*

301.001 Supporting Social Learning in Toddlers with Autism: The Role of Parental Responsiveness and Mediated Learning
X. Liu¹, H. Schertz² and J. Li³, (1)Utica University, Utica, NY, (2)Indiana University, Bloomington, IN, (3)Indiana University, Indianapolis, IN

Background:

Studies regarding parent-implemented interventions for children with autism have focused mainly on increasing parental responsiveness (Jones et al., 2017; Watson et al., 2017), modeling and shaping toddlers' behaviors (Wong & Kwan, 2010) and incorporating naturalistic behavioral strategies into daily activities (Baranek et al., 2015; Kasari et al., 2015). However, the results indicated mixed outcomes regarding improvements in children's social communication (Sandbank et al., 2020). Few studies have investigated parents' influence on children's social communication outcomes. To address this need, this study explored factors that support parents in creating social learning opportunities for their children with autism.

Objectives:

1. To explore pairwise associations between social communication outcomes for toddlers with autism (i.e., initiation of and response to joint attention and social demeanor) and parents' outcomes (i.e., application of mediated learning practices and parental responsiveness).
2. To examine potential differences in the associations between control and intervention groups.

Methods:

This study used secondary data from a randomized control trial, the Joint Attention Mediated Learning (JAML) intervention study (Schertz et al., 2018). It included 119 toddlers aged 30 months or younger who met the criteria for an autism diagnosis and were randomly assigned to experimental or control groups. Intervention Coordinators (ICs) conducted weekly 1-hour home-based sessions with parents for 32 weeks. During these sessions, ICs facilitated parents' learning and reflection on applying mediated learning practices in daily interactions with their children.

The Mediation of Social and Transactional Engagement Measures (MOSTE; Schertz, Horn, et al., 2018) was used to assess parents' application of mediated learning practices. Assessors, trained for reliability, analyzed 10-minute parent-child interaction videos to evaluate parents' application of mediated learning practices. The Maternal Behavior Rating Scale (MBRS, Mahoney, 1998) assessed parental responsiveness. The Preverbal Joint Attention Measures (PJAM; Schertz, 2013) assessed children's social communication outcomes, where their social outcomes were observed from the 10-minute parent-child interaction videos.

Using structural equation modeling, we analyzed pairwise associations between parent practices (mediated learning and responsiveness) and children's social communication outcomes.

Results:

Significant findings included the following:

1. Initiation of joint attention was associated with mediated learning practices but not parental responsiveness.
2. Response to joint attention was associated with parental responsiveness but not mediated learning practices.
3. Positive social demeanor was associated with both mediated learning practices and parental responsiveness, with a high magnitude of association for mediated learning practices and a lower magnitude for parental responsiveness.
4. A positive association between mediated learning practices and toddlers' social communication outcomes was found for the intervention group but not the control group.

Conclusions:

Mediated learning practices were found to be particularly effective in promoting the initiation of joint attention in toddlers with autism. The findings suggest that children with autism are more likely to develop initiation of joint attention when they are actively engaged in social interactions. The presentation will address the implications of enhancing parents' competency in promoting children's social communication outcomes.

301.002 Does Brief Computer-Based Attention Training Prime Responding to a Caregiver-Mediated Intervention for Toddlers with Emerging Autism? Insights from a Randomized Control Trial of the Social ABCs

J. A. Brian^{1,2}, L. A. Sacrey³, I. M. Smith⁴, E. M. Dowds⁵, K. Bernardi⁶, S. Daoud⁷, S. Macwilliam⁸, S. Jilderda⁹, A. Solish¹⁰, A. Hoffman¹¹, S. Wass¹², E. Jones¹³, M. H. Johnson¹⁴, L. Zwaigenbaum¹⁵ and S. E. Bryson¹⁶, (1)Holland Bloorview Kids Rehab Hospital, Toronto, ON, Canada, (2)Department of Pediatrics, University of Toronto, Toronto, ON, Canada, (3)Autism Research Centre, University of Alberta, Edmonton, AB, Canada, (4)Dalhousie University / IWK Health, Halifax, NS, Canada, (5)Autism Research Centre, Holland Bloorview Kids Rehabilitation Hospital-Autism Research Centre, Burlington, ON, Canada, (6)Holland Bloorview Kids Rehab Hospital - ARC, Toronto, ON, Canada, (7)Holland Bloorview, Toronto, ON, Canada, (8)IWK Health Centre, Halifax, NS, CANADA, (9)Alberta Health Services, Edmonton, AB, Canada, (10)Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (11)ARC - Holland Bloorview Kids Rehab Hospital, Toronto, ON, Canada, (12)University East London, London, United Kingdom, (13)Centre for Brain and Cognitive Development, Birkbeck University of London, London, United Kingdom, (14)Centre for Brain and Cognitive Development, Birkbeck, University of London, London, United Kingdom, (15)University of Alberta, Edmonton, AB, Canada, (16)Dalhousie University, Halifax, NS, Canada

Background: Caregiver-mediated, naturalistic developmental behavioral interventions (NDBIs) for toddlers with emerging autism/ASD show evidence of benefits. Participation in one such NDBI, the Social ABCs, yields gains in toddler social communication and a trend toward increased social orienting, as well as caregiver fidelity and self-efficacy.

Objectives: (1) Examine the impact of a computer-based attention training module prior to the Social ABCs (condition). (2) Replicate findings for caregiver fidelity and toddler outcomes immediately following the Social ABCs and at 3-month follow-up (time).

Methods: 67 toddler-caregiver dyads (62 mothers; 30 White, 28 BIPOC) were randomized to receive 6-8 sessions of a computer-based attention training (AT) protocol vs. a sham control condition. All participants then engaged in a 12-week, in-person Social ABCs in their homes. Toddlers (52 boys, 15 girls; 18-32 months old, mean 25.95m, $SD = 3.65$) had confirmed ASD ($n = 32$) or early signs ($n = 29$). Two 10-min videos were collected four times: (T1) Baseline, (T2) Post-Attention Training / Pre-Social ABCs, (T3) Post-Social ABCs, and (T4) Follow-up 3 months after T3. Videos were coded for toddler and caregiver variables, naïve to timepoint and condition, with moderate-to-good inter-rater agreement (mean Kappa across variables: .50 - .66). We analyzed average scores per timepoint using Linear Mixed Modelling to examine change over time across AT conditions.

Results: **Condition effects.** After controlling for significant covariates, two toddler-level variables yielded informative condition effects: Initiations and social orienting. Toddler initiations (rate/min) were significantly higher for toddlers in the attention training condition ($M = .57$ vs. $= .32$), $F(1,208) = 14.86$, $p < .001$. Parent smiling also showed an effect, $F(1,249) = 4.76$, $p = .03$, with families in the sham condition smiling more overall. The condition effect for child social orienting showed a nonsignificant trend, $F(1,245) = 2.86$, $p = .09$. **Time effects** emerged for toddler responsivity ($F(3,235) = 83.14$), social orienting ($F(3,245) = 17.02$), toddler smiling at parent ($F(3,249) = 5.81$), parent implementation fidelity ($F(3,248) = 204.61$, p 's $< .001$) and parent smiling ($F(3,249) = 2.74$, $p = .044$). Post hoc pairwise comparisons showed that T1 and T2 (pre-Social ABCs) differed significantly from T3 (post-ABCs) and T4 (follow-up) for responsivity, social orienting, and parent fidelity; T1 and T2 differed from T4 for child and parent smiling.

Conclusions: (1) Attention-training prior to the Social ABCs appeared to boost toddlers' rate of initiations to their caregiver, with a trend toward fostering increased social orienting. Parent smiling was higher overall for the sham condition, warranting further investigation. The absence of significant condition by time interactions suggests that any effects of such pre-treatment may be subtle. Further refinements may be warranted.

(2) Results replicate previous work wherein participation in the Social ABCs yields significant gains in toddlers' responsivity and increased implementation fidelity and smiling in caregivers. We extend previous findings to include significant increases in toddlers' social orienting and smiling toward their caregivers, which may be explained by an increased emphasis on activities that elicit positive emotion-sharing in this version of the Social ABCs.

301.003 Complex, Low Intensity, Individualised Naturalistic Developmental Behavioural Intervention in Toddlers and Preschoolers with Autism Spectrum Disorder: The Multicentre, Observer-Blind, Parallel-Group Randomised-Controlled a-Ffip Trial
C. M. Freitag¹, M. Kirchner², L. D. Sauer², S. K. Kleber³, L. Polzer⁴, N. Raji⁵, C. Lemler⁵, U. Fröhlich⁶, J. Geissler⁷, M. Ring⁸, V. Roessner⁸, R. Taurines⁷, M. Noterdaeme⁹, K. Teufel⁵, Z. Kim⁵ and J. Kitzrow-Cleven⁵, (1)Autism Research and Intervention Center of Excellence Frankfurt, Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, JW Goethe University, Frankfurt, Hessen, Germany, (2)Institute of Medical Biometry, Heidelberg University Hospital, Heidelberg, Baden-Württemberg, Germany, (3)Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, Goethe Universität Frankfurt, Frankfurt, Hessen, Germany, (4)Autism Research and Intervention Center of Excellence Frankfurt, Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, University Hospital Frankfurt, Goethe University, Frankfurt, Hessen, Germany, (5)Autism Research and Intervention Center of Excellence Frankfurt, Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, University Hospital Frankfurt, Goethe University, Frankfurt, Germany, (6)Josefinum, Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, Augsburg, Augsburg, Bavaria, Germany, (7)Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, Centre for Mental Health, University Hospital of Würzburg, Würzburg, Bavaria, Germany, (8)Department of Child and Adolescent Psychiatry, University Hospital Carl Gustav Carus, Technische Universität Dresden, Dresden, Germany, (9)Child and Adolescent Psychiatry, Augsburg, Germany

Background:

Naturalistic developmental behavioural interventions (NDBI) may improve social communication in toddlers/preschool aged children with Autism Spectrum Disorder (ASD).

Objectives:

Here, we study efficacy of the low-intensity, complex NDBI “Frankfurt Early Intervention Program for ASD” (A-FFIP) over one year by a confirmatory phase-III, prospective, randomized, controlled, parallel-group study with two treatment arms over four centres at Frankfurt, Augsburg, Dresden and Wuerzburg.

Methods:

Main inclusion criteria: ASD (DSM-5), age 24 to 66 months, developmental quotient > 30. *Intervention:* Manualised A-FFIP intervention. *Control intervention:* Early intervention as usual (EIAU). *Primary outcome:* Change in core ASD symptoms between 12 months of intervention (T6) and baseline (T2) based on the blindly rated Brief Observation for Communication Change (BOSCC) total score. *Statistical analysis:* Mixed model for repeated measures with covariates baseline BOSCC-total, chronological age and centre.

Results:

Between July 2018 and October 2021, N=134 children with ASD were randomly allocated to intervention (A-FFIP: n=68, EIAU: n=66). Groups did not differ at baseline with a mean age of 49 (SD 10) months, mean developmental age of 23.3 (SD 13.6) months, and 26 (19.4%) females. The SARS-CoV2 pandemic interfered severely with trial procedures. Intention to treat-analysis in the primary analysis set with at least one post-baseline BOSCC measure (A-FFIP n=64, EIAU n=60) did not find differences in the primary outcome by group. Treatment interruption due to the SARS-CoV2 related lockdown was associated with less improvement across groups. Secondary outcomes showed stronger improvements in parent-rated repetitive behaviour as well as parent- and teacher-rated executive functions for A-FFIP versus EIAU. Adverse events were comparable between groups.

Conclusions:

A-FFIP, which allows individually targeting six core basic abilities and five developmental domains related to longitudinal development in ASD, is a promising, manualised NDBI, which needs to be further studied for long-term effects on social communication and other outcomes in ASD.

301.004 Online Parent Coaching to Target Social and Language Outcomes for Chinese-Learning Autistic Preschoolers: One-on-One and Group Formats Are Comparable

H. W. Hirai¹, K. Y. Y. Ho², E. C. H. Poon², X. Qi³, E. C. L. Lai⁴, C. K. S. To³, J. S. C. Chong⁵ and P. Wong^{1,2}, (1)Brain and Mind Institute, The Chinese University of Hong Kong, Shatin, N.T., Hong Kong, (2)Department of Linguistics and Modern Languages, The Chinese University of Hong Kong, Shatin, N.T., Hong Kong, (3)Academic Unit of Human Communication, Development and Information Sciences, Faculty of Education, The University of Hong Kong, Hong Kong, HK SAR, China, (4)Department of Child & Adolescent Psychiatry, Castle Peak Hospital, Hong Kong Hospital Authority, Tuen Mun, N.T., Hong Kong, (5)Department of Paediatrics & Department of Obstetrics and Gynaecology, The Chinese University of Hong Kong, Shatin, N.T., Hong Kong

Background: Parent-implemented communication programs effectively support the social and communication development of autistic children in daily interactions. However, these programs are typically offered in a One-on-one-format, which can place a financial burden on the healthcare system and be cost-prohibitive for many families.

Objectives: To compare the effectiveness of a One-on-one-format versus a cost-effective Group-format of a completely online, parent-implemented support program to enhance social and language outcomes for Chinese-learning autistic preschoolers.

Methods: This ongoing randomized controlled trial recruited 144 Cantonese-learning preschoolers, who will be followed for two years. All children were diagnosed with or evaluated to be at elevated likelihood of autism by a qualified clinician, and were assessed and classified as “autism” or “autism spectrum” using the Autism Diagnostic Observation Schedule, Second Edition (ADOS-2). Children with insufficient verbal language, determined by a score greater than zero on ADOS-2 Item A1, were included. Families were randomly assigned to either One-on-one-format (n=72) or Group-format (n=72, with up to eight families per group). One parent per child participated in a six-month, 20-session online social communication program taught by a speech therapist. Parents learned seven communication strategies to implement with their child at home, with extensive coaching and video feedback provided throughout the program. A total of 93 children, aged 24-57 months (mean 37.18±8.23), who reached the one-year follow-up with data from the 6-month and/or 12-month assessments, were included in the analysis.

Demographic data were collected at baseline. To measure changes in socialization and language abilities, ADOS-2 and Mullen Scales of Early Learning (MSEL) assessments were performed at baseline and 12-month. Parent-reported Vineland Adaptive Behavior Scales – Third Edition (Vineland-3) were collected at baseline, 6-month (upon program completion) and 12-month as secondary outcomes. Paired t-tests were used to compare baseline and 12-month outcome measures, including: (1) age-adjusted ADOS-2 Comparison Scores, (2) ADOS-2 Social Affect raw score, (3) ADOS-2 Repetitive and Restricted Behavior raw score, (4) age-adjusted MSEL Receptive Language and (5) age-adjusted MSEL Expressive Language. ANCOVA models were applied to assess the influence of the *Intervention format* (One-on-one vs Group). For age-adjusted Vineland-3 Socialization and Communication scores, repeated measure ANCOVAs were applied to evaluate the effect of *Time* (Baseline, 6-month and 12-month) and *Time*Intervention format* interaction.

Results: At the one-year follow-up, children's ADOS-2 Social Affect raw score showed significant improvement in both formats (One-on-one: $p=0.034$, $d=0.32$; Group: $p=0.025$, $d=0.34$), suggesting that both intervention formats were effective in enhancing children's socialization. For age-adjusted MSEL Receptive Language, children in the One-on-one format demonstrated significant improvement ($p=0.003$, $d=-0.45$), while those in the Group-format did not ($p=0.120$, $d=-0.24$); however, the ANCOVA model revealed no significant differences between the intervention formats. For age-adjusted MSEL Expressive Language, improvements were found in both formats (One-on-one: $p<0.001$, $d=-0.87$; Group: $p=0.034$, $d=-0.33$) children. Furthermore, the ANCOVA model indicated that children in the One-on-one-format had greater improvement compared to those in the Group-format ($F=7.714$, $p=0.017$, $\eta^2p=0.391$) (Table 1 and Figure 1).

Conclusions: Online parent coaching with the option of a Group-format is effective in enhancing social and language outcomes for Chinese-learning autistic children.

Oral Session -

302 - Social Interaction and Communication between Autistic and Non-Autistic People

May 1st, 2025, 2:00 PM - 3:00 PM - 6C

302.001 Verbal Collaboration in Same and Mixed Neurotype Groups of Autistic and Non-Autistic Adults

S. J. Foster¹, S. Patel², C. Wilks³, M. Dodd⁴, R. Calderon⁵, R. A. Ackerman⁶, D. Ropar⁷, S. Fletcher-Watson⁸, C. J. Crompton⁹ and N. J. Sasson¹,
(1)Psychology, University of Texas at Dallas, Richardson, TX, (2)University of Texas at Dallas, Richardson/Dallas, TX, (3)University of Edinburgh, Edinburgh, United Kingdom, (4)Nottingham Trent University, Nottingham, United Kingdom, (5)University of Texas at Dallas, Richardson, TX, (6)The University of Texas at Dallas, Richardson, TX, (7)University of Nottingham, Nottingham, UNITED KINGDOM, (8)Salvesen Mindroom Research Centre, University of Edinburgh, Edinburgh, United Kingdom, (9)Centre for Clinical Brain Sciences, University of Edinburgh, Edinburgh, UNITED KINGDOM

Background: Autistic adults often communicate more effectively and establish better rapport with other autistic people than with non-autistic people, both in one-on-one and group settings (Crompton et al., 2020; Morrison et al., 2020; Foster et al., 2024). Thus, differences in social and communicative styles between autistic and non-autistic people (Crompton et al., 2020; Milton, 2012) may affect collaborative success and interpersonal outcomes. However, it is unclear how communication differs between autistic and non-autistic people in group settings, and whether potential differences are affected by the diagnostic composition of the group. One approach to explore this is by examining verbal collaboration (Avry et al., 2020), a term that refers to a sub-category of speech involving collaborative intentions through socio-cognitive and socio-relational processes (Austin, 1975; Dillenbourg et al., 2016).

Objectives: To investigate differences in verbal collaboration among autistic and non-autistic adults in same- and mixed-neurotype groups.

Methods: Seventy-three autistic and sixty-three non-autistic adults participated (table 1). Participants were allocated to one of four conditions with three other participants: all autistic, all non-autistic, autistic neurominority (1 autistic and 3 non-autistic), and non-autistic neurominority (1 non-autistic and 3 autistic), totaling 34 groups. Each group was aware of its diagnostic composition but not participants' specific diagnoses. Groups engaged in a five-minute task to build a tall tower with large Jenga blocks using vague instructions that could be interpreted as collaborative or competitive. Interactions were recorded and transcribed. Two researchers coded instances of collaborative speech, including: propositions (given and elicited), elicited opinions, positive and negative self-directed and other-directed opinions, agreements, and incorporations from an established scheme (Avry et al., 2020). The researchers achieved substantial inter-rater reliability ($k=0.81$).

Results: Autistic participants expressed more positive opinions about the task/group $t(134) = .894, p=.039$ and their contributions $t(134)= 1.53, p=.002$ than non-autistic participants, whereas non-autistic participants prompted more building ideas $t(134)= 2.29, p<.001$ and expressed more negative opinions about the task/group $t(134)= 1.02, p=.003$. Multilevel models indicated that the effect of participants' diagnosis on "negative opinions directed at others" was dependent on the diagnostic composition of the group ($p=.007$). Simple slopes demonstrated that expressions of negativity about the group and task were lowest for autistic participants in the all autistic groups and increased as more non-autistic members were included (no non-autistic: $M=1.04$; one non-autistic: $M=1.62$; all non-autistic: $M=2.78$) (figure 1). No effect of group composition type was found for non-autistic participants ($p=.20$).

Conclusions: Distinct patterns emerged in collaborative speech between autistic and non-autistic participants. Overall, autistic adults verbalized more positivity and less negativity than non-autistic adults. However, they increased negative expressions when in groups of non-autistic adults. These results mirror previous findings indicating that rapport for autistic adults is highest in all autistic groups and diminishes with the presence of non-autistic members (Foster et al., 2024). In contrast, markers of verbal collaboration by non-autistic participants remained stable across group types. Taken together, these findings suggest that autistic adults often benefit socially when interacting with each other and may be more sensitive to group composition than non-autistic participants.

302.002 Can the Double Empathy Problem be Mitigated By Interacting Online? - a Direct Comparison of Online and in-Person Interactions.

L. M. Naudusevics¹, L. E. Marsh², D. Ropar³ and N. Dean Marshall⁴, (1)Psychology, University of Nottingham, Nottingham, Nottinghamshire, United Kingdom, (2)University of Nottingham, Nottingham, United Kingdom, (3)University of Nottingham, Nottingham, UNITED KINGDOM, (4)Psychology, University of Nottingham, Nottingham, Nottinghamshire, United Kingdom

Background:

The Double Empathy Problem (DEP) suggests a bi-directional disconnect between autistic and non-autistic individuals (Milton et al., 2018). Following short in-person interactions, less rapport and reduced information transfer was achieved when autistic and non-autistic people interacted, compared to when individuals of the same neurotype interacted (Crompton et al., 2020). So far, research into the DEP has focused on in-person interactions although online interactions may provide autistic people with visual anonymity, greater flexibility (Benford et al., 2009) and an opportunity to express their true selves (Gillespie-Lynch et al., 2015). Preliminary evidence indicates that the DEP may be mitigated during online interactions (Marsh et al., in prep) although a direct comparison between online and in-person modalities has not been tested.

Objectives:

Here we evaluate whether the DEP is mitigated online by testing whether mixed and matched neurotype dyads achieve equivalent rapport in online compared to in-person interactions.

Methods:

In this pre-registered study, 39 non-autistic and 32 autistic participants completed online and in-person dyadic interactions using a 'speed dating' paradigm. Interactions with mixed and matched neurotype partners were completed for each modality in a within-subject design. Rapport was measured after each interaction. After exclusions, $n=427$ interactions and $n=854$ interaction ratings were analysed.

Results:

Rapport data were analysed using linear multilevel models (LMMs) in R. Models included fixed effects of Dyad Type (Mixed, Matched neurotype), Modality (Online, In-Person), Participant and Partner Diagnosis, and the two-way interactions between them. Random effects for participant and partner were also modelled.

Contrary to previous results, mixed and matched neurotype dyads achieved similar rapport, regardless of modality ($\text{Beta} = .03$, $\text{df} = 314$, $p = .64$). Autistic partners received lower rapport ratings, regardless of Dyad Type and Modality ($\text{Beta} = -.26$, $\text{df} = 56.67$, $p < .05$). Additionally, autistic participants reported experiencing marginally less rapport, regardless of Dyad type and Modality ($\text{Beta} = -.25$, $\text{df} = 66.32$, $p = .06$). Both autistic and non-autistic participants reported greater levels of rapport following in-person, compared to online interactions ($\text{Beta} = 0.31$, $\text{df} = 4.51$, $p < .001$).

Conclusions:

Inconsistent with the Double Empathy Problem, we found no evidence of rapport benefits for matched compared to mixed neurotype interactions. The current study is the first to employ a within-subject design to investigate DEP, providing greater experimental control and power in comparison to previous research, which may explain the contradictory results found. These results are consistent with work that demonstrates that autistic individuals are subject to first impression biases (Sasson et al., 2017) and suggests these biases may extend to short interactions. We also found that greater rapport was achieved after in-person interactions, suggesting online interactions do not improve the DEP as previously suggested (Marsh et al., in prep). DEP assumes autistic matched interactions are beneficial, however, this maybe too simplistic when considering the complex nature of social communication. Future research should consider nuanced individual differences in communication rather than group-level diagnostic differences. Further work is ongoing to investigate the impact of conversational alignment, use and synchrony of facial expressions, and camouflaging on rapport.

302.003 Automatic Detection of Communication Difficulties in Neurodiverse Group Conversations

C. Kobayashi¹, I. Hoshina¹, T. Sakato¹, M. Tsujii^{1,2}, F. Nihei³, C. Takayama³, R. Ishii³, K. Stefanovi^{1,4} and Y. Nakano¹, (1)Seikei University, Musashino-shi, Tokyo, Japan, (2)Chukyo University, Nagoya-shi, Aichi, Japan, (3)NTT Human Informatics Laboratories, NTT Corporation, Yokosuka-shi, Kanagawa, Japan, (4)Monash University, Clayton, VIC, Australia

Background: Recent advancements in AI technologies, particularly in deep learning, have demonstrated surprising performance for identifying and recognizing patterns in large amounts of data. Aiming to show the effectiveness of deep learning techniques in analyzing social interaction between individuals with autism spectrum disorder (ASD) and neurotypical individuals, this study applies deep learning methods to detect communication difficulties that arise in communication between ASD individuals and neurotypical ones.

Objectives: To propose a deep learning technique for detecting communication difficulties in neurodiverse group conversations involving ASD individuals and neurotypical ones.

Methods: A total of 22 neurodiverse group conversations were collected from 11 groups, each consisting of three participants: one ASD individual and two neurotypical individuals. The average age of ASD participants was 29.6 years. The conversation corpus contained 12,016 utterances. Communication difficulties were categorized into two main types: "interaction maintaining", "smoothness of communicative behaviors".

"Interaction maintaining" was sub-categorized into three aspects: engagement (whether ASD individuals were properly engaged in the conversation), turn-taking (whether their turn-taking behaviors were performed appropriately), conversation context (whether their utterances were contextually relevant). "Smoothness of communications behaviors" was also sub-categorized into two aspects: verbal (e.g. word choice, sentence structure), nonverbal (e.g. speech prosody, facial expressions). Based on these categories, deep learning models were created to estimate communication difficulties in terms of (1) engagement, (2) interaction maintaining, and (3) smoothness of communicative behaviors. Additionally, putting all categories together, we defined (4) all-categories to detect any type of communication difficulty across all categories. Four types of features were used as training data: audio features (Audio), language features (Lang), facial expression features of the speaker (Face-sp), and facial expression features of all participants (Face-all). Transformer-based deep learning models were created by fusing these four types of features to perform binary classification (whether a difficulty was detected or not) across the four aspects: (1), (2), (3), (4) as described above.

Results: We created four unimodal models, each trained on only one of the four types of features and one multimodal model that combined Audio, Lang and Face-sp features. The performance of these models was evaluated on test data using F1-score and accuracy as metrics. The highest accuracy was achieved by the audio unimodal model in detecting any communication difficulties across categories ((4): all-categories), with an accuracy of 0.652. Moreover, models using Face-all features outperformed those using Face-sp features.

Conclusions: This study proposed deep-learning techniques to detect four types of communication difficulties in neurodiverse group communications. The evaluation of models leveraging different modalities revealed that the audio unimodal model, in detecting any communication difficulties across categories, achieved the highest accuracy: 0.652.

302.004 Leveraging and Validating an Online Group Interaction Paradigm to Understand Friendship-Making in Autistic Adolescents

M. D. Lerner¹, A. Gurba², C. I. Parenteau^{1,4} and A. S. Nahmias¹, (1)A.J. Drexel Autism Institute, Drexel University, Philadelphia, PA, (2)Psychology and Brain Sciences, AJ Drexel Autism Institute, Philadelphia, PA, (3)Psychiatry and Behavioral Sciences, Center for ASD and NDDs, UCSF Dept of Psychiatry, San Francisco, CA, (4)AJ Drexel Autism Institute, Drexel University, Philadelphia, PA

Background: While research affirms the importance of friendships in autistic youth (Mendelson et al. 2016), *in vivo* friendship-making assessment techniques for this population are lacking. Likewise, little work has explored the *unique* ways in which autistic individuals form friendships (Black et al. 2024), and how this may relate to enduring peer relations. This is particularly important given the rise of online spaces as a modality for socialization in youth. As such, an accessible, engaging online *in vivo* peer interaction paradigm that can provide differential insight regarding friendship-making in autistic youth is needed.

Objectives: 1) Evaluate relations between friendship-making in a brief, novel online paradigm and external friendships in adolescents, and 2) Evaluate differences in these patterns between autistic and non-autistic youth.

Methods: Mixed groups of autistic and non-autistic adolescents participated in a novel Virtual Game Night (VGN) paradigm (Table 1). Groups ($k = 6$) comprised of autistic and non-autistic (min = 2 each) youth attended VGNs together. Paralleling the structure of in-person peer interaction paradigms (e.g., McNair et al., 2023), VGN involved 20 minutes of unstructured interaction and snack, 15 minutes of a minimally-verbal online game, and 15 minutes of a verbally-mediated online game. VGN participants completed a sociometric procedure (Coie et al., 1982) regarding friendship-making in the group. Separately, participants and parents completed the adolescent/parent friendship questionnaire (A/PFQ; Beristain & Wiener, 2020) regarding their external friendships (i.e., “real-world” friendships). Correlations between sociometrics and A/PFQ were examined overall and in the diagnostic subgroups; moderation analyses examined whether such relations were specific to these groups.

Results: Youth whose VGN peers indicated a lower desire to play with them again reported more online and phone contact with external friends, and those whose VGN peers less frequently indicated they became friends (overall, top, and reciprocated) reported *more* in-person contact with external friends, with a similar pattern seen for total number of friends (Table 1). Moderation (Figure 1) analyses revealed these effects to be largely *specific to non-autistic youth*. However, several effects were *specific to autistic youth*: those whose VGN peers reported they liked them *the most* reported more external friends (with this effect corroborated by parent-report), and more in person contact with these friends.

Conclusions: This study provides the first evidence of the utility of a novel, online peer interaction paradigm as an index of friendship-making in youth. Results reveal a unique set of relations among autistic versus non-autistic youth, suggesting that non-autistic youth with more external friends – and more active, multimodal contact with those friends – may have less effectively engaged in the VGN to make new friends.

However, autistic youth with *more* external friends and active in-person contact them may more effectively translate these experiences to become more liked in the VGN. This suggests effective, autistic-specific ways that autistic youth translate social strategies into online settings to build friendships. Overall, these findings highlight the utility of the VGN, and provide novel insights into how friendships are formed – both initially online and more durably – in autistic (and non-autistic) youth.

303.001 Sleep Problems in Autistic Children at the Time of Psychiatric Hospitalization in Relation to Parenting Stress and Parental Self-Efficacy: Moderation By Child Autism Symptoms and Parental Resources

B. J. Taylor¹, K. A. Pedersen^{2,3} and M. Siegel⁴, (1)Center for Clinical and Translational Science, The Roux Institute at Northeastern University, Portland, ME, (2)Center for Clinical and Translational Science, MaineHealth, Portland, ME, (3)Department of Medicine, Tufts University School of Medicine, Boston, MA, (4)Boston Childrens Hospital, Boston, MA

Background: Sleep problems are common and detrimental to children with autism and their families. Converging research shows that sleep problems contribute to daytime behavior problems in children with autism and even predict psychiatric hospitalization. In addition, sleep problems can have a profound impact on parents, the primary agents of child behavior management, by increasing parenting stress and reducing parental self-efficacy. Here, we examine the relationship between child sleep problems at the time of psychiatric hospitalization in relation to parent stress and self-efficacy, to evaluate what factors may buffer or exacerbate the effects of sleep problems on parent outcomes. Identifying protective and exacerbating factors may inform the development of specialized interventions to mitigate the impact of child sleep problems on family functioning. **Objectives:** (1) Which sleep problems in children with autism are associated with indices of parenting stress and self-efficacy? (2) What factors moderate associations between child sleep problems and indices of parenting stress and self-efficacy?

Methods: Participants were parents of 479 autistic children (ages 12.1 ± 3.2 , 81% male) with admitted to a psychiatric inpatient unit participating in the Autism Inpatient Collection, a multi-site study of six specialized inpatient units. Multivariate analysis was performed to examine the effects of sleep problem profiles (i.e., sleep initiation problems, sleep maintenance problems, and both sleep initiation and sleep maintenance problems) on indices of parenting stress (i.e., parental distress, parent-child dysfunctional interactions, and the perception of the child as difficult) and self-efficacy, controlling for child age, child sex, parental marital status, household income, child's verbal ability, autism severity, and the presence of co-occurring intellectual disability.

Results: All types of sleep problems were associated with greater parent perception of the child as difficult (Table 1). Sleep maintenance problems were also associated with more parental distress and more parent-child dysfunctional interaction. Parent marital status and household income moderated effects of sleep problems on parent self-efficacy such that sleep problems were associated with less parent self-efficacy in single parents (p -values <0.01) and in those making less than \$50,000 per year (p -values <0.001). Autism severity and co-occurring intellectual disability also moderated the effects of sleep on the perception of the child as difficult such that sleep problems were associated with greater perception of the child as difficult for children with high autism severity (p -values <0.05) and those with co-occurring intellectual disability (p -values <0.05).

Conclusions: Sleep problems, particularly frequent nighttime awakenings, increase parenting stress. The detrimental impact of sleep problems appears to be compounded when the child has more significant autism symptoms, increasing a parent's sense that their child is difficult to care for. Greater social and financial resources may buffer against the detrimental impact of sleep problems on parent self-efficacy, as sleep problems may deplete self-efficacy for single parents and those with lower incomes. Child sleep problems are a family system-level issue and future studies are needed to examine family level solutions.

303.002 Hippocampal Volume and Sleep Problems in School-Aged Children at High and Low Familial Likelihood of Autism

P. Mungai¹, J. Munson², S. R. Dager³, T. St. John⁴, J. Piven⁵, H. Hazlett⁶, R. T. Schultz⁶, N. Marrus⁷, L. Zwaigenbaum⁸, M. Styner⁹, K. Botteron⁹, S. H. Kim⁹, R. C. McKinstry¹⁰, D. L. Collins¹¹, J. Pandey¹², M. D. Shen¹³ and A. M. Estes¹³, (1)Psychology, Infant Brain Imaging Study, UW Autism Center, Seattle, WA, (2)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (3)Radiology, University of Washington, Seattle, WA, (4)University of Washington, Seattle, WA, (5)University of North Carolina, Chapel Hill, NC, (6)The Center for Autism Research/CHOP, Philadelphia, PA, (7)Washington University in St. Louis, St. Louis, MO, (8)University of Alberta, Edmonton, AB, Canada, (9)Washington University School of Medicine, St. Louis, MO, (10)Mallinckrodt Institute of Radiology, Washington University School of Medicine, St. Louis, MO, (11)Montreal Neurological Institute, McGill University, Montreal, QC, Canada, (12)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (13)Speech and Hearing Sciences, UW Autism Center, Seattle, WA

Background: Healthy sleep during childhood is vital to health, cognition, and brain development. Some of the same subcortical regions associated with altered brain development in autistic children are also associated with sleep problems. The Infant Brain Imaging Study (IBIS) has previously reported that sleep problems are associated with enlarged hippocampal volumes in infant siblings later diagnosed with autism. However, it is unclear whether the relationship between sleep problems and hippocampal alterations persist in autistic school-age children, even though clinically significant sleep problems affect over 80% of the population at this age.

Objectives: To examine the relationship between hippocampal volume and sleep characteristics in school-aged children (7.0-11.11 years) at higher familial likelihood of Autism Spectrum Disorder (ASD) with an autism diagnosis (HL-ASD), no diagnosis (HL-noASD), and lower familial likelihood of autism (LL).

Methods: Hippocampal volumes were measured from awake MRI T1 and T2 images (Siemens 3T Prisma) across 4 sites (University of North Carolina, Washington University, Children's Hospital of Philadelphia, University of Washington) utilizing all available data that has passed QC to date. Left and Right Hippocampal volumes were highly correlated, so total volume is reported here. Sleep was measured with actimetry in the home for 10 days (Phillips Actiwatch and sleep diaries). Children with actimetry within 6 months of MRI were included (HL-ASD $n=11$; HL-noASD $n=36$; LL $n=35$). Sleep variables included average sleep duration (minutes), sleep duration variability (intra-individual standard deviation of sleep duration), average sleep efficiency (proportion of total time spent sleeping/total time spent in bed), and sleep efficiency variability (intra-individual standard deviation of sleep efficiency).

Results: Our findings revealed a significant relationship between enlarged hippocampi and sleep duration variability in both the HL-ASD and HL-noASD groups, adjusting for total brain tissue volume (see Table 1). No significant associations between hippocampal volume and average sleep duration, average sleep efficiency, or sleep efficiency variability were observed. Future analyses will evaluate other subcortical structures to determine whether this relationship is specific to the hippocampus and will include additional children as scans that pass QC become available.

Conclusions: Greater sleep duration variability was associated with larger bilateral hippocampal volume in school-aged children with higher familial likelihood of autism. This was observed in HL children with and without an autism diagnosis. Variability in sleep duration is an under-recognized index of insomnia and sleep dysregulation, which are commonly observed in autism. Sleep duration averages have been a major focus of sleep research, but variability is also important to consider, especially in studies that take place over multiple days. Averages over multiple days can mask the types of sleep problems seen in insomnia and sleep dysregulation, whereas variability captures these real-world sleep challenges. Investigating brain-sleep relationships has the potential to reveal the developmental impacts of sleep problems in this vulnerable population.

303.003 Factor Structure of the Sleep Disturbance Scale for Children in a Cohort of Youth with Autism

E. K. Baker¹, L. Chetcuti¹, E. Spackman², J. F. Hallmayer¹ and M. Uljarevic¹, (1)Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA, (2)Psychiatry and Behavioral Sciences, Department of Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA

Background: Despite the substantial evidence base for poor sleep in autism, sleep problems are frequently under-identified and inefficiently managed. This is, in part, due to available screening tools failing to comprehensively capture the specific sleep phenotypes in autism. The Sleep Disturbance Scale for Children (SDSC) is one of the highest ranked pediatric sleep assessment tools and is thus a highly promising instrument across research and clinical contexts. However, despite comprehensiveness and promising psychometric properties, the SDSC is scarcely used in autism research. Consequently, the utility of the SDSC for identifying sleep disturbances in autism remains unknown.

Objectives: To explore the factor structure of SDSC in a sample of youth with autism and characterize the associations between derived subscales with key demographic, cognitive, and clinical correlates.

Methods: 513 autistic youth, aged 3-18 years (mean: 10.47 years; SD: 3.71; 18.7% female) were drawn from the Healthy Brain Network secondary dataset. Fit of the previously derived SDSC factor structure was appraised using the confirmatory application of the exploratory structural equation modeling (C-ESEM). Fit was evaluated based on the following statistical parameters: comparative fit index (CFI), Tucker-Lewis Index (TLI), root mean square error of approximation (RMSEA) and standardized root mean square residual (SRMR). Associations between derived factors with age, sex, IQ, and emotion regulation were explored.

Results: A range of previous factor models, including 5-factor and 6-factor solutions were tested. Five-factor solution comprising disorders of initiating and maintaining sleep, disorders of arousal (DoA), disorders of excessive somnolence (DoES), sleep breathing disorders (SBD), and sleep-wake transition disorders (SWTD) showed excellent fit (CFI= .973; TLI= .955; RMSEA= .043 [90% CI: .033, .051], SRMR= .051). Item-level analysis suggested two items that were originally hypothesized to load onto the SWTD factor loaded onto the DOA factor, thus, the model was re-specified and additional C-ESEM was run, resulting in a comparable fit with all items loading significantly onto the intended factors. Derived factor solution was stable across sex and age. Internal consistency and model reliability of identified factors were both in the good to excellent ranges, indexed by Cronbach's Alpha and McDonald's Omega values of $\geq .79$. SWTD and sleep hyperhidrosis factors showed significant negative ($r = -.166, p < .001$ and $r = -.191, p < .001$, respectively) and DoA significant positive ($r = .147, p < .001$) associations with age. None of the SDSC subscales were associated with sex or FSIQ. All subscales were significantly associated with emotion dysregulation. DoES ($r = .466, p < .001$) and SWTD ($r = .403, p < .001$) subscales showed the highest associations with internalizing problems, while externalizing problems showed the strongest association with SWTD ($r = .316, p < .001$).

Conclusions: This study provides the first validation of the SDSC in a large sample of well-characterized youth with autism. Notably, the SDSC subscales showed distinct patterns of associations with key clinical correlates, namely age and emotion regulation. Findings are consistent with independent reviews suggesting the SDSC may provide a more effective way to screen for sleep disturbances in individuals with autism, with the potential to advance targeted and individualized treatments.

303.004 Comparing the Relationships between Internalizing and Externalizing Behaviors and Sleep in Autistic and Non-Autistic Youth

E. Gropman, I. C. Reyes, J. M. Phillips, J. McGrath, R. Libove, R. O'Hara, M. Kawai, B. Jo, J. F. Hallmayer, A. Y. Hardan and E. K. Baker, Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA

Background: Sleep in autism spectrum disorder (ASD) is often highly disrupted, affecting up to 80% of children. Sleep problems are commonly associated with internalizing and externalizing behaviors, with bi-directional relationships noted in both children with ASD and non-autistic controls. Specifically, sleep problems may predict internalizing and externalizing behaviors in children, while these behaviors may also contribute to sleep problems. Despite the known relationships between these behaviors and sleep disturbances, there are few studies directly comparing these associations between children with ASD and non-autistic controls. Understanding the patterns of these relationships may aid in the modification of existing sleep interventions for children with ASD.

Objectives: This study aimed to use a multi-method approach to capture the relationships between internalizing and externalizing behaviors and domains of sleep between children with ASD and non-autistic controls.

Methods: Data for this study is part of the ongoing NIH Autism Center of Excellence for Sleep. To date, data has been collected from 20 non-autistic participants (75% male) and 50 participants with ASD (74% male), aged between 4 and 17 years (Mean age = 10.71, standard deviation = 3.65). Autism diagnosis was confirmed using the Autism Diagnostic Interview and the Autism Diagnostic Observation Schedule. Sleep was evaluated using the Child Sleep Habits Questionnaire (CSHQ), while internalizing and externalizing behaviors were assessed with the Child Behavior Checklist (CBCL) and Aberrant Behavior Checklist-Community (ABC-C).

Results: Group comparisons showed significantly higher scores on all subscales of the CSHQ ($p < .01$) for the ASD group, except for the bedtime resistance and sleep onset delay subscales ($p > .05$). Furthermore, a significantly higher proportion of individuals with ASD (90%) had a CSHQ total score above the clinical cut-off compared to controls (55%; $p < .05$). The ASD group also had significantly higher scores on the internalizing and externalizing domains of the CBCL and all subscales of the ABC-C ($p < .05$). Significant relationships were observed between internalizing and externalizing behaviors and sleep anxiety in the non-autistic group (Table 1), while externalizing behaviors (CBCL, hyperactivity, and irritability) were associated with parasomnias in the ASD group, after controlling for age (Table 2). Interestingly, Z-tests on Fisher z-transformed correlation coefficients found the relationships between parasomnias and externalizing behaviors, and sleep anxiety and internalizing and externalizing behaviors significantly differed between the two groups ($p < .05$).

Conclusions: Using a multi-method approach, we have highlighted differences in the patterns of relationships between sleep problems and internalizing and externalizing behaviors in children with ASD compared to non-autistic controls. These different patterns of results were apparent, despite the high rate of sleep problems, comparable to behavioral insomnia, observed in the non-autistic group. These results build upon the existing literature highlighting the nuanced relationships between sleep and internalizing and externalizing behaviors in children with ASD. Our study underscores the importance of interventions that target both underlying emotion regulation challenges and sleep problems simultaneously in order to improve outcomes in children with ASD.

304.001 The Impact of Urban Living Environments on Autistic Traits and Autism Spectrum Disorder: An Exposome-Wide Study in Two Chinese Cohorts

Q. Zhang¹, T. Ren², L. Zhang³, W. Zhou⁴ and F. Li⁵, (1)Xinhua Hospital Affiliated to Shanghai Jiao Tong University School of Medicine, Shanghai, Shanghai, China, (2)Developmental and Behavioral Pediatric Department & Child Primary Care Department, Brain and Behavioral Research Unit of Shanghai Institute for Pediatric Research and MOE Shanghai Key Laboratory for Children's Environmental Health, Xinhua Hospital, Shanghai, Shanghai, China, (3)Xinhua Hospital, Shanghai Jiao Tong University School of Medicine, Shanghai, China, Shanghai, Shanghai, China, (4)Xinhua Hospital Affiliated to Shanghai Jiao Tong University School of Medicine, SHANGHAI, SHANGHAI, China, (5)Department of Developmental and Behavioral Pediatric and Child Primary Care & Ministry of Education-Shanghai Key Laboratory for Children's Environmental Health, Xinhua Hospital, Shanghai Jiao Tong University School of Medicine, Shanghai, 200092, China., Shanghai, Shanghai, China

Background: Individuals are simultaneously exposed to various environmental factors that might combine to influence human health. Although specific urban factors, such as air pollution, has been linked to autism spectrum disorder (ASD) using a one-exposure-to-one-outcome approach, no study has captured the complexity of real-life exposures in relation to ASD.

Objectives: This study systematically evaluates the impacts of a wide range of urban exposures during pregnancy using an exposome-wide approach, aiming to identify the most relevant combinations of environmental factors (environmental profiles) associated with autistic traits and ASD, as well as to determine the contribution of each factor within these profiles.

Methods: This study included 1,610 typically developing children from the Shanghai Birth Cohort (SBC), with autistic traits assessed at age 4 using a Chinese version of the Social Responsiveness Scale-Short Form (SRS-SF). We also established a matched case-control study comprising 387 pairs of ASD and non-ASD children, matching ASD children from the Shanghai Autism Early Developmental (SAED) cohort with those in SBC by sex and birth year. ASD in the SAED cohort were diagnosed by qualified professionals. We evaluated 16 urban environmental factors based on residential address, including 11 air pollution indicators, 1 sound pollution measure, 1 night light pollution factor, and 3 residential green space metrics. The analysis comprised two steps: first, a single exposure analysis to assess the impact of each factor; second, a multi-exposure analysis utilizing principal component analysis (PCA) to identify distinct urban environmental profiles and their associations with autistic traits and ASD. The PCA was performed on data from the SBC to capture distinct environmental profiles. The loadings from the PCA were then applied to the case-control sample to calculate profile scores. Poisson and logistic regressions were used to investigate the association between each factor and environmental profile with SRS-SF score in the SBC and the odds of ASD in the case control study, respectively.

Results: Single-exposure analysis revealed significant associations of PM_{2.5-10}, NO₂, PM_{2.5} constituents (black carbon and sulfate), UFP, noise, and lack of green space with increased autistic traits, particularly in social communication and ASD-like behaviors. Among these factors, high levels of PM_{2.5-10}, NO₂, UFP and noise as well reduced green space were further linked to increased odds of ASD. Light at night exhibited the strongest impact on ASD odds, although it did not show a significant association with autistic traits. In the multi-exposure analysis, PCA extracted four profiles explaining over 85% of the variation of the total environmental factors. The first three profiles were significantly associated with increased autistic traits, while the fourth, characterized by higher soil levels, correlated with lower traits. The second profile, characterized by high light at night, UFP, noise, and limited green space, demonstrated the most substantial impact on ASD across different trimesters.

Conclusions: Our study provides compelling evidence that urban environmental factors affecting autistic traits and ASD. It emphasizes the relevance of specific environmental profiles in understanding ASD influences, suggesting that a comprehensive approach to urban planning and environmental management could be crucial for mitigating these effects.

**304.002** The Association between Clinically Diagnosed Neonatal Jaundice and Autism: A Swedish Register-Based Cohort Study.

A. Kanina¹, M. Taylor¹, Z. Li¹, M. Rosenqvist¹, A. Butwicki^{1,2,3}, H. Larsson⁴, M. I. Martini¹, M. K. Radó¹ and S. Johansson⁵, (1)Department of Medical Epidemiology and Biostatistics, Karolinska Institutet, Stockholm, Sweden, (2)Department of Biostatistics and Translational Medicine, Medical University of Lodz, Lodz, Poland, (3)Division of Mental Health Services, Akershus University hospital, Oslo, Norway, (4)School of Medical Sciences, Örebro University, Örebro, Sweden, (5)Department of Medicine, Karolinska Institutet, Stockholm, Sweden

Background: Neonatal jaundice may increase the likelihood of autism through bilirubin-induced neurotoxicity, which can reduce Purkinje cells essential for cerebellar function. Cerebellar hypoplasia, marked by fewer Purkinje and granule cells, is observed in some newborns later diagnosed with autism. The association between neonatal jaundice and autism is particularly challenging to elucidate due to the influence of numerous prenatal and neonatal confounders.

Objectives: We aimed to assess whether neonatal jaundice increases the risk for autism while accounting for confounding of perinatal factors.

Methods: We conducted a population-based cohort study using data from Swedish national registers, including the Medical Birth Register (MBR), National Patient Register (NPR), and others, covering individuals born in Sweden between 1992 and 2010 (N=1,669,839). The study excluded stillbirths, multiple births, severe congenital malformations, and individuals who died or emigrated before age 3. Participants were followed from age 3 until death, emigration, autism diagnosis, or December 31, 2013.

Neonatal jaundice, identified using ICD-9/ICD-10 codes, was the primary exposure. The outcome was a clinical autism diagnosis after age 3. Cox proportional hazards regression was used to estimate hazard ratios (HRs) and 95% confidence intervals (CI), adjusting for covariates such as sex, gestational age, birthweight, parental age, and socioeconomic factors. We applied both separate and incremental adjustments to assess the influence of each covariate.

Results: The study population included 1,685,321 individuals, with 39,934 (2.39%) diagnosed with neonatal jaundice and 21,038 (1.25%) diagnosed with autism, of whom 662 (0.04%) had both conditions. Neonatal jaundice was more common in preterm, low birthweight, and cesarean-delivered infants. The mean follow-up for those with jaundice was 8.53 years, 0.76 years shorter than those without. In the crude Cox regression, neonatal jaundice was associated with a higher likelihood of autism diagnosis (HR=1.48, 95% CI: 1.37-1.60). In adjusted models, gestational age (HR=1.11, 95% CI: 1.02-1.22) and birthweight (HR=1.18, 95% CI: 1.09-1.29) attenuated this association, reducing the HR to 1.05 (95% CI: 0.96-1.15) when all covariates were accounted for.

Sensitivity analysis revealed that preterm children had the lowest likelihood of being diagnosed with autism, while post-term infants had the highest. Hemolytic jaundice showed no increased likelihood, whereas non-hemolytic jaundice was initially associated with autism but lost significance after adjusting for gestational age and birthweight.

Conclusions: Our results highlight the importance of adjusting for confounders when investigating early life factors and autism, which may not always be genetic or familial.

304.003 Life Expectancies for Medicaid Beneficiaries with Autism Spectrum Disorder in the United States, 2000-2020

G. Li¹, Z. Yang¹, A. Blanchard², C. DiGiuseppi³ and C. Ing¹, (1)Department of Anesthesiology, Columbia University Vagelos College of Physicians and Surgeons, New York, NY, (2)Department of Emergency Medicine, Columbia University Irving Medical Center, New York, NY, (3)Colorado School of Public Health, University of Colorado Anschutz Medical Campus, Aurora, CO

Background: The existing epidemiologic evidence suggests that the overall mortality risk for people with autism spectrum disorder (ASD) is 2 to 3 times the risk in the general population. Although reduced life expectancy was first speculated in the early 1990s, research on mortality and lifespan issues in ASD remains scarce.

Objectives: Calculate life expectancies for Medicaid beneficiaries with ASD during 2000 through 2020 and compare them with all Medicaid beneficiaries and the US general population.

Methods: Medicaid is the largest health insurance program in the US and the primary public insurance program for people with ASD. Research-identifiable files from Medicaid (i.e., Medicaid Analytic eXtract data files and T-MSIS Analytic Files), and the enhanced mortality data (i.e., mortality data through linkage of Medicaid beneficiaries to the National Death Index) from 2000 to 2020 were analyzed to determine age-specific death rates for beneficiaries with ASD. The standard life table method was used to calculate life expectancies for Medicaid beneficiaries with ASD, which were compared with life expectancies for all Medicaid beneficiaries and the US general population as reported by the Centers for Disease Control and Prevention.

Results: During the 21-year study period, we identified a total of 18,268 deaths among Medicaid beneficiaries with ASD over 8,246,921 person-years, yielding an overall death rate of 221.5 per 100,000 person-years. Life expectancies at birth for Medicaid beneficiaries with ASD increased from 64.1 years during 2000-2004 to 65.8 years during 2015-2019, whereas life expectancies increased from 67.9 years to 72.9 years for all Medicaid beneficiaries, and from 77.3 years to 78.6 years for the US general population (Figure 1). In 2020, life expectancies decreased 4.1 years in Medicaid beneficiaries with ASD, 2.6 years in all Medicaid beneficiaries, and 1.6 years in the US general population, compared to the 2015-2029 period (Figure 1). Among Medicaid beneficiaries with ASD, males had almost identical life expectancies as females (Figure 2). In contrast, females in the Medicaid population and the general population had 5 to 7 years longer life expectancies than males (Figure 2).

Conclusions: Due to heightened mortality rates, people with ASD have substantially shorter life expectancies than the Medicaid population and the general population. The reduced life expectancy among those with ASD is more pronounced for females than for males. The COVID-19 pandemic appears to have had a much greater adverse effect on life expectancy for people with ASD than for the general population.

304.004 The Effects of the COVID-19 Pandemic at the Age of 3 on 5-Year-Old Children with ASD

Y. Sakamoto¹, M. Saito², A. Terui³, A. Osato² and K. Nakamura³, (1)Department of Neuropsychiatry, Graduate School of Medicine, Hirosaki University Hospital, Hirosaki, Aomori, Japan, (2)Department of Comprehensive Rehabilitation Science, Graduate School of Health Sciences, Department of Clinical Psychological Science, School of Medicine, Hirosaki University, Hirosaki, Aomori, Japan, (3)Department of Neuropsychiatry, Graduate School of Medicine, Hirosaki University, Hirosaki, Aomori, Japan

Background:

The children's brains are susceptible to both positive and negative influences from their environments. Early childhood is an important period for developments of emotion, language and impulse control so on. Many toddlers spent their crucial period under the COVID-19 pandemic, and the impact on their development is still unclear, especially children with Autism spectrum disorder (ASD).

Objectives:

To assess the effects of the pandemic at the age of 3 on brain development, this study investigated whether there were differences in development at age 5 between children who were exposed to the pandemic at age 3 and those not exposed at age 3.

Methods:

Subjects were recruited from participants who attended both the 3-year-old developmental checkup in Hirosaki City, Japan, from 2018 to 2022, and the comprehensive assessment stage of 5-year-old developmental checkup in the same city from 2020 to 2024. The latter consists of 2 stages: the initial screening stage and the comprehensive assessment stage. In the screening stage, caregivers fill out the Autism Spectrum Screening Questionnaire (ASSQ) and the Strengths and Difficulties Questionnaire (SDQ-P), and teachers also fill out the SDQ(SDQ-T). The SDQ subscales are Emotional Symptoms(ES), Conduct Problems(CP), Hyperactivity/Inattention(HI), Peer Problem(PP), Prosocial Behavior(PB), and total difficulties score(TDS). In the latter stage, caregivers fill out Social Responsiveness Scale Second Edition(SRS-2), and children underwent the Japanese version of Wechsler Intelligence Scale for Children-Fourth Edition (WISC-IV), one of its subscales is Verbal Comprehension Index(VCI). The child psychiatrists diagnosed ASD based on DSM-5. Since the state of emergency was declared in Japan in April 2020, we had divided the children into two groups: children who participated in the 3-year-old checkup before April 2020, the Pre-pandemic group; children who participated after April 2020, the under-pandemic group (Fig.1). Statistical analysis were performed using Shapiro-Wilk test, Levene test, Independent-samples t-test, and Mann-Whitney U test ($p<0.05$).

Results:

524 children and their caregivers participated in and consented to this study. The number of children with ASD was 160. There were significant differences between the two groups on the 5-year-old SDQ-P_ES ($p=.026$), SDQ-T_ES($p=.003$), SDQ-T_HI($p=.005$), and SDQ-T_TDS($p=.001$). Surprisingly, the SDQ-P_ES of the under-pandemic group was lower than that of the pre-pandemic group, meaning that children who were at age 3 during under the pandemic had fewer emotional problems than children who were at age during the pre-pandemic(Fig.2). SDQ-T_ES, SDQ-T_HI, and SDQ-T_TDS were higher in the under-pandemic group. There was a significant difference in VCI between the two groups.. Focusing on children with ASD, SDQ-T_ES ($p=.004$), SDQ-T_HI($p=.017$), and SDQ-T_TDS($p=.011$) of children with ASD who were at age 3 during pandemic were significantly higher than those who were at age 3 during pre-pandemic(Fig.3,4). There was no significant difference in VCI between the two groups.

Conclusions:

This study suggested that the pandemic might had negatively affected the development of emotion and impulse control outside the home in children with ASD, and positively affected the development of emotional control at home and language in children without ASD. We need to follow the long-term effect of the pandemic on child developments.

305.001 Eyes Wide Open: Exploring Eye Tracking As a Tool for ASD Diagnostics and Clinical Characterization

K. Pierce¹, J. Zahiri², C. Andreason¹ and E. Courchesne³, (1)Autism Center of Excellence, Department of Neurosciences, University of California San Diego, San Diego, CA, (2)Autism Center of Excellence, UCSD, San Diego, CA, (3)Neuroscience, Eric Courchesne, San Diego, CA

Background:

Despite the clear biological differences in autism, diagnosis has relied on somewhat subjective DSM criteria for 80 years. Studies indicate that eye-tracking may serve as an effective screening and diagnostic tool, providing objective metrics that are quick to implement and require minimal training. However, eye-tracking for ASD diagnostics faces challenges such as opaque 'black box' bioinformatic analyses, inadequate inclusion of non-ASD delay children, small sample sizes, unclear relationships between eye-tracking data and symptom severity, and limited independent datasets for generalization. Given toddlers' short attention spans, it is vital to explore the effectiveness of eye-tracking across various time periods and paradigms that assess attention to visual social information, social speech (e.g., 'Baby Talk'), and shifting attention, as these domains synergistically promote social development.

Objectives:

- (1) Assess the efficacy of eye-tracking as a diagnostic biomarker tool by leveraging ET paradigms that span multiple social attention domains and include large sample sizes and non-ASD delay subjects.
- (2) Evaluate the utility of an Autism Score based on ET performance as a reliable index of clinical phenotype and symptom severity.
- (3) Compare the accuracy of simple threshold-based classifier (STC) versus more advanced machine learning (ML) classifiers.

Methods:

Using the *Get SET Early* model for recruitment, 2,489 toddlers (N=1,191 ASD, 616 TD, 682 non-ASD delays, aged 12-48 months) participated in 1-6 eye-tracking (ET) tests resulting in 5,428 datasets (**Figures 1-2**). Clinical evaluations were conducted by psychologists blind to ET results. ET metrics included % fixation non-social, saccades per second, total looking time, and child factors such as sex, age, and parental concern. Standard classification metrics were compared between an explainable simple threshold-based classifier (STC) using a 69% fixation threshold on non-social and a 24% fixation on non-target objects during joint attention—in comparison to a comprehensive set of 18 ML classifiers. An Autism Score was generated using both STC and ML classifiers, and relationship with clinical features examined.

Results:

Across both approaches, specificity and positive predictive value (PPV) were high, even with shorter durations and just one eye-tracking test. For instance, the STC approach revealed GeoPref Test specificity of 97% in both the primary (N=1,789) and independent (n=448) datasets. However, this high specificity was associated with low sensitivity, at 19% and 17% respectively. Sensitivity increased with more diverse eye-tracking tests, reaching its peak with five and six tests that assessed all three domains: visual, auditory, and shifting attention. In these cases, sensitivity, specificity, and PPV were 56%, 89%, 92% and 61%, 100%, 100% in the primary dataset and test sets, respectively. The best ML classifier, Logistic Regression, achieved values of 74%, 82%, 90% and 79%, 100%, 100% in the primary and test sets, respectively. Preliminary analyses indicated significant correlations between the autism score and clinical phenotype.

Conclusions:

Given the speed and accuracy of ET based diagnostic classification, combined with its utility with young toddlers, eye-tracking has the potential to transform early identification practices. Leveraging a range of eye-tracking tests that quantify different aspects of social attention may be particularly valuable for understanding subtypes and enhancing sensitivity.

305.002 Exploring Sex Differences in Multi-Domain Neurocognitive Performance in Autistic Children: A Cross-Sectional Case-Control Study

S. Zhu¹, W. T. Chow², M. W. A. Lam³, Y. T. Cheung¹, S. K. Cheng¹, J. Y. T. Kuong¹, K. H. Y. Tsang¹, X. Yang¹ and **O. Wong⁵**, (1)Faculty of Medicine, The Chinese University of Hong Kong, Hong Kong, Hong Kong, Hong Kong, (2)Faculty of Medicine, The Chinese University of Hong Kong, Hong Kong, Hong Kong, Hong Kong (China), (3)Department of Psychology, Department of Psychology, The Chinese University of Hong Kong, Hong Kong, Hong Kong, Hong Kong, (4)Li Ka Shing Faculty of Medicine, The University of Hong Kong, Hong Kong, Hong Kong, Hong Kong, (5)Department of Psychiatry, Department of Psychiatry, The Chinese University of Hong Kong, Hong Kong, Hong Kong (China)

Background:

Neurocognitive function plays a crucial role in neurodevelopmental disorders, with documented sex differences in autism. However, understanding these differences amid co-occurring psychopathology remains challenging. Clarifying sex-specific neurocognitive patterns could shed light on symptom expression and prognostic variations in autistic individuals.

Objectives:

This study aims to explore sex differences in neurocognitive functioning among autistic children.

Methods:

A cohort of prepubertal children with and without autism underwent extensive phenotyping on clinical symptoms and multi-domain neurocognitive function. Co-occurring attention deficit and hyperactivity disorder (ADHD) was clinically assessed, while anxiety symptoms were evaluated using the parent-rated Anxiety Scale for Children-Autism Spectrum Disorder scale. Neurocognitive functions were assessed using the Penn Computerized Neurocognitive Battery (CNB), comprising 1 motor praxis task and 12 domain-specific tasks. Performance metrics included speed and accuracy for the domain tasks and only speed for the motor praxis task. Speed and accuracy of domain-specific tasks were z-transformed before being summarized with factor analysis into 3 speed (Memory, Deliberative and Rapid) and 3 accuracy (Memory, Social and Executive/Complex Cognition) factor scores. ANCOVA was used to examine the main effects of autism, sex and their interaction on the cognitive performance, and controlled for age, anxiety symptoms and ADHD diagnosis.

Results:

The study compared 636 autistic children (Mean age = 8.4 years; Male:Female ratio = 6.8:1; 58.5% females and 51.6% males with co-occurring ADHD) against 412 non-autistic children without psychiatric history (Mean age = 8.6 years; Male:Female ratio = 1.2:1). Female sex and autism were separately linked to slower reaction times in the motor praxis task [$F(1,984) = 8.29, p = 0.004$; $F(1,984) = 9.53, p = 0.002$, respectively], while only female sex exhibited slower responses in Rapid tasks [$F(1,981) = 8.29, p = 0.004$]. Autistic children had poorer accuracies across all 3 cognitive domains: Memory [$F(1,985) = 23.56, p < .001$]; Social [$F(1,985) = 20.33, p < .001$]; Executive/Complex Cognition [$F(1,985) = 4.15, p = 0.042$]. A significant Diagnosis x Sex interaction was observed in the accuracy scores of Executive/Complex Cognition [$F(1,985) = 4.06, p = 0.044$], with autistic males showing the greatest impairment (Figure 1).

Conclusions:

Our findings, with robust controls for confounders, highlight significant sex differences among autistic children in the domain of Executive/Complex Cognition. The distinction may shape the differential developmental trajectories in autistic males and females, given the role of higher-order cognitions in compensation and camouflaging.

305.003 Long-Lasting Effects of Pre-K Education on Autistic Children's Working Memory and Reading Development

S. A. Kim, *School of Education and Information Studies, University of California Los Angeles, Los Angeles, CA*

Background:

Reading is widely accepted as a critical foundation for long-term school outcomes, but autistic children are more likely to struggle with reading comprehension than their neurotypical peers, peers with a learning disability or dyslexia. Successful reading development begins with strong foundational skills such as working memory (WM), which involves sustaining attention and mentally manipulating information. Many autistic children have difficulties with WM, therefore exploring ways to strengthen WM in autistic children through educational opportunities can be a critical step in fostering long-term reading success.

In the United States, many states are offering state-funded Universal Pre-Kindergarten (pre-K) programs for preschool-age children. Evidence suggests that pre-K education equips young children with necessary school readiness skills in general. However, it is unclear to date if pre-K education influences long-term development in WM and reading in autistic children in particular.

Objectives:

This project first examines the longitudinal benefits of pre-K education on the development of WM and reading skills for all children in general, and if pre-K education is particularly beneficial for autistic children. Secondly, it examines the mediating role of autistic children's WM on the longitudinal relationship between pre-K education and their reading development.

Methods:

Using the licensed version of a nationally-representative dataset (ECLS-K:2011) that followed the same cohort of children from kindergarten to 5th grade in the United States ($N \approx 18,170$), a series of multiple regression, interaction analyses, and a mediation analysis were conducted. Of the analytic sample, approximately 310 students were identified as having autism.

Results:

For the general sample, having attended pre-K predicted advanced reading and WM skills upon school entry, yet such benefits faded away after 2-3 years. However, particularly for autistic children, the onset of such benefits started a few years after they started kindergarten, but lasted longer, until end of their elementary school years (spring of 5th grade). Finally, autistic children's WM in 3rd grade mediated the longitudinal relationship between pre-K attendance and their reading skills in 5th grade.

Conclusions:

The current study directs us to look beyond the intrinsic autism characteristics to recognize the role of the learning environment at preschool ages on their longitudinal development. Findings provide us with promising evidence that participating in school-based programs prior to entering kindergarten may produce long-lasting benefits in WM development for autistic children, which in turn foster reading success. The current findings have implications for teachers and parents in that "cognitive endurance" must be promoted when educating children on the autism spectrum. It may be erroneously perceived that autistic children are making limited progress if such a conclusion is based on their short-term gains, which can potentially lead to learned helplessness. However, the above findings demonstrate that autistic children may be undergoing a pattern of cognitive development that is different from their non-autistic peers. In other words, autistic children may be making slower but more steady progress, and pre-K education may be producing a long-lasting and robust influence on autistic children's WM and reading development through socially enriched learning environments.

305.004 The Remote Infant Studies of Early Learning (RISE) Battery for the Assessment of Cognitive and Language Development in Infants at Elevated Likelihood for Autism

E. Tenenbaum¹, S. Jeste², C. Stone³, M. H. Vu⁴, M. Hare⁵, K. Gilyard⁶, A. Waterman¹, M. Harris⁵, A. Dea⁶, S. Arunachalam⁷, E. Bergelson⁴, S. Bishop⁸, M. C. Frank⁹, J. K. Hamlin¹⁰, R. Landa¹¹, C. Lew-Williams¹², M. Libertus¹³, R. J. Luyster¹⁴, J. Markant¹⁵, R. A. Durazo-Arvizu¹⁶, M. Sabatos-DeVito¹, A. Scott¹⁷, S. J. Sheinkopf¹⁸, A. Thurm¹⁹ and J. B. Wagner²⁰. (1)Department of Psychiatry and Behavioral Sciences, Duke University, Durham, NC, (2)Children's Hospital Los Angeles, Los Angeles, CA, (3)Department of Psychiatry and Behavioral Sciences, University of North Carolina Greensboro, Durham, NC, (4)Psychology, Harvard University, Cambridge, MA, (5)Duke University Medical School, Durham, NC, (6)Department of Psychiatry and Behavioral Sciences, Duke University School of Medicine, Durham, NC, (7)Communicative Sciences and Disorders, New York University, New York, NY, (8)Psychiatry and Behavioral Sciences, University of California, San Francisco, San Francisco, CA, (9)Psychology, Stanford University, Stanford, CA, (10)Psychology, Centre for Infant Cognition - University of British Columbia, Vancouver, BC, Canada, (11)Center for Autism Services, Science and Innovation, Kennedy Krieger Institute, Baltimore, MD, (12)Princeton University, Princeton, NJ, (13)Department of Psychology, Learning Research and Development Center, University of Pittsburgh, Pittsburgh, PA, (14)Communication Sciences and Disorders, Emerson College, Boston, MA, (15)Tulane University, New Orleans, LA, (16)Department of Pediatrics, Children's Hospital Los Angeles, Los Angeles, CA, (17)Amherst College, Amherst, MA, (18)Thompson Center for Autism & Neurodevelopment, University of Missouri, Columbia, MO, (19)Office of the Clinical Director, National Institutes of Health - National Institute of Mental Health, Bethesda, MD, (20)Department of Psychology, College of Staten Island, CUNY, Staten Island, NY

Background: To understand developmental processes that occur prior to an autism diagnosis, researchers often study infant-siblings of autistic children. Even in this high likelihood group, five times the target sample must be recruited for the relevant number of autistic participants. Given the heterogeneity of autism, we need methods appropriate for large samples to increase our understanding of early developmental mechanisms. To address this need, we created the Remote Infant Studies of Early Learning (RISE). The RISE battery includes remote tasks assessing cognitive and language skills that are likely sources of heterogeneity in autism.

Objectives: (1) Test the feasibility of remote administration of tasks for social attention, memory, prediction, word comprehension and audiovisual synchrony (Figure 1). (2) Assess group differences between infants with and without an autistic sibling.

Methods: The RISE Battery was administered via the Children Helping Science platform to 55 6-month-old infants and 56 12-month-old infants (49% female, 51% male; 8.3% were reported as Asian, 1.8% as Black, 52.3% as White, and 37.6% as more than one race) recruited from the general population via social media and the platform Registry. We used iCatcher+ to compute gaze direction. Primary analyses were linear mixed-effects models with child and stimulus crossed random effects. Models were fit separately for each age group. To date, we have enrolled 35 infant siblings of autistic children (6 mo, $n = 23$; 12 mo, $n = 12$) for whom coding and analysis is underway.

Results: Most tasks produced expected results in infants without an autistic sibling (Figure 2). In the social attention task, 6 and 12-month-old infants looked reliably more at a child dancing than an abstract geometric figure ($M = 0.62$ (.57 - .67), $p < 0.001$). In the memory task, infants showed preferential attention to novel faces and complex non-face stimuli following familiarization at both ages (Faces: $M = 0.56$ (0.53 - 0.59), $p < .001$; Fribbles: $M = 0.54$ (0.51 - 0.57), $p = .016$), suggesting that infants successfully encoded the familiarized images. In the word comprehension task, 12-month-olds, but not 6-month-olds oriented more to the target stimulus when it was the target than when it was the distracter (12-m: 0.05 (0.01 - 0.08), $p = 0.009$; 6-m: -0.02 (-0.06 - 0.02), $p = 0.267$). In the prediction task, 6- and 12-month-old infants showed anticipatory eye movements to a cued target location ($M = .70$ (0.62, 0.78), $p < .01$). Only the audiovisual synchrony task failed to produce the expected results of preference for synchronous relative to asynchronous stimuli ($p > .05$).

Conclusions: The RISE battery provides a remote and scalable method for assessing early cognitive and language skills in large samples of infants. Before INSAR, we anticipate completion of data collection for the infant siblings that will allow us to address group differences. We are also collecting parent report measures of infant development 6 months following enrollment. Results will be discussed in the context of the feasibility and validity of this remote assessment for digital phenotyping.

306.001 Dysregulation of Cortical Neurogenesis in Autism Pathogenesis: Leveraging the Autism-Associated 3q29 Deletion to Define Cellular and Molecular Mechanisms

E. DiCicco-Bloom¹, X. Zhou², R. M. Pollak³, L. Buchanan⁴, X. Wang⁵, S. Toomey⁶, R. Sebastian⁷ and **J. G. Mulle⁸**, (1)Neuroscience and Cell Biology/Pediatrics, Rutgers Robert Wood Johnson Medical School, Piscataway, NJ, (2)Neuroscience & Cell Biology, Rutgers Robert Wood Johnson Medical School, Piscataway, NJ, (3)Department of Psychiatry, Rutgers Robert Wood Johnson Medical School, Piscataway, NJ, (4)Rutgers University-SAS, Piscataway, NJ, (5)Department of Anthropology, Rutgers University, New Brunswick, NJ, (6)Neuroscience and Cell Biology, Rutgers Robert Wood Johnson Medical School, Piscataway, NJ

Background: Human neuropathological, neuroimaging, and gene enrichment studies consistently link altered neurogenesis, the process by which neural precursor cells (NPCs) proliferate, migrate, and differentiate, to neurodevelopmental disorder (NDD) pathogenesis. The 3q29 deletion confers high risk for autism: males with 3q29 deletion are 15 times more likely to have autism, while the risk rises to 36 times for females. Individuals with the 3q29 deletion who do not qualify for a diagnosis of autism exhibit substantial social disability, and the 3q29 deletion mouse model created by our team also displays changes in social behavior in male mice, indicating that the 3q29 deletion has a global impact on social functioning. Human 3q29 deletion study participants have reduced frontal occipital circumference, and 3q29 deletion mice show smaller head size and brain weight than littermate controls; new data indicate 9% reductions in postnatal day (P) 7 forebrain weight. Our previous single-cell analysis of the transcriptome in human cortical organoids revealed pronounced dysregulation of genes involved in neurogenesis (pathway p-value < 10⁻²³) in immature neurons. Taken together, these data warrant detailed characterization of cortical neurogenesis in 3q29 deletion syndrome.

Objectives: Determine the cellular and molecular mechanisms by which the NDD-risk CNV 3q29 deletion dysregulates cortical neurogenesis.

Methods: We performed structural, immunoblot, and immunohistochemical analysis of embryonic (E13.5-18.5) and postnatal (P0-P21) cortex in 3q29 deletion mouse compared to wild type controls (WT), defining NPC proliferation (VZ/SVZ), S-phase entry (Edu incorporation), apoptosis, and layer formation. Parallel cross-species comparisons using patient and isogenic 3q29 deletion derived cortical organoids from Day 7 to 90 are underway to define how 3q29 deletion impacts developmental neurogenesis.

Results: We identified hyperproliferation of E15.5 cortical NPCs including increases in height of VZ marker, Pax6 (15%), VZ/SVZ marker Ki67 (19%), and a 37% increase in S-phase entry (p<0.003; N=5-7/genotype, 3 litters) in 3q29 deletion cortex compared to WT littermates. Further, there was a 27% increase of endogenous mitotic cell marker, phospho-H3. In contrast, there were no differences at E13.5 nor E16.5. Given reduced forebrain weight at P7, we considered possible altered cell death: Indeed, at E16.5, there was a 64% increase in apoptosis marker, cleaved caspase-3 (N=5/genotype; 2 litters) localized to intermediate zone, suggesting hyperproliferation may be followed by premature termination of corticogenesis. In ongoing studies we are analyzing multiple embryonic ages, assessing cell cycle leaving fraction, and expression of laminar markers (Tbr2, Ctip2, Satb2, Cux1), with select studies at P0, P7, and P21. Preliminary human iPSC-derived organoids suggest increases in NPC proliferation and alterations in levels CTIP2 and SATB2.

Conclusions: Our studies of the autism-associated 3q29 deletion suggest a common neurobiological pathway for autism pathogenesis, specifically altered cortical neurogenesis. Indeed, other CNVs such as 16p11.2 and 22q11.2 as well as rare variants like CHD8, impact similar pathways, suggesting there are convergent mechanisms for autism pathogenesis. Preliminary studies suggest that human cortical organoids exhibit some common phenotypes. Future studies will analyze single cell lineage tracing to determine the genetic and molecular cascade that leads to dysregulated cortical development and may identify possible avenues for intervention.

306.002 Identifying Therapeutic Targets for PTEN-Related Neurodevelopmental Disorders

T. A. Chen^{1,2}, A. E. Clipperton-Allen³, O. S. Cohen³, M. Horger³, A. Zucca³, K. Espinoza¹, J. Levy³ and D. T. Page¹, (1)Norcliffe Foundation Center for Integrative Brain Research, Seattle Children's Research Institute, Seattle, WA, (2)Molecular Medicine and Mechanisms of Disease (M3D) PhD Program, University of Washington, Seattle, WA, (3)Neuroscience, The Herbert Wertheim UF Scripps Institute for Biomedical Innovation & Technology, Jupiter, FL

Background: Autism Spectrum Disorder (ASD) and related neurodevelopmental disorders (NDDs) are influenced by complex genetic factors. *PTEN* (phosphatase and tensin homolog), a prominent ASD risk gene associated with macrocephaly, regulates the PI3K-Akt-mTOR pathway. Variants in *PTEN* contribute to NDDs by disrupting cellular processes crucial for brain development. Despite this, effective therapeutics supporting individuals with *PTEN*-associated NDDs remain limited, emphasizing the need to uncover new molecular pathways and develop targeted interventions.

Objectives: This study employs a candidate genetic modifier approach with two primary goals: 1) to better understand the molecular networks by which *PTEN* influences the development of brain and behavior, and 2) to develop novel therapeutic strategies that may improve the quality of life for individuals with *PTEN*-associated NDDs.

Methods: To identify candidate genetic modifiers, we analyzed genes with the highest spatiotemporal expression correlation with *Pten* in the developing brain, using the Allen Developing Mouse Brain Atlas. Utilizing a *Pten* haploinsufficient mouse model (*Pten*[cHet]) and conditional modification via *Emx1*-Cre, we assessed neuroanatomical features, such as cortical thickness and cellular volumetric changes, alongside behavioral assays for social interaction. Additionally, we are conducting *in silico* kinase activity profiling and biochemical assays to explore pathway-specific effects in the developing cerebral cortex of *Pten*-deficient mice.

Results: Our analysis identified *Csnk1a1* (Casein Kinase 1 Alpha 1, encoding CK1α) as a candidate modifier with high spatiotemporal co-expression with *Pten* during brain development. CK1α, a serine/threonine kinase, regulating Wnt signaling, and cellular proliferation and differentiation, plays an important role in cortical development. In *Pten*[cHet] mice, genetic suppression of CK1α via heterozygous mutation ameliorated cellular hypertrophy and restored social preference in adult animals, indicating its potential role in mitigating *Pten* loss-of-function phenotypes. Ongoing work is investigating the impact of CK1α on protein synthesis and cellular overgrowth in *Pten*-deficient models.

Conclusions: This study identifies CK1α as a potential target to modulate neurodevelopmental phenotypes in *PTEN*-associated NDDs. By elucidating the mechanisms underlying the genetic modifier effect of CK1α, we aim to enhance our understanding of the role of PTEN in neurodevelopment and open pathways for targeted therapeutic strategies to better support individuals with ASD-associated phenotypes.

306.003 Synaptic Density Marker, SV2A, Is Reduced in Autistic Adults and a Mouse Model of Idiopathic Autism

C. Mehra¹, G. Griffioen², E. C. Onwordi³, R. Martins⁴, E. Shatalina⁵, B. Kowalewska⁶, T. Whitehurst⁷, S. Moug⁸, A. J. Abrunhosa⁴, A. P. Rodrigues⁹, S. Natesan¹⁰, J. Ó Muircheartaigh¹⁰, M. M. Petrinovic¹⁰, M. Castelo-Branco⁸, O. Howes¹¹, J. Borg¹² and D. Murphy¹³, (1)Forensic and Neurodevelopmental Sciences, King's College London, London, United Kingdom, (2)Karolinska Institutet, Stockholm, Sweden, (3)Psychiatric Imaging Group, MRC London Institute of Medical Sciences, London, United Kingdom, (4)Coimbra Institute for Biomedical Imaging and Translational Research, Coimbra, Portugal, (5)Institute of Psychiatry, Psychology and Neuroscience, London, United Kingdom, (6)Forensic and Neurodevelopmental Sciences, Kings College London, Institute of Psychiatry, Psychology & Neuroscience, London, United Kingdom, (7)Psychiatric Imaging Group, MRC London Institute of Medical Sciences, London, United Kingdom, (8)Coimbra Institute for Biomedical Imaging and Translational Research, ICNAS, University of Coimbra, Coimbra, Portugal, (9)University of Coimbra, Coimbra, Coimbra, Portugal, (10)King's College London, London, United Kingdom, (11)Imperial College London, London, United Kingdom, (12)Karolinska Institute, Stockholm, Sweden, (13)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, UNITED KINGDOM

Background: Altered synaptic number, structure and function are thought to be key neurobiological mechanisms underpinning many autistic features, as suggested by genetic (Bourgeron, 2015), post-mortem (Nicolini et al., 2015) and animal model (Tang et al., 2014) research. However, there is limited *in vivo* evidence about whether synaptic density is altered in autistic people.

Objectives: We conducted the first multi-site, translational study of synaptic density in autistic people and in 'idiopathic' and 'monogenic' mouse models of autism, using positron emission tomography (PET) and autoradiography, respectively. We hypothesised 1) that synaptic density would be altered in autistic compared to non-autistic adults in fronto-temporal regions (Hutsler & Zhang, 2010; Nakamura et al., 2011; Nicolini et al., 2015), the amygdala (Schumann & Amaral, 2006), the basal ganglia and the cerebellum (Wegiel et al., 2014), and 2) altered profiles of synaptic density differences (compared to wildtypes) in idiopathic versus monogenic mouse models.

Methods: Across three study sites, we included 30 autistic adults (22 males, aged 19–58), and 52 non-autistic controls (42 male) who did not differ on full-scale IQ. No participants had co-occurring physical or developmental conditions. *In vivo* synaptic density was estimated using the radioligand ¹¹C-UCB-J, which binds to the pre-synaptic protein SV2A. Our primary metric was the non-displaceable binding-potential (BP_{ND}) of ¹¹C-UCB-J, where centrum semiovale was used as reference region. Analyses were replicated using the distribution volume (V_t) of ¹¹C-UCB-J.

Autistic traits were quantified using the Social Responsiveness Scale-II.

We performed ³H-UCB-J autoradiography to quantify synaptic density in the BTBR T+tf/J idiopathic autism mouse model (with strong face validity, but unknown genetics), two monogenic mouse models with mutations in synaptic genes linked with autism in humans: *Nlgn3*^{R451C} knock-in and *Nrxn1a* knock-out mice, and wildtype controls specific to each model.

Results: Across hypothesised regions, ¹¹C-UCB-J BP_{ND} was significantly lower (by 5.8 %) in autistic compared to non-autistic people. In region-specific analyses, ¹¹C-UCB-J BP_{ND} was significantly lower in autistic people in the anterior cingulate cortex, the temporal cortex, the nucleus accumbens, amygdala and cerebellum. Greater autistic traits across groups correlated with lower ¹¹C-UCB-J BP_{ND} . Consistent results were obtained using ¹¹C-UCB-J V_t .

In the BTBR mouse model, ³H-UCB-J was lower in the sensory and auditory cortices, the striatum, hippocampus, amygdala, thalamus and hypothalamus, compared to C57Bl6/J wildtypes (Figure 1). In the *Nlgn3*^{R451C} knock-in model, ³H-UCB-J was decreased in the hypothalamus but increased in the amygdala compared to wildtype littermates. There were no significant differences in ³H-UCB-J between *Nrxn1a* knock-out mice and their wildtype controls.

Conclusions: We report findings from the largest *in vivo* study of synaptic density in autistic people. Converging evidence from autistic adults and the BTBR mouse model highlights a significant reduction in synaptic density in 'idiopathic' autism. Implicated brain regions are known to be associated with autistic behaviours. Further, we provide convergent biological validity for BTBR mice as an animal model for pre-synaptic density in idiopathic autism, enabling back-translation.

**306.004** Impact of Generalized Epilepsy on Autistic Phenotypes in SynGAP1-Related Disease

N. Omar¹ and J. P. Hegarty², (1)Stanford University, Palo Alto, CA, (2)Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Palo Alto, CA

Background: Pathogenic variants in the gene *SYNGAP1* cause generalized epilepsy starting in early life (age 2-3) in >90% of affected individuals, and autism spectrum disorder (ASD) in 50% of affected individuals. Other disease co-morbidities include developmental delay/intellectual disability and disrupted sleep wake cycling. *SYNGAP1* is part of an N-methyl-D-aspartate receptor (NMDAR) complex in glutamatergic neurons that negatively regulates Ras GTPase through ERK/MAPK kinases, preventing excessive AMPA receptor insertion into the post-synaptic density. Haploinsufficiency of *SYNGAP1* is thought to result in increased AMPA insertion into the PSD, ultimately resulting in excessive neuronal excitability and seizures/epilepsy. However, the mechanism by which autism results from *SYNGAP1* haploinsufficiency is unclear. We hypothesized that the seizures themselves lead to maladaptive remodeling of brain networks that promotes the development of autistic phenotypes. **Objectives:** Our overarching goal is to determine whether seizures induce or increase autistic behaviors and other co-morbidities, such as cognitive deficits and sleep/wake cycling. In the present study, we examined the temporal association between seizures, autistic behaviors and comorbidities. **Methods:** *SynGAP*^{+/-} mice (*Syngap1* Het) and wildtype (*SynGAP*^{+/+}; WT) littermate controls were implanted for EEG recordings at P50. 24 hour video EEG was recorded with a Pinnacle system at P60, P90, P120, and P150. We quantified the number of seizures in 24 hours, REM/NREM durations, and total sleep time. Behavioral testing at P60 timepoint included: social interaction test, marble burying test, and Y maze. **Results:** In *SynGAP*^{+/-} mice, absence seizures begin at P60, (80 seizures/24 hours) and progressively increase until at P120, when they occur an average of 160 seizures/24 hours. At P60, social interaction performance is equivalent in WT and *SynGAP*^{+/-} mice. However, at P120, while WT mice continue to show social chamber preference over null chamber, *SynGAP*^{+/-} mice display impaired performance, with no preference for social/null zones or cups. *SynGAP*^{+/-} mice also demonstrate excessive marble burying, also consistent with autistic behavior. *SynGAP*^{+/-} mice likewise demonstrate decreased spontaneous alterations in the Y maze test, indicative of impaired spatial working memory. *SynGAP*^{+/-} mice spent more time awake in the dark and in the light across the 24hrs, with decreased NREM duration in the dark. **Conclusions:** We found a temporal association between seizures, autistic behaviors and cognitive impairment and sleep disruption in *SynGAP*^{+/-} mice. These findings validate *SynGAP*^{+/-} mice as models that recapitulate the full spectrum of *SYNGAP1*-related disease in humans. Statistical correlation of these deficits with seizure burden is underway. To directly test the influence of seizures on autistic behaviors and other disease comorbidities, we are pharmacologically blocking seizures with the drug ethosuximide in *SynGAP*^{+/-} mice. We will determine whether seizure blockade normalizes social interaction, cognition and sleep-wake cycling. *This investigation is ongoing and analyses will be completed with updated data.

307.001 Comparison of Laboratory-Based Versus Remotely Administered Assessments for Infants at Elevated Likelihood for Neurodevelopmental Disorders

M. R. Talbott, S. Dufek, L. Marizcal Gonzalez, D. Nagra and M. Miller, Psychiatry and Behavioral Sciences, UC Davis Health, MIND Institute, Sacramento, CA

Background: Although there has been an exponential increase in the use of remote assessments for studies of infant and toddler development in the last several years, few studies have reported on direct comparisons between remote and existing standardized, laboratory-based tasks. The existing validation studies have primarily focused on diagnostic assessment tools for toddlers. There are no remote observational developmental assessments for infants that have been compared to existing gold-standard measures.

Objectives: To systematically compare existing gold-standard laboratory-based measures of infant and toddler development used widely in autism research to a remote assessment protocol intended to measure the same constructs.

Methods: We recruited participants from an ongoing longitudinal laboratory-based study of infants with a family history of autism, ADHD, or neither. We enrolled 112 infants and completed telehealth visits at one or more target ages: 6 or 9, 12, or 18 months. Telehealth visits were completed following a manualized protocol, the Telehealth Evaluation of Development for Infants (TEDi) by examiners naïve to family history group and to laboratory assessment. Laboratory-based examiner-administered measures include the AOSI/ADOS (Bryson et al., 2008; Lord et al., 2012) and MSEL (Mullen, 1995). Behavioral observation from parent-coached activities in TEDi sessions were used to score AOSI ratings and the ESDM Infant-Toddler Curriculum Checklist (Rogers et al., 2020). Both sessions included coding of ADHD-related behaviors, parent-reported representativeness, and examiner concerns.

Results: We completed total of 249 telehealth visits: 81 at 6 or 9 months, 84 at 12 and 84 at 18 months. Visits took place, on average, 8 days following the in-person assessment ($M = 8$ days, $SD = 4.7$; range 1 – 41 days). Overall, we found some small but statistically significant differences in mean scores across the two contexts for measures using the same rating systems (Table 1). Within-construct correlations were moderate-to-strong for all domains except parent-rated representativeness (Table 2). The language and cognitive domains showed the strongest association, ranging from 0.72 to 0.82.

Conclusions: Overall, these findings support the use of telehealth-based assessments to expand the reach of studies on early developmental trajectories of infants with elevated likelihood for neurodevelopmental disorders. Findings related to group- and age-specific patterns will also be discussed.

307.002 Birth Cohort Assessment of Access, Equity, and Accuracy of Universal Autism Screening within a Large, Diverse, Health System

M. Maye¹, T. Johnson-Hooper¹, L. Ma¹, X. Song¹, W. Guthrie², K. Redmond-Payne¹, J. Braciszewski¹ and H. H. Yeh¹, (1)Henry Ford Health, Detroit, MI, (2)Children's Hospital of Philadelphia, University of Pennsylvania, Philadelphia, PA

Background: Universal autism screening in pediatric primary care with the Modified Checklist for Autism in Toddlers with Follow-up (M-CHAT/F) at the 18-and-24-month well-child-visit (WCV) is promoted by the American Academy of Pediatrics (AAP) to reduce age of first diagnosis. However, implementation of universal screening in two large pediatric networks that use the M-CHAT/F demonstrated lower overall screening accuracy than previously observed (sensitivity:33.1, 38.8; positive predictive value [PPV]:17.8, 14.6), with significant disparities in screening rates and accuracy among marginalized children. Conclusions from these studies emphasize possible limitations of the M-CHAT/F's validity in community samples. However, findings from these studies also point to modifiable patient, clinic, system, and policy factors that could impact observed sensitivity and PPV.

Objectives: We examined universal screening access, accuracy, and equity of the M-CHAT-R within a large, diverse, health-system serving Metro Detroit, Michigan across birth cohorts that experienced variations of patient, clinic, system, and policy factors that could impact receipt of diagnosis (e.g., electronic screening/scoring, referral practices, access to/completion of diagnostic assessment). For each birth cohort, we examined: 1) screening and referral rates of all patients; 2) screening and referral rates across demographics; 3) sensitivity and positive predictive value of the M-CHAT-R.

Methods: Data were extracted from electronic health records of over 30,000 pediatric patients who were born between 2013 and 2019, and visited primary care clinics for a WCV, between 2013 and 2023. To align with both AAP screening guidelines, and M-CHAT-R screening window, screening age range was restricted to 15 to 30 months. ASD diagnoses were identified using ICD-9 codes (299.XX) and ICD-10 codes (F84.XX).

Results: We found that: 1) screened once rates of birth cohorts ranged from 43%-to-86%. Later cohorts were significantly more likely to be screened twice, coinciding with changes to screening administration ($p<.05$). Referral rates ranged from 45%-to-53% across cohorts; 2) Overall, patients who were white, living in neighborhoods with lower education, or insured by Medicaid were significantly less likely to be screened. Additionally, patients who were white or from higher-income neighborhoods demonstrated the largest increases in screening rates; 3) When considering the whole sample, the sensitivity of the M-CHAT-R was 36.8% and the positive predictive value (PPV) was 34.7%. However, across birth cohorts sensitivity ranged from 18%-to-63%, while PPV ranged from 25%-to-47%.

Conclusions: Across cohorts, universal screening rates and referral rates increased and some identified disparities in screening access decreased. Some of these increases were linked to implementation changes (e.g., electronic administration/scoring). Additionally, Michigan's autism insurance mandate went into effect the year before our first cohort (2012) and may have increased access to diagnostic evaluations. Thus, the increases seen in universal screening rates, referral rates, and likely increased access to diagnostic visits may have contributed to an increased likelihood of identifying "true positives" within our health system – resulting in the general increase of sensitivity and PPV values across birth cohorts. More research is necessary. However, this study demonstrates that sensitivity and PPV of the M-CHAT-R within health systems is not static and that implementation factors may impact these values.

307.003 Sense to Know, a Digital Phenotyping Mobile App for Assessment of Autism-Related Behaviors in Children from 1.5 to 8.5 Years of Age

G. Dawson¹, V. Aikat², P. R. K. Babu², K. L. Carpenter⁴, J. M. Di Martino³, N. O. Davis⁴, B. Eichner⁵, S. Espinosa³, J. Green², J. Howard⁴, L. Franz⁶, M. Spanos⁴ and G. Sapiro⁷. (1)Department of Psychiatry and Behavioral Sciences, Duke University, Durham, NC, (2)Duke University, Durham, NC, (3)Department of Electrical and Computer Engineering, Duke University, Durham, NC, (4)Department of Psychiatry and Behavioral Sciences, Duke University Medical Center, Durham, NC, (5)Department of Pediatrics, Duke University, Durham, NC, (6)Duke Center for Autism and Brain Development, Duke University, Durham, NC, (7)Princeton University, Princeton, NJ

Background:

There is a critical need for scalable, quantitative, and objective tools for autism screening and outcome monitoring to complement clinician and caregiver-report measures. To address this, we developed SenseToKnow, a tablet- or smartphone-based mobile digital phenotyping app, which uses computer vision and machine learning to automatically measure autism-related behaviors, including gaze, attention, facial and head movements, blink rates, and motor skills. SenseToKnow can detect autism in 18–36-month-old toddlers with high diagnostic accuracy when delivered in primary care (Perochon et al., 2023) or remotely by caregivers (Krishnappa Babu et al., 2024). In toddlers, digital phenotypes correlate with standardized clinical measures (Coffman et al., 2023). Here, we present a study that examined (1) whether the SenseToKnow app can detect autism-related behaviors in preschool- and school-age children and (2) correlations between the digital phenotypes and a caregiver-report behavioral measure.

Objectives:

Determine whether the SenseToKnow app can detect autism-related behaviors in preschool- and school-age children and examine correlations between individual digital phenotypes and a caregiver-report behavioral measure.

Methods:

149 children (107 boys, 42 girls), aged 40.2–102.6 months, participated. 45 were neurotypical; 104 were diagnosed with autism spectrum disorder based on the Autism Diagnostic Observation Schedule-2 or the Brief Observation of Symptoms of Autism. Standardized measures of cognitive abilities and the Vineland Adaptive Behavior Scales-3 were administered.

SenseToKnow was delivered on an iPad. The tablet's front camera recorded children's responses to brief movies and touch data were gathered during a game. Computer vision and touch data quantified gaze, head/facial movements/complexity, attention (facing forward), blink rates (lower = higher attentional engagement), and motor skills.

Results:

Based on Mann-Whitney U tests, we found autistic children spent significantly less time gazing at social stimuli and showed less focused patterns of gaze compared to neurotypical children. Autistic children showed significantly lower correlations between their gaze and actors' speech. Autistic children displayed significantly more frequent head movements and lower complexity of their eyebrow and mouth movements and higher blink rates. Results remained significant using age and sex as covariates. Group differences in gaze (e.g., social attention) and head movement complexity remained after controlling for developmental quotient.

For autistic children, all VABS-3 subscales were significantly correlated with app features, including gaze, facial/head movements, overall attention, blink rates, and motor skills (Table 1).

Conclusions:

Combined with earlier work with toddlers, these findings indicate that SenseToKnow, a brief digital phenotyping app, can automatically detect and quantify several autism-related behaviors in children ranging from toddlerhood to school age. In the present sample, we found that the digital phenotypes correlate with several aspects of children's behavior as assessed by the Vineland Adaptive Behavior Scales. Autistic children with higher VABS communication, daily living, socialization, and motor skills exhibited higher levels of social attention and coordinated gaze with speech, less frequent head movements, higher complexity of facial movements, higher overall attention, lower blink rates (attentional engagement), and higher visual motor skills. These findings suggest that SenseToKnow can detect and quantify autistic behaviors in children across a wide age range, with potential usefulness for outcome monitoring.

307.004 Preliminary Psychometrics of the M-CHAT-S, a Novel Screening Tool for Identifying School-Age Children with Possible Autism

A. de Marchena¹, A. T. Wieckowski¹, G. Perez Liz¹, A. Taylor², H. S. Cheng³, A. Seak², T. Kolter⁴, G. Vivanti⁵, M. Barton⁶, D. A. Berger⁶ and D. L. Robins¹, (1)A.J. Drexel Autism Institute, Drexel University, Philadelphia, PA, (2)Drexel University, Philadelphia, PA, (3)A.J. Drexel Autism Institute, A. J. Drexel Autism Institute, Philadelphia, PA, (4)3020 MARKET ST, Drexel University, PHILADELPHIA, PA, (5)A.J. Drexel Autism Institute, AJ Drexel Autism Institute, Philadelphia, PA, (6)Psychological Sciences, University of Connecticut, Storrs, CT

Background:

Although autism can be diagnosed in many children as early as two years old, age of first diagnosis is still 4 years in the US. Efforts to lower this age have focused on improving screening tools and practices to identify children in need of assessment. One widely used tool, the Modified Checklist for Autism in Toddlers, Revised with Follow-up (M-CHAT-R/F), is recommended as part of universal autism screening at 18- and 24-month well-child pediatric visits. However, universal autism screening in toddlers is limited by inequality in access to pediatric preventive care and differences in implementation of screening across clinicians. To address these issues, we developed the Modified Checklist for Autism in Toddlers – School (M-CHAT-S) to screen young school-age children, following PROMIS guidelines for measure development, including an extensive literature review of existing measures and cognitive interviews with end users. This study resulted in two versions of the M-CHAT-S, for verbally fluent and minimally verbal children (Wieckowski et al., 2024). The current pilot study presents data on this new tool.

Objectives:

The objective of this study was to test the psychometric properties of both versions of the M-CHAT-S, for caregiver and educator informants.

Methods:

Participants ($n=276$; Table 1) completed one version of the M-CHAT-S on Qualtrics. Participants were either caregivers or educators of children ages 4-8 years old. There were no exclusions based on child diagnosis; thus, children in this sample had autism diagnoses, but also global developmental delay, ADHD, and others. In addition to the M-CHAT-S, participants completed the Social Responsiveness Scale, 2 (SRS-2) for convergent validity and the Child Behavior Checklist (CBCL) for discriminant validity.

Results:

Cronbach's alpha ranged from .78 to .92 across the two versions of the M-CHAT-S and two informant types, demonstrating acceptable to excellent internal consistency (Table 1). Convergent validity was demonstrated by moderately strong to strong correlations with the SRS-2, with weaker correlations demonstrated with both the internalizing and externalizing scales of CBCL, demonstrating discriminant validity.

As a preliminary test of predictive validity, we compared M-CHAT-S total scores for children with and without a diagnosis or educational classification of autism. In both versions, and with both informant types, M-CHAT-S score was lower in the non-autistic sample (Table 2); however, this difference was statistically significant only for the verbally fluent version ($p<.001$, $d=1.05$ for caregivers; $p=.028$, $d=0.61$, for educators).

Conclusions:

The M-CHAT-S shows promise as an easy-to-implement tool that may help identify children who would benefit from an autism diagnostic assessment. The results of this study suggest that the M-CHAT-S better discriminates autistic and non-autistic children who are verbally fluent, compared to those who are minimally verbal; however, this could be an artifact of the relatively low rate of minimally verbal non-autistic children in this sample. Future research is needed to determine if the M-CHAT-S can detect autistic school-age children who were not previously identified, thereby helping lower the age of autism diagnosis and access to services.

**Oral Session -****308 - Support Well-Being During Transition and Adulthood**

308.003 The Impact of Group-Based DBT Skills Training on Emotion Dysregulation and Coping Skills Use for Autistic Adults

A. M. Brewe^a, M. Scott^b, E. M. Lamarche^c, L. R. Guy^d and L. A. Ritschel^e, (1)TEACCH Autism Program, University of North Carolina, Carrboro, NC, (2)UNC TEACCH Autism Program, Carrboro, NC, (3)TEACCH Autism Program; Psychiatry, UNC TEACCH Autism Program, Chapel Hill, NC, (4)Psychiatry, UNC TEACCH Autism Program, Greensboro, NC, (5)Psychiatry, The University of North Carolina, Chapel Hill, NC

Background: Autistic adults without intellectual disability experience higher rates of co-occurring mental health problems and increased emotion dysregulation compared to non-autistic peers, yet research examining effectiveness of interventions for autistic adults is limited. Dialectical behavior therapy (DBT) is designed to improve emotion dysregulation, suicidality, and co-occurring mental health by building skills across four areas: mindfulness, distress tolerance, emotion regulation, and interpersonal effectiveness. Though the evidence is growing, more studies are needed to determine whether participation in a DBT group is associated with improved mental health outcomes in autistic individuals.

Objectives: We examined whether participation in group-based DBT skills training (DBT-ST) led to significant changes in skills use, dysfunctional coping, and emotion dysregulation for 18 autistic adults.

Methods: 18 autistic adults (aged 18-67 years; *M* age: 31.72; 56% male; 80% White; no intellectual disability) completed an adapted DBT-ST group within several community-based autism clinics. Groups meet weekly for 1.5 hours over 24 weeks and were initially held in person, although groups transitioned online following the pandemic. Groups included about five autistic adults, two group leaders from outpatient autism clinics, and a trainee. Only data from group members who consented to participate in research were included. Participants completed the Difficulties in Emotion Regulation Scale (DERS) and DBT Ways of Coping Checklist (WCCL) pre- and post-group.

Results: At the group level, paired samples t-tests showed significant reductions in emotion dysregulation ($t = 4.33, p < .001$) and dysfunctional coping ($t = 3.30, p = .005$) and significant increase in skills use ($t = -4.19, p < .001$). At the individual level, reliable change indices were calculated by dividing the difference of baseline and endpoint scores by the standard difference, which accounted for test-retest reliability of the measures. Considering the DERS, nine of the 18 participants experienced a statistically significant reduction in emotion dysregulation, six experienced a non-significant reduction, and three experienced no change or non-significant increases. Considering skills use on the WCCL, seven of the 17 participants significantly increased their skills use, seven experienced a non-significant increase in skills use, and three experienced no change or non-significant decreases. Five participants had significantly decreased dysfunctional coping, eight had non-significant decreases, and four had no change or non-significant increases. No participants had significant worsening on any measures. See Figure 1.

Conclusions: This open trial utilizes a community-based implementation framework to examine the efficacy of DBT-ST groups. Initial data suggest that group-based DBT-ST may be effective in reducing emotion dysregulation and maladaptive coping and increasing healthy coping for autistic adults. It is important to note that these data are based on participation in a 24-week DBT-ST group and not a comprehensive DBT program (i.e., no individual therapy required; no coaching calls). Future research should examine factors that impact DBT-ST efficacy for certain autistic adults and how DBT-ST may lead to downstream effects on mental health (i.e., anxiety or depression) and positive outcomes (e.g., flourishing, life satisfaction).

308.004 Diverse, an Innovative Curriculum for Supporting Autistic Individuals in the Workplace Developed By the Neurodiverse Community: A Pilot Efficacy-Implementation Trial

R. VanDaalen¹, L. Zhao², S. M. Woo³, Y. J. Hsiao², H. Karsting⁴, C. Zhen⁵ and L. K. Fung⁵, (1)Department of Psychiatry and Behavioral Sciences, Stanford University, Palo Alto, CA, United Kingdom, (2)Department of Psychiatry and Behavioral Sciences, Stanford University, Palo Alto, CA, (3)Brown University, Providence, RI, (4)Columbia University, New York, NY, (5)Stanford University, Palo Alto, CA

Background:

Autistic individuals face challenges in securing and maintaining competitive employment. Our team co-developed a training curriculum titled DIVERSE (Developing Inclusive Vocational Education and Resources for Success in Employment) with multiple stakeholders using community-based participatory research (CBPR) for job coaches (JCs), employers, family members (FMs) in providing effective, strengths-based support. The DIVERSE curriculum adapts an existing curriculum and utilizes user-centered design methods. We incorporated diverse perspectives from community stakeholders (including JCs, educators, employers, FMs, autistic individuals, and adults with other intellectual and developmental disabilities (I/DD)) in the development of DIVERSE.

Objectives:

This study has two objectives: (1) assess the efficacy of DIVERSE for JCs, employers, and FMs in increasing their competency in working with autistic individuals and individuals with I/DD; (2) determine the barriers and facilitators to improve the feasibility and dissemination of the curriculum in the neurodiverse community.

Methods:

DIVERSE consists of seven core modules, each comprised of captioned videos, handouts, and quizzes on an online learning management platform. The modules were developed. Each video was ~15-20 minutes long.

Efficacy Trial: A pilot prospective cohort study of DIVERSE was conducted with JCs (n=44), FMs (n=22), and employers (n=12), testing changes in knowledge, self-confidence, and self-efficacy in working with people with I/DD. Before starting the DIVERSE curriculum and after the six-week period or completion, participants completed a battery of surveys (a DIVERSE knowledge quiz and a questionnaire measuring attitudes, norms, and self-efficacy). Pair sample t-tests were used to assess the change before and after the delivery of DIVERSE.

Implementation Trial: We utilized a mixed methods design to understand barriers and facilitators to the implementation of DIVERSE and whether these factors differed by group membership. 78 JCs, parents, and employers completed the DIVERSE training and at least one quantitative survey (Acceptability of Intervention Measure (AIM), Intervention Appropriateness Measure (IAM), and Feasibility of Intervention Measure (FIM)). A subset of 25 individuals completed semi-structured interviews. Interview questions and analysis were based on the Consolidated Framework for Implementation Research.

Results:

Eighty-one participants (94%) completed all seven modules of the DIVERSE curriculum within six weeks. Seventy-eight (91%) responded to at least one post-training survey. DIVERSE was shown to increase objective knowledge ($p=.00002$; $d=-.52$) and subjective knowledge about autism ($p=.00386$; $d=-.46$) in quizzes and self-rated questionnaires, respectively. Furthermore, JCs who completed DIVERSE demonstrated increased self-efficacy ($p=.00098$ and $d=-.54$) and self-confidence ($p=.00121$ and $d=-.54$) in coaching autistic clients and clients with autism.

DIVERSE was found to have high acceptability, feasibility, and appropriateness levels, as indicated by quantitative measures. There were no differences by participant type or demographic group. Major facilitators included the belief that DIVERSE is helpful and easy to complete, its fulfillment of a need in the community, and its compatibility with personal or organizational values. Major barriers included the applicability of curriculum content and the need for specific topics.

Conclusions:

The study demonstrated a preliminary signal for DIVERSE's efficacy in JCs, FMs, and employers. DIVERSE is feasible, acceptable, and appropriate training for supporters of neurodivergent employees that fit the needs of various stakeholders.

Oral Session -**309 - Sociability Among Autistic Children and Adults**

309.001 Examining Individual Differences in Sociability Among Children with Autism Using the Child Social Preference Scale

L. Chetcuti^{1,2}, A. Y. Hardan¹, E. Spackman³, E. K. Baker⁴, T. W. Frazier⁴ and M. Uljarevic⁵, (1)Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA, (2)Telethon Kids Institute, University of Western Australia, Perth, Western Australia, Australia, (3)Psychiatry and Behavioral Sciences, Department of Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA, (4)Psychology, John Carroll University, Cleveland, OH, (5)Department of Psychiatry and Behavioral Sciences, Stanford Medicine, Stanford University, Stanford, CA

Background: Research indicates that, at the group level, individuals on the autism spectrum exhibit lower levels of trait sociability compared to the neurotypical population; however, significant individual variability exists *between* individuals on the autism spectrum. The approach-avoidance motivation framework, which examines how individuals balance motivations to approach or avoid social interactions, offers valuable insights into these diverse tendencies. Studies suggest distinct forms of (un)sociability: (1) shyness, involving reluctance due to discomfort; (2) unsociability, characterized by indifference and a preference for solitude; and (3) social avoidance, where solitude is coupled with active avoidance of social contact. However, the lack of assessment tools capable of accurately distinguishing between these forms in autism limits efforts to characterize individual differences and understand their clinical implications. The Child Social Preference Scale (CSPS), validated across diverse child populations and adapted for adolescents and young adults, provides a framework to delineate these unsociability types, yet its psychometric properties in autism require further exploration.

Objectives: Assess the factor structure of the CSPS among children on the autism spectrum, establish its psychometric properties, and explore the associations between various forms of unsociability and other key individual differences.

Methods: Parents of 689 children diagnosed with autism, aged 5-to-17 years ($M [SD]=11.23 [3.56]$; 76% male), completed the CSPS. Confirmatory application of exploratory structural equation modeling was employed to test the original three-factor structure of the CSPS, including correlated factors and bi-factor models. Model fit was evaluated using comparative fit index (CFI), Tucker–Lewis index (TLI), root mean square error of approximation (RMSEA), and its 95% confidence interval. The stability of the final factor solution was examined across sex and age. Reliability was assessed using Cronbach’s alpha and McDonald’s omega coefficients. T-tests analyzed sex differences in CSPS subscales, while Spearman’s rho correlations explored relationships with age and various individual difference factors: attachment and affiliation (Social Responsiveness Scale-2nd Edition [SRS-2]), and conduct, emotion, and peer problems (Strengths and Difficulties Questionnaire [SDQ]).

Results: The bifactor model demonstrated superior fit ($CFI=0.973$, $TLI=0.944$, $RMSEA=0.108$ [90% CI: 0.099, 0.117], $SRMR=0.024$) compared to the correlated factors model ($CFI=0.955$, $TLI=0.922$, $RMSEA=0.126$ [90% CI: 0.118, 0.134], $SRMR=0.038$). All CSPS items exhibited strong and significant loadings on their intended factors and minimal loadings on non-hypothesized factors (**Figure 1**). High reliability and internal consistency were observed across factors: shyness ($\omega=0.730$, $\alpha=0.760$), unsociability ($\omega=0.837$, $\alpha=0.848$), and social avoidance ($\omega=0.845$, $\alpha=0.842$). There were no sex differences for shyness ($t(667)=0.446$, $p=.656$), unsociability ($t(667)=1.371$, $p=.171$), or social avoidance ($t(667)=1.397$, $p=.163$). Age exhibited weak positive correlations with shyness ($r=0.092$, $p<.05$), unsociability ($r=0.163$, $p<.001$), and social avoidance ($r=0.151$, $p<.001$). CSPS subscale scores positively correlated strongly with SRS-2 attachment and affiliation, and weakly with SDQ peer problems. Only unsociability significantly correlated with conduct problems, while shyness and social avoidance (but not unsociability) correlated with emotional problems (**Figure 2**).

Conclusions: These findings support the CSPS factor structure in children on the autism spectrum and underscore the heterogeneity in sociability within this population. Utilizing the CSPS could enhance understanding of individual differences in autism and inform the personalization of therapeutic supports.

309.002 Camouflaging and Impression Management: Using Structural Equation Modeling to Chart Shared Dimensions and Relations to Motivations, Cognitive Skills, and Mental Health

W. Ai¹, Y. A. Wang¹, W. A. Cunningham¹ and M. C. Lai^{1,2,3,4}, (1)Department of Psychology, University of Toronto, Toronto, ON, Canada, (2)Campbell Family Mental Health Research Institute, Centre for Addiction and Mental Health, Toronto, ON, Canada, (3)Department of Psychiatry, National Taiwan University Hospital and College of Medicine, Taipei, Taiwan, (4)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, United Kingdom

Background: Some autistic individuals “camouflage” by hiding their autistic traits to appear socially neurotypical. They do so to secure friendships, find employment, and navigate hostile environments, likely at psychological costs. Recent evidence suggests the continuity of camouflaging across autistic and non-autistic people in the general population, involving similar strategies, motivations, and mental health consequences. Hence, camouflaging may be a form of general impression management (IM). However, no study has empirically assessed camouflaging in conjunction with established IM constructs. It remains unclear whether camouflaging and IM constructs share underlying dimensions, and whether these dimensions are uniquely associated with social pressure, cognitive traits, and mental health.

Objectives: First, we identified the joint dimensional structure underlying validated measures of camouflaging and established IM constructs. Second, we charted the relationships among the identified overarching IM dimensions with motivational, cognitive, and mental health factors, and examined whether these relations were moderated by neurodivergent traits.

Methods: The sample included 972 adults from a representative US general population sample (461 cisgender men, 491 cisgender women, 20 gender-diverse, $M_{age}=44.2$ yrs, 72.7% Caucasian, 7.51% neurodivergent). Participants completed an online survey with measures for impression management (camouflaging, compensation, self-presentation, self-concealment, and self-monitoring), social pressure (internalized stigma, belonging needs, social anxiety), cognitive skills (executive functioning, perspective taking), mental health (anxiety, depression, fatigue, authenticity), and autistic and ADHD traits. We used exploratory factor analysis (EFA) on 50% of the sample to elucidate the latent dimensions underlying camouflaging and IM measures. Then, we used structural equation modeling (SEM) to comprehensively map the relations between these IM dimensions and their predictors and outcomes across motivational, cognitive, and mental health domains.

Results: The EFA and subsequent item review showed that camouflaging, compensation, self-presentation, and self-concealment measures converge into an “intention” dimension, reflecting one's subjective intent or frequency of engaging in IM. Self-monitoring loaded onto another “ability” dimension, capturing one's subjective competence in executing IM. The SEM results (**Table 1 & Figure 1**) showed that IM intention was driven by social pressure and predicted by greater perspective-taking but lower executive functioning. On the other hand, IM ability was unrelated to social pressure but positively linked with both perspective-taking and executive functioning. IM intention was a significant mediator; it linked internalized stigma and interpersonal needs with poorer mental health. Elevated autistic and ADHD traits intensified the relationship between IM intention and more severe clinical outcomes, including increased fatigue, anxiety and depression symptoms, and inauthenticity. IM ability, however, was positively linked to better mental health.

Conclusions: These novel findings demonstrate the convergence between camouflaging and IM. Camouflaging shares conceptual common grounds with established IM constructs, but this overarching IM phenomenon is multi-faceted. “Intention” and “ability” emerged as two distinct IM facets, each differently associated with motivational, cognitive, and mental health variables. Importantly, IM partly manifests in neurodivergence-dependent ways; individuals with elevated autistic or ADHD traits and stronger IM intent face higher risks of negative psychological experiences. These insights guide future research unpacking the implications of IM intent versus ability and unique IM features across social and neurodiverse groups.

309.003 Stability & Discrepancy : Exploring Autistic Youth and Parent Report of Social Behaviors in Two Clinical Trials

H. M. Mattern^a and **S. Scherf^b**, (1)Developmental Psychology, Penn State University, University Park, PA, (2)Pennsylvania State University, University Park, PA

Background:

The Social Skills Improvement System (SSIS) measures social emotional competencies in youth (ages 3-18 years) by multiple raters (parents, teachers, youth). It is recommended as an outcome measure to assess social communication behaviors in autism (Anagnostou et al., 2015). Although the SSIS has good test-retest and inter-rater reliability between parent- and teacher- reports, informant discrepancies emerge when youth reports are evaluated (Gresham et al., 2017). This is not uncommon; there is emerging literature about these kinds of informant discrepancies, which may reflect unique contributions of each reporter on the youth's experience (De Los Royes & Epkins, 2023). For example, among autistic youth, self-reported behaviors are generally reliable and even exhibit associations with behavioral and physiological measures that are not evident with parent-report (Bakhtiari et al., 2021). As a result, there are increasing calls to "add the missing voice" of autistic youth in evaluating behavior and behavioral change (Kenworthy et al., 2021).

Objectives:

Our goals were to evaluate 1) the stability of *autistic youth's* self-report ratings on the SSIS over time and 2) potential informant discrepancies between parents and youth in two randomized clinical trials evaluating the effectiveness of a psychosocial intervention, Social Games for Autistic Adolescents (SAGA)(Scherf et al., 2018).

Methods:

In SAGA1, 40 autistic adolescents were randomized to either the intervention or treatment as usual condition. In SAGA2, 41 autistic adolescents were randomized to either the intervention or a placebo control condition. Youth participants and their parent each completed the SSIS at the pre- and post-intervention testing sessions. Total scores for social skills and problem behaviors were computed for each rater at each time point. We computed the test-retest reliability for the youth and parents separately for each condition (intervention, control) in each RCT (SAGA1, SAGA2). Finally, we assessed inter-rater agreement between youth and parent responses using the pre-test scores in each RCT separately.

Results:

Autistic youth in both studies and conditions provided stable reports of their social skills and problem behaviors with moderate to good reliability (Table 1). Similarly, parents generally provided stable reports of their adolescent's behavior with moderate reliability. In contrast, there was poor inter-rater reliability between the parent- and youth-reports of behavior at the pre-test session for social skills (SAGA1 $ICC = 0.16$, SAGA2 $ICC = 0.23$) and problem behaviors (SAGA1 $ICC = 0.23$, SAGA2 $ICC = -0.10$). Youth specifically reported higher social skills (SAGA1 $M=104(SD=16)$, SAGA2 $M=89(SD=18)$) than parents did (SAGA1 $M = 79(SD=14)$, SAGA2 $M = 80(9)$) and lower problem behaviors (SAGA1 $M = 99(SD=12)$, SAGA2 $M = 106(SD=13)$) than parents (SAGA1 $M=119(SD=12)$, SAGA2 $M=121(SD=10)$).

Conclusions:

The observed stability of autistic youth self-reports across studies and SSIS subsections suggests that youth report their own social skills and problem behaviors consistently over time. Furthermore, the striking differences between youth and parent report emphasize the need for researchers to evaluate when and how autistic self-reports should be included in research. Autistic self-report may provide a unique insight into the autistic experience and may contribute to more complete interpretations of research and study results.

309.004 Continuous, Objective Measures of Social Contact in Inclusive Preschool Classrooms Distinguish Children with and without Autism

M. Siller¹, D. S. Messinger², D. Sarker³, C. Song⁴, L. K. Perry⁵, B. Schirmer⁶, L. Morgan⁶ and S. Gillespie⁷, (1)Emory University School of Medicine, Atlanta, GA, (2)Department of Psychology, University of Miami, Coral Gables, FL, (3)University of Miami, Miami, FL, (4)University of Miami, Coral Gables, FL, (5)Marcus Autism Center, Atlanta, GA, (6)Georgia College & State University, Milledgeville, GA, (7)Department of Pediatrics, Emory University, Atlanta, GA

Background: Young children with autism spectrum disorder (ASD) show characteristic deficits in social communication. Recent longitudinal studies and clinical trials show that measures of ASD social engagement capture an important mechanism in children's social communication development and mediate treatment effects on social communication. Preschool classrooms and other natural environments where interactions occur with peers provide a unique context for development. Efforts to increase access to and participation in preschool settings for children with ASD have been hampered by a lack of scalable methods for measuring children's social engagement.

Objectives: This research employs modern location tracking technology to measure social contact by capturing second-by-second tracking of children's and teachers' interpersonal distance in inclusion preschool classrooms. Computational methods from statistical physics were used to derive continuous, objective measures of social contact (a) with peers only (%*peer*) and (b) with both peers and teachers simultaneously (%*peer&teacher*).

Methods: Data were collected across two school years in three age-grouped classrooms of a university-affiliated inclusion preschool focused on autism (i.e., classrooms for 2-, 3-, and 4-year-olds). The sample included $N = 61$ children, including 24 children with ASD; $n = 16$ children attended the program across two school years (**Table 1**). During each school year, objective measures were collected on 3-4 consecutive days during fall, winter, and spring. On each day, data were collected during two free-play periods, in the classroom and on the playground. In total, we collected 519 and 454 location tracking measures in the classroom and on the playground, respectively.

Results: Repeated objective measures of %*peer* and %*peer&teacher* were evaluated as outcome using general linear mixed effects regression models (**Table 2**). Across both diagnostic groups, results from fixed effects analyses revealed that %*peer* was significantly higher on the playground, 48.8% (46.2%, 51.4%), compared to the classroom, 43.6% (41.0%, 46.1%), $p < .001$. Moreover, classroom measures of %*peer* were significantly lower for children with ASD, 40.1% (36.3%, 44.0%), compared to children without ASD 45.7% (42.7%, 48.7%), $p < .01$. Similarly, playground measures of %*peer* were significantly lower for children with ASD, 42.2% (38.3%, 46.2%), compared to children without ASD 53.0% (49.9%, 56.0%), $p < .001$. Importantly, results showed a significant setting*diagnosis interaction effect, suggesting that diagnostic differences in %*peer* were larger on the playground, compared to the classroom, $p < .05$. Finally, while results for %*peer&teacher* showed significant differences by setting (classroom: 48.7% [47.3%, 50.1%], playground: 15.8% [14.4%, 17.2%], $p < .001$), diagnostic group differences were not statistically significant (ASD: 32.1% [29.1%, 35.1%], TD: 33.2% [30.9%, 35.5%], *ns*).

Conclusions: Results from this research contribute to our understanding of the construct validity of objective measures of social contact in inclusive preschool classrooms, providing developmental and intervention researchers with an innovative tool for studying the social development of children with ASD in naturalistic contexts. Further, results show that diagnostic differences in social contact with peers were no longer significant when teachers were simultaneously involved, suggesting that trained teachers may play an important role in facilitating the social engagement of children with ASD in inclusive preschool classrooms.

310.001 Diagnostic Overshadowing? Autistic Children Are Less Likely to Carry an Anxiety or Depression Diagnostic Code When Prescribed SSRIs

C. Faulk¹, R. M. Benecke¹, Y. Y. Yu¹, J. Foy², L. K. Steinbeck¹, C. J. Zampella¹, A. Bennett¹, R. Prasad³ and J. D. Herrington¹, (1)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (2)Child Psychiatry and Behavioral Science, Center for Autism Research (CHOP), Philadelphia, PA, (3)The Children's Hospital of Philadelphia, Philadelphia, PA

Background: Anxiety and depression co-occur frequently with autism, and are high-priority foci for the autism community. Selective Serotonin Reuptake Inhibitors (SSRIs) are increasingly prescribed in autism, despite relatively little data on their efficacy vis-à-vis core autism characteristics as well as co-occurring depression and anxiety symptoms. There are very few studies to date examining the extent to which SSRI prescriptions in autism are typically accompanied by diagnostic codes representing the primary conditions for which they have FDA-approved indications (depression and anxiety disorders). The present study examines this in a large Electronic Medical Health Record (EHR) database from a primary care setting.

Objectives: To examine rates of co-occurring anxiety and depression EHR diagnostic codes among autistic children being treated with SSRIs.

Methods: Approximately 10 million primary care patient encounters were examined among 365,341 unique individuals seen at the Children's Hospital of Philadelphia. 10,486 of these patients had an autism spectrum code noted at least once in their EHR.

Results: See Fig. 1 for an illustration of the proportion of patients with autism, anxiety, and/or depression codes in the EHR. Among the 354,855 total patients without an autism diagnostic code in their record, 9,152 (3%) have ever been prescribed an SSRI at some point over the course of their care. As expected, anxiety and depression codes were common in this group (7,607 patients, 83% of the total non-autistic patients taking SSRIs). Among the 10,486 patients with an autism diagnostic code in their record, 1,207 patients (12%) had ever been prescribed an SSRI over the course of their care (see Table 1). However, only 867 (72%) of these patients on SSRIs have an anxiety or depression code among any of their patient encounters – significantly fewer than the non-autism patients (Chi-Squared=90.5, $p<.001$).

Conclusions: The present findings of decreased anxiety and depression diagnostic codes among autistic individuals undergoing SSRI treatment have at least two salient interpretations. First, it is possible that SSRIs are frequently prescribed in autism to treat symptoms that do not fit squarely within depression/anxiety symptom categories, and may be more related to autism characteristics (in particular, repetitive behaviors and behavioral inflexibility). Second, decreased anxiety/depression diagnostic codes may reflect diagnostic overshadowing – the tendency to attribute most or all symptoms presented by an autistic person as part of their autism rather than another condition. The present study shares several limitations with all studies relying on EHR datasets – in particular, that diagnostic codes may not be fully equated with bona fide psychiatric diagnoses, and evidence of psychiatric concerns may be manifest in other parts of an EHR clinical encounter (besides diagnostic codes). It is nevertheless striking that the use of a depression or anxiety diagnostic code is so much less frequent among autistic children undergoing a mainstream treatment for these two common co-occurring conditions. Future research will benefit from a more in-depth examination of SSRI prescription practices in primary care, and the specific symptoms they are typically prescribed to treat among autistic individuals.

310.002 A Transdiagnostic Approach to Autism, Anxiety, and Social Adaptation in Adolescent Girls and Boys

M. Lyons¹, A. L. Lee¹, S. Schillinger¹, G. Emory¹, A. Knox¹, C. Faulk¹, L. J. Fulop¹, M. Cola¹, A. Yates Flanagan¹, J. Pandey¹, R. T. Schultz² and J. Parish-Morris¹, (1)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (2)The Center for Autism Research/CHOP, Philadelphia, PA

Background: Strategies utilized by the autistic community to conceal or compensate for neurodivergent traits are sometimes referred to as camouflaging or masking (Hull et al., 2018) and are a form of social adaptation. The Camouflaging Autistic Traits Questionnaire (CAT-Q) measures social adaptation across three dimensions: compensation (making up for social difficulties), assimilation (blending in with others in social situations), and masking (hiding autistic characteristics; Hull et al., 2018). Autistic girls report engaging in more social adaptation than autistic boys (Wood-Downie et al., 2021), and anxiety is more frequently diagnosed in adolescent girls than boys (Parodi et al., 2021); however, little is known about how anxiety, autism, and social adaptation interact and whether sex differences in adaptation exist in anxious teens as well as autistic teens. Anxiety, autism, and camouflaging are all considered risk factors for poorer long-term outcomes (Essau et al., 2014; Bernardin et al., 2021), and it is therefore important to explore how social adaptation unfolds in the context of autistic and anxious youth.

Objectives: In the current study, we use a transdiagnostic approach to examine: (a) whether self-reported social adaptation differs for autistic (AUT) vs. anxious (ANX) vs. neurotypical (NT) youth, (b) whether self-reported social adaptation differs in girls vs. boys, and (c) whether measures of anxiety associate dimensionally with social adaptation across diagnoses.

Methods: 244 adolescents with autism ($n=78$, 23F), anxiety ($n=106$, 69F), or neurotypical development ($n=56$, 27F) completed the CAT-Q as part of a larger study. The CAT-Q includes 25 questions related to social adaptation across 3 domains: compensation, assimilation, and masking. Two-way ANOVAs examined effects of sex and diagnosis on CAT-Q subscores, with Tukey's HSD post-hoc tests for planned pairwise comparisons. Pearson correlations tested the relationship between self-reported anxiety (MASC; March, 2012) and overall CAT-Q scores.

Results: Results revealed a main effect of diagnosis on social compensation ($F=15.97$, $p<.001$) and assimilation ($F=34.88$, $p<.001$) but not masking ($F=0.76$, $p=0.47$), such that compensation and assimilation scores were higher in ANX and AUT ($ps<.001$) vs. NT. There was a significant main effect of sex on all measured aspects of social adaptation: compensation ($F=13.60$, $p<.001$), assimilation ($F=17.28$, $p<.001$), and masking ($F=10.66$, $p<.01$). Planned post-hoc comparisons revealed that social adaptation was consistently higher in females than males (all $ps<.01$). No other main effects or interactions emerged. Pearson correlations revealed a strong positive dimensional relationship between anxiety and social adaptation across sex and diagnosis (Spearman=0.68, $ps<.001$).

Conclusions: Autistic and anxious adolescents report more compensation and assimilation behaviors than typically developing peers, which is consistent with previous literature (Pyszkowska, 2024; Lorenz & Hull, 2024). Furthermore, adolescent females, regardless of diagnosis, report engaging in more social adaptation than males. Extreme social adaptation (also known as camouflage or masking) is a transdiagnostic risk factor for poor mental health, but lower levels can be normative during adolescence. Additional research is needed to gain a better understanding of how anxious and autistic youth utilize social adaptation, and how exactly it affects their social and psychological well-being during this critical developmental window.

310.003 Anxiety Diagnoses in Very Young Autistic Children with Varying Intellectual Abilities

A. L. Hogan^{1,2}, K. E. Caravella³, J. G. Smith¹, K. Hills⁴, A. S. Carter⁵ and J. Roberts^{2,4}, (1)Department of Communication Sciences and Disorders, University of South Carolina, Columbia, SC, (2)Carolina Autism and Neurodevelopment (CAN) Research Center, University of South Carolina, Columbia, SC, (3)Carolina Institute for Developmental Disabilities, University of North Carolina, Chapel Hill, NC, (4)Department of Psychology, University of South Carolina, Columbia, SC, (5)Department of Psychology, University of Massachusetts Boston, Boston, MA

Background: Autistic youth are at increased risk for anxiety disorders, which significantly impact daily functioning and quality of life. Little is understood about anxiety symptoms and diagnoses during early childhood, when intervention may be most impactful, particularly in children with co-occurring intellectual disability (ID). Two recent studies reported high rates of anxiety diagnoses in autistic preschoolers (Chan et al., 2023: 65.2%; Vasa et al., 2023: 26.7%). However, both studies relied heavily on clinical diagnostic interviews designed for older children, which may be less accurate in early childhood, when the manifestation of anxiety symptoms is quite different. Furthermore, increased diagnostic complexity due to co-occurring intellectual and/or language impairment requires multi-method assessments that integrate direct observations and clinical judgment in autistic children.

Objectives: (1) Characterize rates of DSM-5 anxiety diagnoses in autistic preschoolers with varying intellectual abilities utilizing a clinical best estimate (CBE) diagnostic procedure that incorporates multiple sources of information; and (2) Determine whether anxiety diagnoses are associated with sex at birth or common indicators of autistic heterogeneity (e.g., IQ, language level).

Methods: Participants included 47 autistic preschoolers [$M(SD)$ age=3.59(0.47) years; 85.11% male] and 31 non-autistic (NA) preschoolers [$M(SD)$ age=3.43(0.64) years; 77.42% male]. Groups were similar on chronological age, $t(76)=1.26$, $p=.212$, and sex distribution, $\chi^2(1)=0.75$, $p=.387$. The autism group had significantly lower IQ, $t(76)=13.88$, $p<.001$, and 78.72% ($n=37$) had IQs<70. DSM-5 anxiety diagnoses were determined through a clinical best estimate (CBE) diagnostic review procedure that incorporated information from a clinical diagnostic parent interview designed for preschool-aged children (the Preschool Age Psychiatric Assessment), direct observations, parent-report questionnaires (e.g., the Preschool Anxiety Scale-Revised), and clinician judgment.

Results: Twenty-two (46.81%) autistic preschoolers met diagnostic criteria for a DSM-5 anxiety disorder, compared to eight (25.81%) NA preschoolers, $\chi^2(1)=3.48$, $p=.062$. Specific phobia was the most common diagnosis in the autistic preschoolers (38.30%; $n=20$) and was diagnosed at significantly higher rates than in the NA group, $\chi^2(1)=5.95$, $p=.015$ (Table 1). Rates of anxiety diagnoses were similar across the following autism subgroups (a) children with IQ <70 v. those with IQ ≥70, (b) speaking v. nonspeaking children, and (c) males v. females, all $\chi^2 \leq 1.10$, $ps \geq .295$.

Conclusions: Our study suggests that when a multi-method CBE diagnostic process is utilized, nearly half of autistic preschoolers meet diagnostic criteria for a DSM-5 anxiety disorder. This rate falls between those recently reported by two studies that relied primarily on clinical diagnostic interviews designed for older children. Importantly, our findings also suggest that during the preschool developmental period, risk for DSM-5 anxiety disorders does not vary by sex, IQ, or language level. In line with previous work, specific phobia was the most common DSM-5 disorder in our preschool-aged sample. Given evidence from studies of NA children that specific phobia in early childhood increases likelihood for later onset of a variety of mental health problems, future studies should investigate whether early specific phobia impacts long-term mental health outcomes in autistic children.

310.004 Early Childhood Brain Structure Predicts Later Emergence of Specific Phobia Differently in Autistic Youth with and without Intellectual Disability

O. J. Surgent¹, C. M. Kerns², B. Winder-Patel³, T. Liggins⁴, A. Dakopoulos⁴, D. S. Andrews⁴, J. K. Lee¹, M. Solomon¹, D. G. Amaral¹ and C. W. Nordahl¹, (1)Department of Psychiatry and Behavioral Sciences, UC Davis MIND Institute, Sacramento, CA, (2)University of British Columbia, Vancouver, BC, Canada, (3)MIND Institute, MIND Institute, UC Davis Medical Center, Sacramento, CA, (4)Department of Psychiatry and Behavioral Sciences, MIND Institute, UC Davis Medical Center, Sacramento, CA

Background: Autistic individuals often experience severe anxiety (Kerns & Kendall, 2012; South & Rodgers 2017). Specific phobia is among the most predominant anxieties in autistic youth, especially autistic youth with an intellectual disability (ID) (Kerns et al., 2021). Theoretical models of specific phobia suggest that heightened sensory responsivity, which is often experienced by autistic individuals, leads to maladaptive learning and ultimately extreme fear of something that poses no true danger (Green & Ben-Sasson, 2010). While many brain structures contribute to heightened sensory responsivity and sensory-based learning in autism, differences in the striatum may be particularly important for the development of specific phobia as the striatum integrates sensory information with cognitive and affective information to drive learning (Parkinson et al., 2009). However, it is still unknown if early differences in striatal structures influence sensory-based learning and drive later emergence of specific phobia in autism. Further, it remains unclear if these mechanisms are similar or different in autistic youth with and without ID.

Objectives: 1) Determine if early development of striatal structures predicts later childhood specific phobia in autism 2) Evaluate striatal-specific phobia associations in autistic youth with and without ID.

Methods: Early childhood striatal volume (2.0 - 4.5 years) as well as middle childhood specific phobia and intellectual ability (9.1 - 13.7 years) were collected from 67 autistic individuals (15 female). Striatal volume was parcellated into substructures associated with different aspects of sensory (putamen), cognitive (caudate nucleus), and affective (nucleus accumbens) processing using a multi-atlas approach (Mori et al., 2016). Clinically significant specific phobia was assessed using the ADIS-ASA (Kerns et al., 2017) and intellectual ability was assessed using the Differential Ability Scales-II (Elliot et al., 2007). ID was operationally defined as IQ<70. Logistic regression determined if early childhood striatal volumes differently predicted later childhood specific phobia in autistic individuals with and without ID.

Results: 61% of autistic participants had specific phobia and 28% had ID. 57% of the participants with ID had specific phobia. Larger putamen (Fig A, Left: $p=.04$, Right: $p=.03$) and left nucleus accumbens ($p=.02$) volumes during early childhood were significantly associated with the later emergence of specific phobia, regardless of ID status. However, ID did influence the associations among early childhood volumes of both the bilateral caudate nucleus (Fig B, Left: $p=.04$, Right: $p=.02$) and right nucleus accumbens (Fig C, $p=.04$) and later childhood specific phobia. Specifically, for autistic children with ID, larger early childhood striatal volumes were predictive of later specific phobia but there were no significant associations in autistic children without ID.

Conclusions: Results suggest that unique brain mechanisms related to different aspects of sensory integration and striatal-based learning may contribute to specific phobia in autistic youth with and without ID. While early differences in striatal-based sensory processing contribute to specific phobia across autistic individuals, early differences in striatal-based cognitive and emotional integration additionally contribute to specific phobia in autistic individuals with ID. These distinct associations suggest that early patterns of striatal differences may be viable markers of future anxiety in subgroups of autistic youth.

Oral Session -**311 - Autism in Underserved Communities: Diagnosis, Service Utilization, and Culturally Inclusive Interventions**

May 1st, 2025, 3:00 PM - 4:00 PM - 611-614

311.002 Advancing the Diné (Navajo) Parents Taking Action Program: Findings and Future Directions from a Mixed Methods Pilot Study*C. L. Running Bear¹, D. E. Henderson², B. R. Kirby³, A. Johns³, R. L. Whitman³ and O. J. Lindly³, (1)Western New Mexico University, Gallup, NM, (2)Communication Sciences and Disorders, Northern Arizona University, Flagstaff, AZ, (3)Health Sciences, Northern Arizona University, Flagstaff, AZ*

Background: Parents Taking Action (PTA) is an evidence-based autism parent education and training program originated for Latinx immigrant families in the United States. PTA uses a community health worker delivery mode whereby parents of a child with autism (i.e., family advisor) are trained to deliver PTA lessons to other parents in the same community who have a child with autism (i.e., parent participant). PTA has been adapted for various communities (e.g., Black/African-American, Chinese, Colombian) using the Ecological Validity Framework. Recently, PTA was adapted for Navajo (hereafter Diné) families (Figure 1). Information is needed on the fidelity, feasibility, acceptability, and initial outcomes of the Diné program so it may be further improved, more rigorously tested, and spread to other rural and Indigenous communities who lack culturally responsive autism services.

Objectives: We examined the fidelity, feasibility, acceptability and initial outcomes of the adapted Parents Taking Action program for Diné parents of children with autism ages 2-12 years.

Methods: A convergent mixed methods study was conducted from 2022 to 2024 with 13 Diné mothers who had a child with autism. Fidelity was assessed using checklists completed by family advisors and study team members. Feasibility was determined by the number of participants enrolled and the number of lessons completed. Acceptability and initial outcomes were assessed through parent reported surveys including measures of social validity, as well as child and parent outcomes. Qualitative data on program acceptability were also collected from family advisors and participants. Descriptive and bivariate statistics were computed for quantitative data, and thematic analysis was used for qualitative data.

Results: High fidelity was reported by the family advisors: 109 lessons (out of the 110) had 100% fidelity, and one lesson had 86% fidelity. Of the 13 parents enrolled, nine completed all program lessons and surveys, and ten completed all or some of the lessons, indicating reasonable feasibility. Social validity questionnaire results indicated high acceptability. Family advisors reported that parent participants enjoyed the program including the ability to connect with someone they could identify with. Family Outcome Survey results indicated high reliability overall and on all subscales (understanding child's strengths, needs, & abilities; knowing your rights and advocating for your child; helping your child develop and learn; having support systems; accessing the community) and improvement when comparing the baseline and completion survey scores (Table 1).

Conclusions: The Diné PTA program was delivered with high fidelity, was feasible and acceptable, and showed promising initial outcomes. As of April 2024, the Diné PTA is being sustained and spread through the Autism Support, Community, and Education in the Navajo Nation through the Diné Parents Taking Action (ASCEND) project in partnership with a 638 clinic within Navajo Nation. ASCEND includes a randomized waitlist control trial with 25-30 Diné parents/guardians of children with autism to better determine the effectiveness of the Diné PTA program regarding parent/family and child outcomes. This research is advancing health equity for Diné families, so the adapted program can be delivered to more Diné families and other tribal and/or rural communities in the future.

**311.003** Age at Diagnosis, ASD-Service Utilization, and Presence of an IEP in Spanish- and English-Consented Latino Children in SPARK*K. Cortese¹, A. Daniels¹, O. Kanoute¹, J. Polite¹ and W. Chung², (1)Boston Children's Hospital, Boston, MA, (2)Department of Pediatrics, Boston Children's Hospital, Boston, MA*

Background:

SPARK launched in 2016 to recruit and retain a cohort of individuals with autism and their family members across the United States. In 2022, enrollment opened to Spanish-speakers. The experience of Spanish-speaking Latinos with autism in the United States is not well documented, given challenges with recruitment and retention (Burkett et al., 2021). Autism prevalence is lower in regions with more Spanish-speaking households (Dickerson & Dickerson, 2020). Autistic Latinos, regardless of language, face disparities in access to services (Blacher et al., 2019). Few studies have examined the heterogeneity within the broader Latino autism community (Elliott et al., 2022). More research should examine within-group differences, given the exclusion of non-English-speaking individuals from much pediatric health research (Chen et al., 2022).

Objectives:

To examine differences in age at autism diagnosis, ASD service utilization, and presence of an IEP between Spanish- and English-consented Latino children in SPARK.

Methods:

A total of 3,885 Latino individuals were included, 555 autistic children whose guardians consented to their participation in Spanish from 2022-2024, and 3,330 autistic children whose guardians consented in English in the same period. Given differences in participation by method of recruitment (Daniels et al., 2023) individuals not recruited by a clinical site were excluded. Data utilized in this analysis included information about autism diagnosis, service utilization, and clinical and sociodemographic characteristics. The adjusted association between language of consent (English or Spanish) and age at diagnosis was examined using linear regression. Logistic regression was used to examine adjusted odds of service utilization and IEP utilization by language of consent.

Results:

Most children were male, with a mean age of 6 years at enrollment for the English-consented and 7 years for the Spanish-consented children. Their racial identities were heterogeneous; half of Spanish-consented children identified as “other” or “more than one” race and lived in the south. The Spanish-consented group had lower language levels and were more likely to have cognitive impairment. After controlling for known confounders, Spanish-consented children were diagnosed 6 months earlier than their English-consented counterparts ($p < .001$). The adjusted odds of ASD service utilization and having an IEP were respectively 1.65 and 1.46 for Spanish-consented children, compared with the English-consented children (95% CI [1.28, 2.13]; 95% CI [1.2, 1.8]).

Conclusions:

A younger age at diagnosis and higher utilization of services and IEPs for Latino children with autism enrolled by their Spanish-speaking guardian, compared to those enrolled by English-speakers, suggests a diagnostic severity bias. The study did not include a measure of socioeconomic status, and ascertainment by clinical sites may limit generalizability. Future research should examine differences in diagnosis, treatment, and outcomes among Latinos with autism by sociocultural and demographic factors, accounting for the role spoken language plays in moderating developmental trajectories.

311.004 Exploring the Association between Autism Spectrum Disorder and Immigration in Manitoba, a Population-Based Approach
M. F. Ricci¹, L. Zwaigenbaum² and M. Urquia³, (1)Department of Pediatrics and Child Health, University of Manitoba, Winnipeg, MB, Canada, (2)University of Alberta, Edmonton, AB, Canada, (3)Max Rady College of Medicine Community Health Sciences, University of Manitoba, Winnipeg, MB, Canada

Background: Higher rates of autism spectrum disorder (ASD) among immigrants have been described in several countries. We previously conducted the first ever Canadian study examining this association; a retrospective review that identified an overrepresentation of immigrant families among children ≤ 6 years diagnosed with ASD at Manitoba's primary and only publicly funded site for ASD assessment, the Rehabilitation Center for Children (RCC). While a useful first step, the study lacked granular data on immigration. We now aimed to further research this association by examining population-level data.

Objectives: To determine differences in the incidence of ASD among children ≤ 6 years of age living in Manitoba during May 2016-December 2022 who belong to immigrant vs. nonimmigrants families, and related factors.

Methods: We linked the RCC ASD dataset to the Manitoba Population Data Repository, which contains health, education, sociodemographic (including immigration) data from all Manitoba residents. Children were classified as: Group 1- no immigration, Group 2 - one/both parent(s) immigrants + child born in Canada, Group 3 - parents and child immigrants to Canada. Sociodemographic information including country of origin and refugee status was collected. Diagnoses of ASD at RCC were made by developmental pediatricians and/or psychologists. Cumulative incidence of ASD (95% CI) was calculated for each group; adjusted relative risk (RR) with 95% CI were calculated to compare groups.

Results: Cumulative incidence of ASD per 1000-person, and adjusted RR according to immigration is shown in Table 1. Among those in Group 3, when risk was calculated by child's age of arrival to Canada (<3 years vs. ≥ 3 years (ref.)), adjusted RR for those who arrived at <3 years of age was 6.60 (4.52, 9.63). Association between immigration characteristics and ASD by region of origin and refugee status is shown in Table 2.

Conclusions: This population-based Manitoba study identified an increased incidence of ASD among children of immigrant families, especially among those born in Canada or those who immigrated within the first three years of life. While a non-European region of origin was associated with an increased risk for ASD, refugee status was not. Further studies are needed to better understand the association between ASD and immigration.

Moderator: Rhiannon Luyster, Communication Sciences and Disorders, Emerson College, Boston, MA

312.001 Anticipatory Language Processing in Autism: Evidence from Eye-Tracking in Preschool-Aged Children

Z. Hua¹, T. Li^{2,3}, R. Shi⁴, R. Wei⁵ and L. Yi^{6,7}, (1)School of Psychological and Cognitive Sciences & Beijing Key Laboratory of Behavior and Mental Health, Peking University, Beijing, China, (2)Department of Psychology, Normal College, Qingdao University, Qingdao, Shandong, China, (3)Department of Psychology, School of Education Science, Qingdao University, Qingdao, Shandong, China, (4)Faculty of Education, University of Macau, Macao, China, (5)Graduate School of Education, Peking University, Beijing, Beijing, China, (6)School of Psychological and Cognitive Sciences & Key Laboratory of Behavior and Mental Health, Peking University, Beijing, China, (7)PKU-IDG/McGovern Institute for Brain Research, Peking University, Beijing, China

Background: Anticipatory language processing, the ability to anticipate upcoming words in spoken discourse, is a crucial component of efficient language comprehension. Previous studies have shown that neurotypical (NT) children's anticipatory language processing skills pave the way for fluent communication and social interaction. However, the extent to which autistic children engage in anticipatory language processing remains less understood. Given that autistic children often experience difficulties in language skills, it is important to examine whether these challenges extend to anticipatory language processing. Understanding these differences in early language development may provide insight into the unique cognitive and linguistic profiles of autistic children, offering potential pathways for tailored interventions.

Objectives: This study aims to investigate the anticipatory language processing of preschool-aged autistic children using eye-tracking techniques.

Methods: The study included 45 autistic children (5 females; $M_{age} = 5.67$, $SD = 0.98$, range = 3.80-8.05) and 52 age-, gender- and verbal-IQ-matched NT children (7 females; $M_{age} = 5.40$, $SD = 0.92$, range = 3.02-7.04). Children completed an eye-tracking task adapted from the visual world paradigm. In the task, participants heard subject-verb-object sentences that contained two semantically informative cues (an agent and an action) that corresponded to the sentence-final patient. As the sentences were spoken, participants viewed visual arrays containing four images (Figure 1): target patient, agent-related distractor, action-related distractor, and unrelated distractor. Children were told to point to the image that matched the sentence they heard. Upon hearing the verb, children should have gathered sufficient information to generate anticipatory looks to the target.

Results: We employed two complementary analytical approaches: the growth curve analysis (GCA) and the divergence point analysis (DPA). The GCA examined group differences in the overall trajectory of fixations, whereas the DPA offers a more fine-grained analysis of when anticipatory looking emerged. The GCA revealed a significant main effect of group ($\beta = -0.15$, $p < .001$), with the autistic group showing lower overall fixation proportions to the Target than the NT group, and a significant interaction between the linear time term and group ($\beta = -0.87$, $p < .001$), indicating that the autistic group exhibited a slower rate of increase in fixation proportions to the Target over time compared to the NT group. The DPA revealed that the NT group reached the divergence point (where anticipatory looking to the Target rather than the Agent-related distractor emerged) significantly earlier than the autistic group ($p < .001$). Specifically, the estimated divergence points for the NT group occurred at 1254.20 ms (95% CI [1150, 1350]) after the sentence onset, whereas for the autistic group, it occurred at 1415.46 ms (95% CI [1350, 1500]; Figure 2).

Conclusions: Findings suggest that autistic children exhibit delayed and less robust anticipatory language processing compared to their NT peers, as manifested by the slower rate and later emergence of anticipatory looks. This delay could contribute to broader challenges in language comprehension and social communication in autistic children. The results underscore the importance of early identification and intervention strategies tailored to support language processing skills in autistic children.

**312.002** Grammatical Markers Development in Mandarin-Speaking Autistic Children: Quantitative but Not Qualitative Variations

Z. Meng¹, L. Wang², H. W. Hira³ and P. Wong⁴, (1)the Chinese University of Hong Kong, Hong Kong, Hong Kong, Hong Kong (China), (2)Brain and Mind Institute, The Chinese University of Hong Kong, Hong Kong, HK SAR, (3)Brain and Mind Institute, The Chinese University of Hong Kong, Hong Kong, HK SAR, China, (4)Brain and Mind Institute, The Chinese University of Hong Kong, Shatin, N.T., Hong Kong

Background: Past research has revealed large variations in language profiles, including the morphosyntactic domain, between typically developing (TD) and autistic children (e.g., Brynskov et al., 2017; Su & Naigles, 2023). However, little is known about such variations were *quantitative* (e.g., different acquisition rates) or *qualitative* (e.g., different developmental trajectories, different ultimate acquisition outcomes), which provides new insights into the relationship between language and cognition. In addition, most of previous autism research has focused on the development of English grammatical markers (e.g., -ing, -ed), and no studies have yet examined how grammatical markers develop in Mandarin-speaking autistic children. Different from English, Mandarin Chinese has no inflectional morphemes. A recent study by Huang et al. (2022) found their TD participating children acquired Mandarin grammatical markers in a different pattern from English children. This implies Mandarin-speaking autistic children may experience particular difficulties, which calls for specific research on Mandarin.

Objectives: This study aimed to compare the development of a wide range of Mandarin grammatical markers (e.g., aspect markers, negative markers, etc.) between Mandarin-speaking TD and autistic children.

Methods: Data were collected at three timepoints with 80 autistic children ($M_{age} = 43.11$ months, $SD = 9.64$; 67 boys) at Time 1, 52 ($M_{age} = 49.21$ months, $SD = 10.06$; 43 boys) at Time 2, and 10 ($M_{age} = 62.2$ months, $SD = 12$; 8 boys) at Time 3. At each timepoint, their caregivers reported their child's language performance using the Chinese Communicative Development Inventory Putonghua (Mandarin) version (CCDI-P; Tardif and Fletcher, 2008). Following the grammatical marking rescoring method used by Huang et al. (2022), all Mandarin grammatical markers (see Table 1 for the full list) were coded in the grammatical complexity section of the CCDI-P. We ranked the acquisition order for all the markers based on parents' reports. Finally, we compared our autistic children's results with that of Huang et al.'s (2022) TD participants ($M_{age} = 26.98$ months, $N = 338$).

Results: We found a clear acquisition order of Mandarin grammatical markers (see Table 1). Furthermore, Kendall's rank correlation suggested a significant correlation between autistic and TD children's acquisition orders ($\tau = .71, p < .001$), though autistic children's scores of all 14 grammatical marker categories were significantly lower than that of TD children ($t(13) = 8.05, p < .001$).

Conclusions: It suggested although autistic children acquired the grammatical markers at a slower rate, their developmental trajectories were similar to that of TD children. This supports the hypothesis that autistic children's language development is quantitatively but not qualitatively different from those of TD children. The results of Time 3 suggested autistic children may eventually catch up and acquire most of the grammatical markers (except for markers aspect "zheng4" and negative "bie2").

Significance: This is the first large-scale study that comprehensively investigates Mandarin-speaking autistic children's development of morphosyntax. The findings have critical implications for language acquisition theories and intervention research, especially for China, which has a large population of autistic children.

312.003 Parent Underestimations of Verb Vocabulary in ASD and TD

K. J. LeGrand and L. R. Naigles, *Psychological Sciences, University of Connecticut, Storrs, CT*

Background: Development of verb vocabulary is a growing area of interest in ASD, likely due to the integral role of verbs in language acquisition. Two tools employed to measure children's verb vocabulary are spontaneous language samples and parent-report measures (e.g., MacArthur-Bates Communicative Development Inventory [CDI]; Fenson et al., 1993). However, these two tools can yield incongruent results: parent report is less consistent and accurate for verbs than nouns in ASD and TD (Arunachalam et al., 2022; Kover et al., 2023), and parents of lower-verbal children with ASD underestimated their child's grammatical development more frequently than parents of children (TD, ASD) with higher language skills (Jyotishi et al., 2017). Thus, verbs and children with ASD with poorer language seem disproportionately affected by underestimation on parent reports. Prior work reporting verb-related shortcomings of the CDI included young children aged 1.5-3.5 years; we study a later timepoint (2-4 years), when some children have progressed linguistically and others remained delayed, to ask whether these issues (underestimation for verbs and for autistic children with language challenges) compound over time.

Objectives: To compare children's verb production (TD, ASD) via spontaneous language samples and parent report.

Methods: 67 children ($N_{ASD}=32$; $N_{TD}=35$) from a longitudinal dataset (Naigles & Fein, 2017) participated in six parent-child play sessions (V1-V6), each four months apart. Here, we analyze data from V2 and V3. Parents reported children's vocabulary on the CDI Words and Sentences form. Play sessions were transcribed, and verbs were extracted. We calculated number of underestimations (i.e., verbs produced in the play sessions that parents marked as "not produced" on the CDI) for each child at each visit (Table 1). We ran a linear mixed effects model predicting number of underestimations, with fixed effects of group (ASD vs. TD), visit (V2 vs. V3), number of different words (NDW) calculated from the transcripts, and interactions, with random slopes by participant for verb vocabulary.

Results: 21 parents in the ASD group and 34 in the TD group underestimated their children's verb vocabulary. Models revealed fixed effects of group (more underestimations for TD than ASD), visit (more underestimations at V3 than V2), and NDW (more underestimations at higher NDW; Figure 1a). There were significant interactions between group and visit (underestimations in the ASD group did not change from V2 to V3, but underestimations in the TD group did; Figure 1b) and between NDW and visit (relationship between NDW and underestimations was stronger at V3 than V2).

Conclusions: Especially at V3, parents of TD children underestimated their children's verb production at higher rates than parents of children with ASD. In both groups, parents of children with larger vocabularies underestimated more verbs than parents of children with smaller vocabularies. More underestimations may be due to fewer language-related concerns among parents of children with better language, possibly leading to less attention to/inaccurate reporting of individual words. Contrary to predictions, these results suggest that the CDI may be a valid measure for children with ASD and language issues, but a more problematic measure for children developing typically.

312.004 An Innovative Tool to Evaluate Politeness Use in Autistic Youth

H. E. Elsayed¹, K. Reduzzi¹, P. Meulenbroek², D. Sullivan¹ and H. Genova¹, (1)Kessler Foundation, East Hanover, NJ, (2)Radford University, Radford, VA

Background: Employment plays a vital role for adults with Autism Spectrum Disorder (ASD), as it not only provides financial independence but also promotes meaningful social connections and community involvement. Difficulties with pragmatic language skills, which are essential for social interactions, can hinder the ability to develop and maintain effective work relationships which is a crucial component of successful employment. A fundamental pragmatic skill in workplace communication is the appropriate use of politeness, which involves recognizing and considering the feelings and thoughts of others. Politeness can be evaluated using politeness markers (PMs). PMs are categorized into two types: positive PMs, which convey appreciation or praise, and negative PMs, which aim to prevent conflict by showing consideration for the listener's feelings.

Objectives: This study investigates the effectiveness of an employment-focused social communication assessment tool, the Voicemail Elicitation Task (VET), in individuals with ASD. VET is a language sampling procedure which measures PMs in employment-based scenarios.

Methods: The current cohort comparative study involved a sample of young adults with ASD ($n = 65$) and neurotypical controls (NTC; $n = 26$), aged between 15 and 26 years. All participants completed the VET, a standardized computerized language sampling procedure designed to evaluate politeness markers (PMs) during work-related role-play scenarios. The primary measure of the VET is PMs per minute (PMpM), calculated by dividing the total number of PMs by the speaking time in minutes. A higher PMpM indicates greater use of politeness markers, while a lower PMpM reflects less use. Additionally, parent reports were collected using the Social Responsiveness Scale, 2nd edition (SRS-2), to assess the severity of social challenges.

Results: The preliminary results showed that participants with ASD had a significantly lower total PMpM (mean = 13.72, SD = 5.00) compared to NTCs (mean = 18.35, SD = 4.79), with $p < .001$. Post hoc analysis revealed that this group difference was primarily due to the ASD participants using significantly fewer negative PMs (mean = 6.31, SD = 3.12) than the NTC group (mean = 10.54, SD = 3.62), $p < .001$. However, both groups had similar levels of positive PMs use ($p = 0.569$). Additionally, significant negative correlations were found between total negative PMpM and the SRS total score ($r = -.321$, $p = .002$), as well as with the SRS subscales for social communication and interaction ($r = -.320$, $p = .002$), social awareness ($r = -.321$, $p = .002$), and social cognition ($r = -.360$, $p < .001$).

Conclusions: This study indicates that the VET could be used as a potential screening tool to predict performance of autistic individuals in employment settings. The findings suggest that people with ASD exhibit differences in PMs use, that could possibly affect their interpersonal relationships in the workplace. Understanding differences in politeness use can potentially lead to designing interventions that could help in improving employment outcomes in this population.

313.002 Investigating Sleep Disruptions in a CHD8 Haploinsufficient Mouse Model Using Behavioral and Electrophysiological Methods

S. F. Dhanani¹, E. Mager Garfield², D. Rivas², J. M. Luna³, A. Christoforatos³, G. Turi^{1,2}, Y. Peng⁴, M. Jin^{1,2}, C. A. Denny^{1,2} and R. A. Muhle², (1)New York State Psychiatric Institute, New York, NY, (2)Psychiatry, Columbia University, New York, NY, (3)Barnard College, New York, NY, (4)Pathology, Columbia University, New York, NY

Background: Mutations in the gene Chromodomain Helicase DNA Binding Protein 8 (*CHD8*) are linked to an increased likelihood of autism diagnosis in people. *CHD8* acts as a transcriptional regulator during neurodevelopment, and a loss of function (LOF) of *CHD8* has been shown to disrupt gene regulatory networks during this critical period (Yim et al. 2024). People with *CHD8* LOF mutations have reported disrupted sleep (Dingeman et al., 2022; Bernier et al., 2014; Coll-Tané et al., 2021). Animal models with LOF mutations in *CHD8* have also supported a role in sleep: reduction of the gene *kismet*, the *Drosophila* ortholog of *CHD8*, was associated with difficulty falling asleep as well as frequent and prolonged awakenings at night (Coll-Tané et al., 2021), and zebrafish with mutations in *chd8* showed decreased sleep length and increased number of rest bouts (Weinschutz Mendes et al., 2023). Utilizing a mouse model of *CHD8* haploinsufficiency (*Chd8*^{+/−}), we investigated the effect of *CHD8* disruption on the sleep architecture of adult mice using behavioral and electrophysiological methods.

Objectives: We used Piezo sleep boxes to behaviorally assess sleep in *Chd8*^{+/−} mice. Piezo sleep boxes are highly sensitive to breathing movements and can quantify the respiratory rate of mice by detecting the frequency of chest wall extensions which are a reliable marker of sleep states (Vanneau et al., 2021). Following the Piezo box analysis, we assessed sleep in the same cohort using video-EEG/EMG, to confirm our findings and to detect different sleep states. We hypothesized that we would see decreased sleep length and increased number of sleep bouts in a the *Chd8*^{+/−} mouse.

Methods: All experiments were conducted on a 12-hour light/dark cycle. We used Piezo boxes to assess sleep in a cohort of 32 mice of both sexes (8 animals per group). Data analysis (excluding the first day) was conducted using SleepStats, ClockLabs, and Prism. We then implanted head mounts to record brain activity in same-sex pairs for three days and nights with EEG and movement with EMG using Pinnacle Inc.'s tethered system. Data was recorded using the Sirenia package, and analyzed using a custom MatLab script.

Results: In the sleep boxes, *Chd8*^{+/−} mice showed an increase in number of sleep bouts and sleep length, and a decrease in sleep bout length. These results validate the sleep disturbance issues observed in *Drosophila* and zebrafish models of *CHD8* loss. Our initial analysis of EEG/EMG recordings found that *Chd8*^{+/−} mice exhibited a significant increase in total duration of sleep, as well as time in REM sleep. An increase of the number of REM bouts in the *Chd8*^{+/−} mice compared to the WT mice approached significance.

Conclusions: Overall, using behavioral methods we observed similar phenotypes of sleep disruption in *Chd8*^{+/−} mice compared to other animal models of *CHD8* loss, while differences in sleep state architecture were implicated using video-EEG/EMG studies. Cross-validation across additional cohorts and in conditional mouse models is on-going, and will further our understanding of the biological mechanisms regulating *CHD8* loss-related sleep disturbance.

313.003 Production of a Nonhuman Primate Model of the CHD8 Form of Autism Spectrum Disorder

D. G. Amaral¹, A. S. Nord², J. Ryu³, K. Cichewicz⁴, J. Zarrabi⁵, C. Hanna³, P. Leung³, F. Burch³, N. Piekarski³, E. Mishler⁴, K. Burd³, B. Dozier³, J. Hennebold³ and C. A. VandeVoort³, (1)Department of Psychiatry and Behavioral Sciences, UC Davis MIND Institute, Sacramento, CA, (2)Department of Psychiatry and Behavioral Sciences, UC Davis Center for Neuroscience, Davis, CA, (3)Oregon National Primate Research Center, Portland, OR, (4)UC Davis Center for Neuroscience, Davis, CA, (5)University of California, Davis, Davis, CA, (6)Oregon National Primate Research Center, Portland, CA

Background: Autism Spectrum Disorder is an incredibly heterogeneous condition with varied co-occurring symptomatology and multiple genetic risk factors. We have been particularly interested in one form of autism that manifests with profound core and co-occurring symptoms as well as macro- or megalencephaly. Children with this form of autism have intellectual disability with meager gains in IQ during childhood and impoverished language function. They benefit less from standard behavioral therapies and thus have a poorer prognosis than autistic children with normal brain size (Amaral et al., 2017). While many genetic variants are associated with autism and megalencephaly, one gene that has gained substantial attention codes for chromodomain-helicase-DNA-binding protein 8 (*CHD8*). *CHD8* is a chromatin modifier that affects thousands of genes throughout the genome. An initial publication by Bernier et al. (2014) identified a human phenotype of *CHD8* mutation that included a diagnosis of autism, macrocephaly or megalencephaly, intellectual disability, specific facial features, gastrointestinal problems, and sleep disorders. While most autism risk genes are not highly penetrant, loss of function mutations of *CHD8* produce autism in 87% of individuals and 80% demonstrate macrocephaly. While several *Chd8* modified mouse models have been produced, none have captured the full phenotypic profile of human *CHD8* autism.

Objectives: We have endeavored to produce a rhesus monkey model of CHD8 autism by using CRISPR-cas9 and in vitro fertilization technologies. Studies were carried out both at the California National Primate Research Center and the Oregon National Primate Research Center (ONPRC).

Methods: We first designed two guide RNAs (gRNA) to target the upstream and downstream introns of a *CHD8*. Our CRISPR-Cas9 strategy uses two guide RNAs targeting introns flanking *CHD8* exon 4 at the zygote stage to generate exon-specific deletions, disrupting normal *CHD8* reading frame. Mature oocytes were harvested from superovulated females, which were inseminated through in vitro fertilization; presumptive zygotes were injected with the two gRNAs and Cas9 mRNA. Embryos that advanced to blastocyst stage underwent trophectoderm biopsy for genotyping and vitrification for later transfer to female surrogates.

Results: We injected 231 zygotes that resulted in 23 blastocysts, 10 of which had two distinct PCR bands, one indicating exon deletion and another represented non-deleted exon 4, confirmed by Sanger sequencing. These were transferred to 7 females, leading to a first pregnancy of an edited fetus. This pregnancy resulted in a live birth on September 29, 2024. Both mother and *CHD8* edited infant are healthy and developing as expected. Behavioral evaluations are underway, and initial MRI analysis will occur at 30 days and then periodically thereafter. Initial blood genotyping indicates that the infant carries the targeted *CHD8* exon 4 deletion mutation, and the allele is well represented in blood DNA.

Conclusions: Efforts are underway to produce additional *CHD8* edited animals to verify phenotypic characteristics and analyze neurobiological features of this form of autism.

313.004 Cerebellar Pathogenesis in CHD8 Haploinsufficient Mice: Implications for Autism Spectrum Disorder.

C. P. Canales¹, N. Seban², K. Cichewicz², S. Lozano², K. Jackson², D. Rahbarian², M. Corea², A. Kopley-Smith², M. Ramachandran², D. Fioravante³ and A. S. Nord¹, (1)Department of Psychiatry and Behavioral Sciences, UC Davis Center for Neuroscience, Davis, CA, (2)UC Davis Center for Neuroscience, Davis, CA, (3)Neurobiology, Physiology and Behavior Center for Neuroscience, UC Davis Center for Neuroscience, Davis, CA

Background: The cerebellum (CB) is well-recognized for its essential role in proprioception and motor control, but emerging evidence strongly implicates it in higher-order cognitive functions linked to intellectual disability and Autism Spectrum Disorder (ASD). Despite this, the non-motor contributions of the CB remain underexplored in ASD research. Mutations in the chromatin-remodeling factor CHD8 are highly associated with ASD, and studies in *Chd8* haploinsufficient mouse models have primarily focused on forebrain abnormalities, particularly in the cerebral cortex, where ASD-relevant genomic, neuroanatomical, and behavioral disruptions have been identified. However, our initial studies using these *Chd8* mice reveal region-specific perturbations in the CB, although the molecular pathology at a cell type-specific level remains unknown.

Objectives: We aimed to investigate cerebellar pathogenesis in *Chd8* haploinsufficient mice by characterizing cell type-specific molecular and epigenetic changes, including differential gene expression and chromatin accessibility, using snRNA-seq and snATAC-seq. We also sought to assess developmental trajectory disruptions through Pseudotime analysis, validate transcriptional and structural alterations via immunohistochemistry, RNA FISH, and electrophysiology, and explore the functional impact of these changes on circuit assembly and neuronal properties, particularly focusing on Purkinje neurons and molecular layer interneurons.

Methods: By pairing snRNA-seq and snATAC-seq, we integrate differential gene expression (DE), chromatin accessibility (DA), and developmental trajectory analysis (Pseudotime) to characterize cell type-specific developmental molecular pathogenesis. Gross neuroanatomy was assessed through immunohistochemistry (IHC), while RNA fluorescence in situ hybridization (FISH) used to validate cell type-specific DE. Additionally, we analyzed electrophysiological properties of key CB neurons through patch-clamp recordings, and assessed their morphology via Sholl analysis.

Results: Our findings to date indicate no gross alterations in CB anatomy or major cell populations as assessed by IHC. However, we observed significant cell type-specific DE and associated DA in *Chd8* mutants, indicative of a broad developmental asynchrony phenotype, particularly in Purkinje neurons and molecular layer interneurons. This suggests potential disruptions in circuit assembly and function. Transcriptional perturbations in Purkinje neurons have been corroborated by functional assays, and further validation through electrophysiology and RNA FISH is ongoing.

Conclusions: Our initial results lay the groundwork for expanded future investigations, with the overarching aim of elucidating how *Chd8* mutations affect the development of specific cerebellar cell types and circuits, and how these alterations may contribute to ASD-relevant neuropathology.

Oral Session -**314 - Social Dynamics and Attention in Early Autism Development**

May 1st, 2025, 3:00 PM - 4:00 PM - 4C-1,2

na

314.001 Familiarity of a Social Partner during Interactions Increases Attention in Toddlers with Autism: Evidence from a Live Eye Tracking Study**G. K. Bell**, S. Hamilton, P. G. Srinivasan, B. Gordon, S. Macari, A. Vernetti and K. Chawarska, *Child Study Center, Yale University School of Medicine, New Haven, CT*

Background: Differences in social attention are a defining feature of autism. Screen-based eye tracking studies highlight that limited attention to social partners is a promising biomarker of autism (Chawarska et al., 2013; Chita-Tegmark, 2016; Shic et al., 2019, 2023), but the familiarity of the social partner could modulate this effect. A live eye-tracking study of school-age children with and without autism showed no group differences in social attention to familiar vs unfamiliar adults during a painting activity (Clin et al., 2024), while other studies in live settings showed that children with autism were more attentive and socially engaged with familiar compared to unfamiliar adults during non-interactive and interactive play respectively (Kasari et al., 1993; Slaughter & Ong, 2014). The impact of familiarity on toddlers with and without autism in a live social interaction is has yet to be investigated.

Objectives: Investigate the impact of familiarity of the social partner (parent vs. examiner) in a live face-to-face interaction on social attention in toddlers with autism (AUT), neurodevelopmental conditions (NDC), and typical development (TYP).

Methods: Participants included 98 toddlers ($M_{age}=23.71$ months, $SD=5.85$), with AUT ($n=22$), NDC ($n=37$), or TYP ($n=39$). Participants were seated in a highchair across from a social partner, where gaze coordinates were collected using a Tobii Spectrum eye tracker. Each participant was administered eight 15-second trials in each of two conditions: parent and examiner. During the trials, the adult engaged the participant using ostensive cues including positive affect, eye contact, and child-directed speech, or they minimized gaze and speech. Trials were excluded if valid looking time was less than 15%, or calibration accuracy was below 1°. Attention to the social partner was indexed as a ratio of time looking at social partner/trial duration (%Person). A linear mixed model analysis was conducted with fixed factors of diagnosis (3) and condition (2).

Results: Analysis revealed a significant main effect of diagnosis ($F(2, 162.17)=4.04, p=0.014$), a marginally significant effect of condition ($F(1, 100.29)=3.44, p=0.067$), and a significant diagnosis by condition interaction ($F(2, 87.35)=3.20, p=0.046$). In the examiner condition, %Person in the AUT group was significantly lower than in the NDC ($p<0.001$) and TYP ($p=0.001$) groups. In the parent condition, %Person in the AUT group was comparable to that in the TYP group ($p=0.208$), but significantly lower than the NDC group ($p=0.042$). The TYP and NDC groups did not differ in %Person in the examiner ($p=0.989$) nor parent ($p=0.941$) conditions (Figure1).

Conclusions: When the social partner in a face-to-face interaction was an examiner, the toddlers with autism showed diminished attention compared to controls; however, when the social partner was a parent, the toddlers with autism showed social attention similar to typically developing peers. These findings indicate that face-to-face interactions with a familiar partner facilitates greater social attention in toddlers with autism. As concepts familiarity and predictability are intertwined, results of this study prompt further examination of such aspects on social differences in toddlers with autism.

**314.002** Caregiver-Infant Contingency in Dyadic Interaction: Evaluating Social Smiling Behaviors in Early Autism Development**J. D. Douglas-Brown**¹, E. Kushner^{1,2}, J. Jumbo³, H. Walum¹ and S. Shultz¹, (1)Marcus Autism Center, Emory University School of Medicine and Children's Healthcare of Atlanta, Atlanta, GA, (2)Department of Psychology, Emory University, Atlanta, GA, (3)Department of Neuroscience and Behavioral Biology, Emory University, Atlanta, GA

Background: Dyadic interactions between infants and their caregivers serve as a critical arena for infant socio-emotional development. These interactions aren't driven by either partner alone, but rather co-produced by caregivers and infants in tandem, with each partner adapting their behavior in an iterative, turn-taking fashion. Interactive behaviors promoting socio-emotional engagement, like smiling, are particularly foundational. Given that autism (ASD) is characterized by core differences in reciprocal social communication, early trajectories of social smiling may be differentiated for infants later diagnosed with autism (ASD infants). While previous studies report differences in social smiling in ASD infants compared to typically-developing infants by as early as 6-months of age (Lambert-Brown et al., 2015; Messinger & Fogel, 2007), few studies have investigated differences in social smiling in infants' first 6 postnatal months, the period during which social smiling first emerges and is then further refined via dyadic interaction.

Objectives: To 1) map trajectories of rate of smiling and shared-smiling (i.e., simultaneous infant and caregiver smiling) during dyadic infant-caregiver interactions between 2- and 6-months of age; and 2) identify when differences in smiling first emerge between ASD and typically-developing infants.

Methods: Preliminary analyses were conducted on a sample of 32 infant-caregiver dyads (53.1% ASD-infant, 43.8% female-infant, 68.8% White-infant, 38 sessions total). Dyads engaged in live, screen-mediated interactions between 2-6 months. Infants received autism diagnostic evaluations at 24- to 36-months. Unaware of infants' diagnostic outcomes, coders assigned binary codes to every frame (30 frames/second) of each interaction, indicating the presence or absence of a smile. The proportion of interaction time that infants and caregivers spent smiling, and the proportion of time spent in shared smiling was calculated. Generalized Additive Models (GAM) were used to construct trajectories of caregiver, infant, and shared smiling, and linear mixed-effect models were used to evaluate between-group smiling differences.

Results: ASD infants smiled less than typically-developing infants ($DF=28$, $t=2.342$, $p=0.027$), but caregivers' proportion of time spent smiling did not significantly differ between groups ($DF=30$, $t=1.558$, $p=0.130$). Typically-developing dyads spent significantly more time smiling simultaneously ($DF=30$, $t=2.985$, $p=0.006$). GAM models indicated a rapid increase in smiling for typically-developing infants from 2.7-4.2 months, consistent with prior reports of social smiling emergence in typical infancy. ASD infants did not show a significant increase in smiling rate until 4.3 months and the proportion of time they spent in shared-smiling remained low (see Figures 1&2).

Conclusions: Our findings suggest that social smiling—a critical social communicative milestone—is disrupted in infants later diagnosed with autism by as early as the second month of life. Smiling and shared smiling increased rapidly in typically-developing infants soon after month 2, whereas social smiling in ASD infants did not increase until 4.3 months and the proportion of time they spent smiling simultaneously with their caregivers remained low. These findings highlight how autism may alter the dynamics of infant-caregiver interactions, one of infants' earliest and most foundational learning experiences. Immediate next steps include coding of additional dyads and analyses of within-session temporal contingency.

314.003 Social Behaviors Forecast Physiological Regulation for Infants with ASD and TD Infants

J. Yurkovic-Harding^{1,2}, V. Narayanan³, J. E. Richards⁴ and J. Bradshaw⁴, (1)Department of Psychology, University of South Carolina, Columbia, SC, (2)Carolina Autism and Neurodevelopment Research Center, University of South Carolina, Columbia, SC, (3)Computer Science and Engineering, University of South Carolina, Columbia, SC, (4)University of South Carolina, Columbia, SC

Background: Infants rapidly gain social skills during the first months of life while undergoing significant physiological and neurodevelopmental growth. Physiological regulation, indexed by respiratory sinus arrhythmia (RSA), may significantly contribute to increasing social abilities, with high RSA supporting stimulus engagement (Richards, 1985) and later social abilities (Mateus et al., 2018). Accordingly, theories posit that RSA supports moment-by-moment social engagement (Porges & Furman, 2011), both of which are evidenced to be lower in infants and toddlers with ASD (Gangi et al., 2014; Patriquin et al., 2013). RSA predicts social outcomes in infants at elevated likelihood for ASD (Bradshaw & Abney, 2021), providing further evidence that physiological regulation may underly social development.

Objectives: The current study aims to address two major gaps in the literature. First, despite a theorized relationship, there is a paucity of research on the moment-by-moment dynamics of RSA and social behavior. Second, little is known about these dynamics in infants who later develop ASD. The current study therefore captures the directionality and strength of the temporal relationship between social behavior and RSA in young infants with and without ASD.

Methods: Infant heart activity was recorded during a 5-minute interaction with their caregiver when they were 3-, 4-, and 6-months old ($n=117$). Infants at elevated (EL, $n=34$) and low likelihood for ASD (LL, $n=83$) were determined to have ASD ($n=31$) or typical development (TD; $n=86$) between 24-36 months. Infant look to parent and smile were coded by reliable coders. RSA was calculated using a novel approach that allowed for continuous RSA estimation (3-second moving windows). RSA change (difference between RSA in sequential moving windows) was applied to a Granger causality analysis that assessed the degree to which look+smile together "forecasted" RSA change and vice versa. Generalized linear mixed models determined the effect of ASD-likelihood, diagnosis, and age on the proportion of infants for whom Granger causality was significant and on the strength of the relationship, determined by the log-transformed F-statistic.

Results: Look+smile significantly forecasted RSA change for 78% of infants, and the percentage increased with age ($F(1,94)=3.69$, $p=.05$; Figure 1). The strength with which look+smile forecasted RSA change increased substantially with age for EL-ASD infants and decreased with age for EL-TD infants ($F(1,71)=4.23$, $p=.04$; Figure 2). Conversely, RSA change forecasted change in look+smile for only 13% of infants, regardless of age, ASD-likelihood, or diagnosis (all $p>.46$).

Conclusions: Our findings revealed that infant social behavior precedes physiological responses, contrasting with theories that physiology begets social engagement. Further research that captures moment-by-moment physiological regulation may further elucidate the complex dynamics between social and physiological development. This is especially important for EL infants, who demonstrated a strong developmental relationship between RSA and social engagement. The developmental increase for EL-ASD infants in the strength in social-physiological dynamics suggests substantial task demands of face-to-face interactions and therefore strong recruitment of physiological systems. EL-ASD infants may therefore be less able to adapt to increasingly complex social interactions. Further, significant developmental change in social-physiological dynamics for EL infants may point to a genetic mechanism of psychophysiological development.

314.004 Social Context and Audiovisual Characteristics of a Stimulus Affect Consistency of Visual Attention in Autistic Toddlers
N. R. Fram¹, L. A. Edwards², W. Jones³ and M. D. Lense¹, (1)Vanderbilt University Medical Center, Nashville, TN, (2)Emory University School of Medicine, Marcus Autism Center, Atlanta, GA, (3)Marcus Autism Center, Atlanta, GA

Background: Autistic toddlers extract different information from complex social scenes than nonautistic peers (Jones & Klin, 2009), exhibiting more idiosyncratic attentional patterns when viewing scenes of others interacting (Avni et al., 2020). Such idiosyncrasies contribute to challenges developing social skills (Klin et al., 2015). However, these patterns may be impacted by social contexts and characteristics. In particular, child-directed song (CD-Song) is a highly appetitive dyadic activity for autistic and nonautistic toddlers (Lense & Camarata, 2020). CD-Song contains predictable temporal structure and patterns of audio and visual cueing that dynamically scaffold visual attention in nonautistic infants more strongly than dyadic, face-to-face engagement through child-directed speech (CD-Speech) (Alviar et al., 2023; Lense et al., 2022).

Objectives: We investigated how consistency of visual attention varies across common social contexts (peer interactions, CD-Song, and CD-Speech) in autistic and nonautistic toddlers. We also explored how characteristics of CD-Song (i.e., temporal predictability, visual motion, and audio volume) affected consistency of visual attention.

Methods: Autistic (n=81, 64 male) and nonautistic (n=61, 32 male) toddlers between 14 and 40 months old were eye-tracked while watching videos of other children in social settings (Peer), caregivers speaking to them (CD-Speech), and caregivers singing to them (CD-Song), along with versions of the CD-Song videos manipulated to remove predictable temporal structure. We computed spatial inter-subject correlations (ISCs) for each participant's eye position and every other participant with the same diagnosis and predicted overall video ISC by stimulus type and diagnosis. Within CD-Song, we compared ISCs between manipulated and unmanipulated stimuli to assess how rhythmic predictability influences visual attention. To examine moment-to-moment viewing dynamics within CD-Song, we computed variability in participants' eye position (dispersion) at each frame within diagnostic group, and predicted dispersion by frame-to-frame visual motion and audio volume change.

Results: ISCs (Figure 1) were highest overall in Peer videos, followed by CD-Song, with the lowest ISCs in CD-Speech (all p 's<.001). Yet while the diagnostic difference in ISC value was also largest in Peer (-0.16, p <.001; negative coefficient means lower in autism), it was smallest in CD-Song (-0.03, p <.001). ISCs did not differ between Peer and CD-Song clips for autistic toddlers. In CD-Song clips, removing temporal predictability reduced ISCs significantly more for autistic than nonautistic toddlers (-0.04, p <.001). Frame-by-frame similarity in eye location within diagnostic groups (Figure 2) was enhanced by more motion (β =-0.06, p <.001; negative coefficient means less dispersion) and reduced by larger changes in sound volume (β =0.03, p <.001).

Conclusions: Consistency in visual attention is driven by social context and time-varying stimulus characteristics including movement and sound intensity. CD-Song is highly effective at consistently scaffolding attention both within and across diagnostic groups. This consistency is driven by a combination of temporal predictability and visual motion. Autistic toddlers are particularly sensitive to temporal predictability, implying they may be relying on rhythm-based mechanisms to parse child-directed signals more than their nonautistic peers. Furthermore, researchers should consider stimulus characteristics as explanatory variables in study design, as they may reveal mechanisms driving attention in autism.

Poster Session

401 - Autism Community Issues and Experiences I

May 1st, 2025, 12:30 PM - 1:30 PM - Hall 4A

401.001 Qualitative Investigation: Client Family Perceptions of Handle® As Related to Foundational Principles

Y. Bensinger-Brody¹ and S. Leiser², (1)Doctor of Physical Therapy Department, Touro University, School of Health Sciences, NY, NY, (2)Department of Occupational Therapy, Touro University, School of Health Sciences, NY, NY

Background: The Holistic Approach to Neurodevelopment and Learning Efficiency (HANDLE®) is an evaluation and treatment approach for individuals diagnosed with a neurodevelopmental difference such as Autism Spectrum Disorder (ASD). Following in-depth clinical observation and interview, practitioners devise a customized home program consisting of sensorimotor activities to help strengthen identified weak sensorimotor systems and to support function. Often, suggestions for lifestyle and/or environmental modification are provided as well. HANDLE home programs are reviewed and updated at regular intervals usually for a period of six months to a year. While HANDLE is based on established neuroscientific principles, it has limited representation within the literature.

Objectives: The primary objective of this research is to establish face validity of the HANDLE Approach by investigating if client experience matches interventionists' intentions as related to the foundational principles including Gentle Enhancement®, presumption of competence, holism, and neuroplasticity. The secondary objective of this research is to understand parents' lived experiences while raising a child diagnosed with ASD or another neurodevelopmental differences.

Methods: This qualitative study included 8 interviews with 6 parents of children who received HANDLE based intervention. Semi-structured interviews with a combined phenomenological and theory driven approach were conducted to learn about participants' lived experiences related to raising a child diagnosed with ASD and other neurodevelopmental differences, and specifically their experience with implementing HANDLE as an intervention. Each interview was recorded, transcribed, and coded using inductive and deductive approaches. Each interview was coded by at least two investigators and then codes were reconciled. Codes were integrated into categories and categories were developed into themes.

Results: Four themes were identified. First, *pre-HANDLE therapeutic journey* describes the parental feelings of disappointment, anxiety, guilt, isolation, and experiences with behavioral, biological, and social issues during their child's early years prior to implementing the HANDLE Approach. Second, *family/parent profile* describes shared characteristics of families who were able to fully and successfully implement HANDLE. These include being driven to seek solutions beyond status quo, having great levels of commitment, dedication, and resilience, having high levels of education, being open to change and having time and financial resources. Third, *experience with HANDLE* captures parents' reported benefits of implementing the HANDLE Approach, including how it gave them a new perspective, it enabled them to understand their child's behavior, access joy and establish stronger family bonds all while accepting their own vulnerability. This theme further describes their child's developmental improvements via the foundational principles of HANDLE. Fourth, *continuous concerns*, highlights how their children continue to struggle, specifically during transitional periods of adolescence and adulthood, and as related to lack of awareness about neurodiversity in the general community.

Conclusions: Results suggest that client experience with HANDLE reflects the practitioners' intentions, specifically as related to the foundational principles. Further, themes suggest that HANDLE provided many benefits to the children diagnosed with ASD/neurodevelopmental differences and to their families, and as such, it is a framework that rehabilitation professionals should consider implementing for this population.

401.002 Strength Building Reduces Autistic-Related Needs in Child Behavioral Health Systems: A Longitudinal and Supervised Machine Learning Approach

M. R. Altschuler¹, K. I. Tumlin², O. Vsevolozhskaya³, W. T. Turner⁴, M. Voit¹, J. Lyons¹ and X. Tong¹, (1)Center for Innovation in Population Health, Department of Health Management and Policy, and Department of Psychology, University of Kentucky, Lexington, KY, (2)Athletic Training and Clinical Nutrition, University of Kentucky, Lexington, KY, (3)Biostatistics, University of Kentucky, Lexington, KY, (4)Center for Innovation in Population Health, University of Kentucky, Lexington, KY

Background:

Strengths among autistic individuals have been found to predict better quality of life and subjective well-being. Moreover, dimensional and neurodiversity frameworks suggest categorical classification and medical models based on a diagnosis of autism spectrum disorder (ASD) may limit supporting the needs and promoting the strengths of children with autistic-related challenges.

Objectives:

To (1) validate a person-centered approach to understanding autistic-related needs in child behavioral health systems through a supervised machine learning calculation of an autistic-related needs score (ARNS) for children with and without ASD diagnoses, and to (2) to determine whether building strengths reduces autistic-related needs over time.

Methods:

A total of 39,253 children aged 1-21 years-old served by a large midwestern child behavioral health system between 2018 and 2020 were evaluated approximately every 6-months, with 66% of children having follow-up assessments for a total of four years (figure 1). Each evaluation included an assessment for ASD diagnosis and Child Adolescent Needs and Strength (CANS) semi-structured interview. Using supervised machine learning, a dimensional ARNS was calculated as a weighted sum of actionable items from CANS core needs domains, standardized to a value between 0 and 1. Weights were determined by supervised machine learning modeling of diagnosed ASD by the CANS items at each assessment. Strengths were calculated by summing 15 items in the CANS strength domain. Strength building was defined at a given assessment as the median improvement of strength relative to the baseline strength (from -15 to +15), up to the point of said assessment. Longitudinal change was modeled in ARNS by strength building over a period of 6 to 48 months while controlling baseline strengths, demographics (age, gender, race/ethnicity), and change in ARNS over time.

Results:

Children diagnosed with ASD had greater mean number of needs (18.1, 95% CI = 17.1 ~ 19) relative to children without an ASD diagnosis (11.2, 95% CI = 11.1 ~ 11.4). Children diagnosed with ASD also had higher mean ARNS (95% CI = 0.29 ~ 0.36) relative to children without an ASD diagnosis (95% CI = 0.041 ~ 0.048). Among the full sample of children with and without ASD diagnoses, children with higher strengths at baseline had lower ARNS both at baseline (0.0030 mean reduction in ARNS per initial strength, $p < 0.0001$) and over time (0.0012 mean reduction in ARNS each year per initial strength, $p < 0.0001$); moreover, after accounting for baseline strengths, children showed lower ARNS over time based on the number of strengths built (0.0023 mean reduction in ARNS each year per strength build, $p < 0.0001$).

Conclusions:

Consistent with a neurodiversity framework, a supervised machine learning analytic approach that allowed for modeling a dimensional ARNS revealed that both initial baseline strengths, and building strengths over time, predicted a reduction in ASD-related needs over time. Taken together, results suggest focusing on building strengths among children with ASD-related needs may improve outcomes and promote resilience, indicating a need to shift towards strength-based, person-centered care and focus on practice and policy efforts that promote strength building among neurodiverse children.

401.003 "It's Made Me a Better Doctor": Resident Physicians' Experiences with an Adult Autism Training Designed with Autistic Adults and Family Members

D. Gilmore¹, J. M. Hyer¹, H. DeVassie¹, D. Radford¹, A. B. PREPARE for Autistic Adults¹, L. Juckett¹, C. Hanks², S. Haverkamp³, D. Coury⁴ and B. N. Hand⁵, (1)The Ohio State University, Columbus, OH, (2)The Ohio State University Wexner Medical Center, Hilliard, OH, (3)College of Medicine, Nisonger Center, Ohio State University, Columbus, OH, (4)Developmental-Behavioral Pediatrics, Nationwide Children's Hospital, Columbus, OH, (5)General Internal Medicine, The Ohio State University, Columbus, OH

Background: Physicians rarely receive training in providing care for adults with disabilities, like autistic adults, in their medical education. Many physicians have low self-efficacy in meeting autistic adults' needs. We partnered with autistic adults and family members of autistic adults to develop an innovative autistic adult-focused training program for resident physicians called Promoting Residents' Excellence in Patient-centered cARE (PREPARE) for Autistic Adults. The training includes six pre-recorded presentations, six case studies with accompanying "Why is this case important?" videos, and two standardized patient encounters.

Objectives: To pilot test feasibility, acceptability, appropriateness, and effectiveness of PREPARE for Autistic Adults.

Methods: In this single-group pre-test post-test pilot study, we recruited residents from Internal Medicine, Family Medicine, and Internal Medicine and Pediatrics at one institution. The training was delivered virtually over eight weeks and consisted of six pre-recorded lectures, six facilitator-led case studies, and two standardized patient encounters. Participants completed an autism knowledge assessment before and after the training. After the training, they also completed the Feasibility of Intervention Measure (FIM), Acceptability of Intervention Measure (AIM), Intervention Appropriateness Measure (IAM) and completed qualitative interviews. Quantitative data were analyzed with descriptive statistics, and changes in autism knowledge were analyzed with Wilcoxon-signed rank tests. Qualitative interviews were analyzed using thematic analysis.

Results: Fourteen residents consented to participate and N=11 completed the post-test. Most FIM, AIM, and IAM items had a median of 5 (highest possible score) for the training as a whole and for each of the individual components, indicating strong feasibility, acceptability, and appropriateness. The median completion rate was 76.9% of all training components, indicating high completion rates. Examination of change in participants' knowledge revealed a median increase of 11.8 points (Interquartile Range: 5.9-17.6; $p=0.015$). We interviewed 11 participants.

Qualitative analysis revealed four themes. First, "flexibility facilitates feasibility" highlights how the more flexible the training is, the more feasible it is for participants to participate in. Second, "high-value experiences increase acceptability" captured how hearing from autistic adults in the "Why is this case important?" videos and standardized patient encounters is a rich experience and how the training offered participants a safe space to practice newly learned skills that required leaving their comfort zone. Third, "other practicalities affecting implementation" captured other factors that either increased or decreased feasibility, acceptability, and appropriateness, including that some topics or strategies were still unclear to participants at the end of the training and would benefit from additional clarity. Fourth, "it's made me a better doctor," highlighted that participants felt the training filled a gap in their medical education and that participants are already applying their newly learned skills in clinical practice or have thought about how they would apply them.

Conclusions: Results suggest PREPARE for Autistic adults is perceived as highly feasible, acceptable, and appropriate, can be carried out with good completion rates, and significantly improves residents' knowledge about autistic adults. Next, we will make refinements to the training and conduct a waitlist-controlled study among residents measuring self-efficacy, attitudes and beliefs, and knowledge about providing care for autistic adults.

401.004 "Like Two Wolves in My Brain:" Descriptions of AuDHD on X (Formerly Twitter)

S. E. Woods, Discover Psychology Services, Lacey, WA; University of Washington Autism Center, Seattle, WA

Background: Research suggests that 40 to 70% of Autistic people have ADHD (Hours et al., 2022; Rong et al., 2021). Traditional research has treated autism and ADHD as separate conditions. The concept of "AuDHD," a colloquial term for the overlap between autism and ADHD, has recently gained attention in online Autistic communities. Craddock (2024) describes AuDHD as "more than the sum of its parts; a thing in and of itself" just like purple is more than blue plus red. The concept of AuDHD has important implications for clinicians and researchers. X (Formerly Twitter) offers opportunities for exploring new concepts, especially from marginalized groups whose own descriptions of their experiences have tended to be limited in academic literature.

Objectives: The goal was to better understand AuDHD by exploring tweets of people who publicly identify as having it.

Methods: An advanced search of X was conducted using the phrase "AuDHD is" with dates from 10/15/2021 to 10/15/2024, resulting in 479 public tweets. Each tweet was assessed to determine whether the author identified as having AuDHD. Sometimes this was clear from the tweet (e.g., "my AuDHD") or the author's bio. If the bio only mentioned autism or ADHD, other public tweets were explored. When the author's AuDHD status could not be determined, the tweet was removed, resulting in 374 tweets. The steps of thematic analysis described by Braun & Clarke (2006, 2023) were used to explore the content of the tweets and the overall themes.

Results: Five major themes were generated: **1) AuDHD as a set of paradoxes:** (e.g., routine versus novelty, intense focus versus "going down rabbit holes," needing rules versus wanting freedom). Some described these paradoxes as "painful," but if managed properly, the combination of opposite traits was described as potentially helpful (e.g., intense focus helps with in-depth study, while novelty-seeking helps with switching tasks). **2) "The best thing that ever happened:" the importance of identification and diagnosis:** individuals described the benefits of knowing that they have AuDHD and difficulties associated with not knowing. **3) "Perpetually drowning:"** people described executive functioning problems and difficulties with activities of daily living that they related to AuDHD, as well as struggles finding the right medications. **4) "I'm home:" Community as creating and validating identity:** people discussed how other AuDHDers helped them accept themselves while they felt rejected by other groups, **5) "A Wild ride:"** individuals shared examples of how their AuDHD-related curiosity and interests gave them pleasure.

Conclusions: AuDHD is described as a unique identity, separate from ADHD and autism. Researchers and clinicians should attend to how autism and ADHD interact, rather than focusing on only one or the other. Placing an emphasis on identifying AuDHD early and helping people find community is key. Although many AuDHDers recognize the benefits of their neurotype, they also describe ways in which it can be disabling in certain contexts. Future research should include AuDHDers in exploring assessment practices and interventions, including ways to modify environments to maximize the benefits of AuDHD while helping people overcome the challenges.

401.005 "Multiple Masks Weigh Us Down": A Qualitative Exploration of Autistic Intersectional Performativity

E. Taylor^a, D. C. Florindez^a, J. M. Rios^a, A. M. Angell^b and M. D. Franklin^c, (1)Mrs. T. H. Chan Division of Occupational Science and Occupational Therapy, Chan Division of Occupational Science at the University of Southern California, Los Angeles, CA, (2)Mrs. T. H. Chan Division of Occupational Science and Occupational Therapy, University of Southern California, Los Angeles, CA, (3)Occupational Therapy, Chan Division of Occupational Science at the University of Southern California, Gainesville, FL

Background: Performativity refers to how people appear, behave, and communicate to conform with dominant societal norms. Autistic masking encompasses the conscious and implicit ways that autistic people perform as non-autistic. Autistic masking is associated with health detriments, including elevated suicide risk. Multiply marginalized autistic community members report engaging in intersectional performativity, e.g., masking their autism and “passing” as cisgender. However, studies to date have mostly focused on autistic masking in isolation, sans intersectional analyses. Researchers have yet to empirically explore autistic intersectional performativity experiences and their subjective health implications.

Objectives: To explore how autistic people experience intersectional performativity and its health impacts, via the narratives of autistic participants with multiply marginalized identities.

Methods: For this qualitative study, the principal investigator (presenting author) conducted semi-structured narrative interviews with 10 autistic participants. Interviews focused on participants’ experiences of autistic masking and gender, sexual orientation, and racial/ethnic performativity. Participants were purposefully sampled for a range of relevant multiply marginalized autistic identities (e.g., autistic and transgender). Inclusion criteria were: 1) English language fluency; 2) 18 years or older; 3) lives in the United States; and 4) formally diagnosed or self-identifies as autistic. Self-identified autistic participants were included given formal diagnostic disparities among multiply marginalized autistic populations. The principal investigator and an external autistic coder employed thematic and narrative analyses on the data. To increase rigor, they discussed and resolved all coding differences. Both further drew from and reflexively examined their insider positionalities as multiply marginalized autistic researchers.

Results: 3 major themes were identified: 1) The Intersectional Nature of Autistic Performativity; 2) The Necessity and Consequences of Autistic Intersectional Performativity; and 3) Urgent Needs for Research and Resources. Participants described their experiences of autistic masking as deeply interconnected with their gender, racial/ethnic, and sexual orientation performativity. Many recounted incidents wherein they had to engage in intersectional performativity (e.g., simultaneously masking autism, passing as cisgender, and “code-switching” as White) to avoid violence (e.g., during police encounters) resultant from overlapping oppression (e.g., ableism, transphobia, and racism). Participants reported their intersectional performativity as necessary for basic survival, but as highly draining and health detrimental. Finally, participants indicated urgent needs for increased autistic intersectional performativity research and resources tailored for multiply marginalized autistic communities.

Conclusions: Study findings initially elucidate the complex and health-impactful nature of autistic intersectional performativity. This performativity may bear both advantages (e.g., increased safety) and detriments (e.g., poorer health) for multiply marginalized autistic people. As masking by itself is associated with negative outcomes, we recommend that researchers further examine autistic intersectional performativity and its health implications. Such scholarship would help address the present dearth of autistic intersectional performativity literature and resources.

401.006 "My Brain Works Fine. It's a Great Brain. It Does a Lot of Great Things." Examining Autistic Individuals' Metacognition As It Relates to Learning in School

S. R. Cohen¹, E. G. Kilgallon², N. Nadwodny³, S. Levinson⁴, M. Amato⁵ and A. Eisenhower², (1)University of California - San Diego, La Jolla, CA, (2)Department of Psychology, University of Massachusetts Boston, Boston, MA, (3)Psychology, University of Massachusetts Boston, Boston, MA, (4)Eating Disorders Center for Treatment and Research, University of California San Diego, San Diego, CA, (5)University of California, San Diego, La Jolla, CA

Background: Educational institutions have historically been inequitable for neurodivergent students (e.g., Mueller, 2021). Schools and educators use generalized labels for students (i.e., “autism”) that activate standardized, intensive therapy, rather than individualized interventions. Few educators draw on students’ self-awareness of their own learning which has increasingly shown to be effective in predicting both emotional well-being and academic learning outcomes for neurotypical and neurodivergent individuals (Arguedas et al., 2016; Demetriou et al 2020; Roberts et al., 2016). Some argue that autistic children’s metacognition is less developed than their neurotypical peers, and thus they have less self-awareness of their own learning needs (Grainger et al., 2016); there is a need for research that combats this assertion and centers first-person autistic student perspectives.

Objectives: The purpose of this study was to understand autistic students’ metacognition and self-awareness in the school context. We will consider how these views relate to those of teachers and peers and the ways that this self-awareness relates to learning in school.

Methods: We interviewed 19 autistic adolescents and adults between the ages of 16 and 43 who reported being diagnosed by age 12.5 years, on average. Participants were invited to take part in interviews via video conferencing, audio, or asynchronous methods. Interviews were analyzed using a reflexive, thematic approach.

Results: Three themes emerged from qualitative analysis. First, autistic students have a strong, well-developed self-awareness of how they learn in the school setting. For example, one respondent noted, “I am continuously learning every day about myself. I think that it's obviously a good path for me to understand that here's what I end up wanting. Here's what I need. Here's what I need to say in order to get what I want...” Second, there is often a mismatch between the messages autistic students get from their teachers and peers and their own understanding of themselves. One respondent noted, “I was a top-performing student, but I think my teachers and staff always focused on me being quiet and awkward rather than being successful at other things.” Third, autistic students have had to develop this self-awareness or metacognition as a means of adapting and coping with an environment not built for them. Autistic students reported having to develop a keen sense of their own learning needs and preferences, including their sensory and mental health needs, and their social communication preferences because the school environment was not accommodating.

Conclusions: Findings suggest that teachers and school staff should recognize autistic students’ metacognition and empower students to share these insights with their teachers. To quote one interviewee, “even back in kindergarten and first grade, had I been asked, “Is there a way to make this easier?” I could've given them seven different ways that would've helped.” Consistent with the goal of presuming competence, educators should engage with their students in problem-solving around their needs, with the expectation that autistic students are self-reflective about their learning. Collaborating with students may engender more effective learning environments for them and their autistic peers.

401.008 "You Can't Change Certain Aspects of Who We Are": Autistic Adolescents' Perspectives and Experiences with Behavioral Interventions

K. M. Baiden¹, C. McLean¹, A. Narayanan¹, R. K. Schuck², A. Denman¹, C. Fong³ and M. Wang¹, (1)Gevirtz Graduate School of Education, University of California, Santa Barbara, Santa Barbara, CA, (2)Department of Psychiatry and Behavioral Sciences, Department of Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA, (3)College of Osteopathic Medicine, Michigan State University, East Lansing, MI

Background: Behavioral interventions (BIs) are commonly used to teach new skills to autistic children. Despite their popularity and empirical evidence, they have received considerable pushback from autistic advocates who highlight that these interventions are not neurodiversity-affirming and can cause harm due to emphasizing compliance and “normalization” (i.e., encouraging behaviors perceived as more neurotypical). While these critiques are primarily found on non-academic forums, preliminary empirical investigations with autistic adults echo such concerns. However, hearing from younger individuals who have recently or are receiving BI is also crucial.

Objectives: This study aims to elicit perspectives on common BI goals, practices, and procedures from the point of view of autistic adolescents who have participated in BI.

Methods: Ten semi-structured interviews with autistic adolescents (age 13-17) were conducted. Questions were asked about adolescents’ experiences with BI and their perspectives on intervention goals, practices, and different support strategies and components of intervention models. Interviews were recorded, transcribed, and analyzed using reflexive thematic analysis.

Results: Five themes were generated: 1) Compliance-focused intervention is triggering; 2) Quality of life goals are important; 3) Accommodations over normalization; 4) Messages of Ableism; 5) Importance of nuance and individualization. Statements related to the first theme generally related to negative experiences. One participant noted that being “forced to do something not preferred” or comply with demands was not helpful. Statements categorized into the second theme related to skills that were seen as important (e.g., communication, self-advocacy), and participants connected them to larger outcomes (e.g., making friends, independence). One participant said, “Those are good goals because they will teach you to—you know—communicate and advocate for yourself. When you become an adult, communication is extremely essential in your daily life.” The third theme related to providing individuals accommodations instead of focusing on teaching them to be more “normal.” Participants mentioned environmental modifications as positive intervention tools but advised not to aim to change the individual. The fourth theme showed up in multiple ways. Some participants indicated that goals may be necessary for the good of those around them (e.g., “Yeah, because when people have an emotion change, it can be distracting to others.”). Others noted that people should be less ableist (e.g., “You can’t change our certain interests, or how we have a strong aversion to a certain thing. And you sort of just have to accept that about someone”). Finally, most noted that goals and intervention strategies should be individualized.

Conclusions: This analysis provides valuable insight into how autistic adolescents view BI. Themes generated from these interviews could be helpful for professionals as they attempt to address issues identified by autistic individuals and create more neurodiversity-affirming support. Specifically, intervention should focus on quality of life over compliance and providing accommodations instead of emphasizing “normalization.” Additionally, given that there is considerable nuance in *when* and *how* goals should be targeted, practitioners should be sure to individualize support. Finally, it is crucial to consider potential messages of ableism that may be implied in BI and determine how to replace these with more neurodiversity-affirming messages.

401.009 First Impressions Matter: Investigating Children's Biases Toward Autistic Peers

N. G. Van Esch¹, T. Q. Boucher², G. Iarocci² and N. E. Scheerer¹, (1)Psychology, Wilfrid Laurier University, Waterloo, ON, Canada, (2)Psychology, Simon Fraser University, Burnaby, BC, Canada

Background: Many autistic individuals face social challenges which may partly stem from their interaction partners, especially when biases toward autistic people are present. Research has shown that non-autistic adults and adolescents often display strong implicit and explicit biases towards autistic children and adults. These biases can surface after very brief exposure (less than 10 seconds) to autistic people and tend to persist over time. Since educational interventions have proven effective in reducing autism-related stigma, it is essential to gain a better understanding of when and how negative perceptions form in children to better address and mitigate them.

Objectives: This study investigated whether school-aged children have negative first impressions of school-aged autistic children.

Methods: Thirty-seven non-autistic children aged 5-12 years ($M=8.19$, $SD=1.98$; 15 Male, 22 Female) viewed brief (~10 seconds) videos of 10 autistic and 10 non-autistic children speaking about their hobbies. Following each video, participants rated the child’s traits (e.g., awkwardness, likeability, etc.) and their behavioral intentions towards the child (e.g., willingness to live near the stimulus child). Parents of the child raters filled out questionnaires regarding the child’s social competence (Multidimensional Social Competence Scale), and demographic information. Children’s IQ was assessed with the Wechsler Abbreviated Scale of Intelligence, 2nd Edition, Full-scale 2.

Results: Autistic children were rated less favorably overall ($F(1,36)=6.06$, $p=0.019$, $\eta_p^2=0.066$). There was also a significant interaction between video stimulus (autistic or non-autistic) and trait/behavioural intention item ($F(5,39,193.85)=2.54$, $p=0.026$, $\eta_p^2=0.144$). Specifically, autistic children tended to be rated as more awkward ($p=0.003$), more aggressive ($p=0.016$), and less likeable ($p=0.030$), but the child raters did not demonstrate less willingness to interact with the autistic children depicted in the videos. Overall autism bias was not related to age, IQ, sex, or social competence.

Conclusions: Children as young as 5 years old demonstrated negative first impressions of autistic children’s traits, regardless of the rater’s age, sex, IQ, or parent reported social competence. However, we did not find evidence of biases in behavioral intentions toward autistic children. These findings are consistent with previous research showing that autistic individuals are often perceived as more awkward and less likable than their non-autistic peers. This is concerning, as the perception of autistic children as more awkward or aggressive may contribute to their being viewed as an “outgroup,” potentially leading to increased bullying and social alienation.

The finding that negative biases emerged in children as young as 5, after only brief exposure, highlights the need for early educational interventions to improve perceptions of autistic individuals. Future research should aim to pinpoint which specific traits of autistic children contribute to these negative perceptions as they can then be targeted in educational interventions. Although these negative judgements were confined to perceptions of autistic children’s characteristics and did not influence behavioral intentions, this distinction highlights the importance of fostering both understanding and acceptance of autistic traits. By developing more effective educational tools to promote neurodiversity awareness and appreciation, we can work toward reducing the stigma surrounding autism and fostering more inclusive environments for all autistic people.

401.010 "the Best School Environment for Me": A Qualitative Exploration of Autistic Student’s Perspectives on Supporting Participation at School

S. Abraham¹, S. Thompson-Hodgetts², H. M. Brown³ and T. Barlott⁴, (1)Faculty of Rehabilitation Medicine, University of Alberta, Edmonton, AB, Canada, (2)Occupational Therapy, University of Alberta, Edmonton, AB, Canada, (3)Educational Psychology, University of Alberta, Edmonton, AB, Canada, (4)University of Alberta, Edmonton, AB, Canada

Background: Despite a significant body of research related to inclusive education, widely available resources, and the availability of professional support, current practices are not meeting the needs of autistic students or their educators to enable participation of autistic students in mainstream schools. Existing research primarily represents the perspective of non-autistic researchers, clinicians, school administrators and teachers, rather than prioritizing children's perspectives on what they would find supportive at school. Shifting approaches to capture the perspective of autistic students might be key to advance understanding of how to best support autistic students.

Objectives: This in-depth exploration of the experiences of autistic children at school aimed to: (1) explore autistic students' perceptions of what created the optimal environment to support their participation at school, and (2) prioritize autistic children's perspectives and thoughts as central to understanding their experiences.

Methods: The conceptual framework of relational ethics guided this study as we endeavored to generate data *with*, not *for*, autistic children. Within this paradigm, a collective case-study approach was used, with each case anchored by an autistic student. A variety of creative methods were used to help autistic students share their thoughts and experiences, including interviews, photo-elicitation, photovoice, beans and pots, write-draw-tell, researcher field notes, and participant observations. In each case, researchers attempted to garner experiences of successful and unsuccessful participation experiences in the school environment. Data were analyzed first within and then across cases through an iterative process of reflexive thematic analysis.

Results: Participants included four autistic students (ages 9-11 years; grades 4-6, 75% male; all co-diagnosed with ADHD; 3 with full/shared educational assistant) enrolled in mainstream education (i.e., not segregated or specialized programming beyond IEP). Each participant used spoken language, of varying sophistication, to communicate. Even though we did not use the words belonging or connection during data collection, our participants overwhelmingly emphasized that *Belonging and connection are necessary for a positive school experience*. This overarching theme anchored two themes that reinforced that the 'best school environment' was one in which students' felt that they were accepted for who they are as they are, and where they felt seen, heard and valued without judgment and experienced connection with others. Theme 1, *Autistic students deserve to feel psychologically safe at school*, reflected the importance of their relationship with their teachers, influence of bullying, and support for different ways of learning. Theme 2, *Sensory experiences at school impact my ability to engage and participate*, reflected the extent to which the physical school environments were overstimulating and benefits of having student-driven (as needed) regulating breaks in calm spaces.

Conclusions: We anticipated learning about environmental, academic and/or task adaptations that would help autistic students participate better at school. However, our data suggested that the best school environment for autistic elementary students is one in which they feel a strong sense of belonging and connection with others, including feeling both psychologically and physically safe in the sensory and social environments. Findings can be used to shift how inclusion is envisioned and enacted in schools.

401.011 A DEEP Dive into the Health Perceptions of Mothers with Autism Spectrum Disorder: A Hermeneutic Phenomenological Study

K. Gautam¹, W. M. Freysteinson², T. Fletcher³ and R. Schultz⁴, (1)Pediatrics, 9928 Easton Sky Ln, Cypress, TX, (2)Nelda C. Stark College of Nursing Texas Woman's University, Houston, TX, (3)Texas Woman's University, Dallas, TX, (4)Texas Woman's University Nelda C. Stark College of Nursing, Houston, TX

Background: In the field of autism, the perceptions and experiences of mothers regarding their health and well-being remain less visible in the literature as compared to the children's health. These mothers are the family warriors playing multiple roles in the family while taking care of their children with autism spectrum disorder (ASD).

Objectives: This qualitative study aimed to investigate an in-depth understanding of these mothers using Ricoeur's hermeneutic phenomenology. **Methods:** The researcher interviewed fifteen participants with at least one child with ASD in person and audio-taped Zoom sessions using semi-structured questions.

Results: Two environmental themes were (a) nonsupport to support and (b) stillness to rumble. Three phenomenological themes were (a) flood of emotions, (b) self-talk, and (c) me-time. The study's findings illustrate the perceptions of mothers of children with ASD regarding their health, contributing factors, and mothers' perceived barriers or positive methods that helped them maintain good health.

Conclusions: The stories of these mothers have provided awareness of the experiences lived by these mothers and the challenges that mothers face playing multiple roles in the families while taking care of their children with ASD and managing time for self-care. The findings highlight the immediate need for community interventions to develop programs that provide support to these mothers so that they can take care of their mental and physical health. This study also emphasizes the urgency of support networks for mothers to improve their overall health outcomes.

401.012 A Mixed Methods Analysis: Autistic Adults Describe Facilitators and Barriers to Autistic Community Connectedness

K. E. Breitenfeldt¹, M. R. Miller¹, N. M. Johnson², A. U. Tassone¹, T. Andrzejewski¹ and C. G. McDonnell¹, (1)Department of Psychology, University of Wyoming, Laramie, WY, (2)Disability Support Services, University of Wyoming, Laramie, WY

Background: Prior literature has framed the unique value and benefit of concepts such as ‘autistic infrastructure’ and ‘autistic community’ (Ryan Idriss, 2021; Bagatell 2010). Autistic people report greater comfort in socializing and easier communication with each other (Crompton et al., 2020). Autistic identity and internalized stigma have been linked to autistic community connectedness in prior literature (Botha et al., 2022). However, little is known about specific barriers and facilitators that autistic adults experience related to autistic community connectedness.

Objectives: This study used a mixed-methods approach to understand how autistic adults are involved with the autistic community and what barriers and facilitators are described in relation to autistic community connectedness. Comparisons between qualitative reports of barriers and facilitators were assessed in relation to measures of internalized stigma about autism and autistic identity.

Methods: 10 autistic adults in the United States (21-63 years, $M=36.1$; 50% cisgender women; 50% trans or non-binary, 100% white/non-Hispanic; 70% formally diagnosed) completed a brief questionnaire and a 1-hour chat-based qualitative interview. The qualitative interview involved open-ended questions eliciting information about their experiences with the autistic community. Transcripts were evaluated via thematic analysis to uncover reoccurring themes of facilitators and barriers. Code frequencies were calculated per transcript as both a total number of times a barrier or facilitator was coded (including repeated codes) and as a number of unique codes present in the transcript. The brief questionnaire included an autism specific internalized stigma scale (Botha & Frost, 2018) and the Autism Spectrum Identity Scale (ASIS positive difference/spectrum ability subscales; McDonald, 2017).

Results: Autistic adults engaged in the autistic community in a variety of ways, most frequently participants reported having autistic friends/peers (7/10), and engaging with the autistic community online (6/10) and asynchronously (i.e., books, blogs; 6/10). Participants identified several factors (facilitators) that led to becoming or staying involved in the autistic community. Most commonly they described increased self-acceptance or exploration (7/10), support with common challenges (7/10), similar social styles (5/10), and finding people with shared interests (5/10) and through another role (e.g., as a parent, teacher, therapist, researcher; 5/10). Several factors that made it difficult to initiate or sustain involvement with the autistic community (barriers) were also described by participants. Common themes included misinformation online or in autistic spaces (6/10), internalized stigma (6/10), interpersonal challenges (4/10) and masking (4/10). Exemplar quotes of facilitators and barriers are included in Table 1. Correlations between qualitative (frequency) and quantitative measures (Table 2) showed that internalized stigma was correlated with fewer facilitators ($r = -.731, p = .016$) and greater barriers ($r = .790, p = .007$) identified during qualitative interviewing. More positive autistic identity correlated with greater identification of facilitators, but not barriers, during interviewing ($r = .652, p = .041$). Correlations were non-significant between internalized stigma and autistic identity.

Conclusions: Participants described a range of experiences relative to autistic community involvement. Descriptions of facilitators and barriers may inform future work supporting community connectedness. Internalized stigma and autistic identity may be important to consider related to supporting autistic community connectedness.

401.013 Fostering Self-Advocacy: Parent Perceptions of the Impact of This Is Me (TiME) for Transition-Aged Students with Autism and Other Intellectual/Developmental Disabilities

J. R. Kleiner¹, D. Evans², A. Kern³, D. Reikowsky³, K. Smidl⁴ and E. Muller², (1)Clinical Psychology, Catholic University of America, Washington, DC, (2)Ivymount School and Programs, Rockville, MD, (3)Kennedy Krieger Institute/Powder Mill Campus, Beltsville, MD, (4)Kennedy Krieger Institute/Inpatient Neurobehavioral Unit, Baltimore, MD

Background: Self-advocacy is a critical skill for transition-aged students with autism and/or intellectual and developmental disabilities (I/DD) – especially those with co-occurring communication challenges – as they prepare to navigate new environments in post-secondary education, vocational, and community settings. Fostering self-advocacy in this population leads to greater independence, increased engagement in decision-making, and improved long-term outcomes, including higher rates of employment. This is Me (TiME) is a customized, electronic transition tool developed by speech-language pathologists to mitigate losses of key information during transitions, and to assist students to more independently communicate their strengths, needs, and preferences across postsecondary settings. This strengths-based tool encourages direct student participation to the greatest extent possible. The present study addresses a gap in the literature by focusing on parent perspectives on the impact of TiME, building on prior research which demonstrates that TiME assists novel adults in understanding students' support strategies.

Objectives: To 1) identify parent/caregiver perspectives on TiME's impact on students, and 2) determine whether parents who mentioned self-advocacy as a key benefit of the tool were more likely to indicate intent to share the tool broadly as part of students' transition processes.

Methods: Researchers conducted a thematic analysis of interviews with 26 parents/caregivers of students with I/DD and/or autism (ages 15-22 years; 10:16 Female:Male; 11 White, 10 Black/African American, 3 Asian, 1 Multiple Races, 1 Hispanic/Latino(a)), attending non-public special education school. Thematic analysis of transcripts was based on methods described by Clarke & Braun (2021): 1) Lead authors engaged in data reduction by independently reviewing the data corpus and labeling statements that pertained to the primary research questions. 2) Authors met regularly to organize quotes and generate themes. Differing opinions were resolved via consensus. 3) After finalizing the coding system, lead authors revisited all transcripts to formally code them using the agreed-upon codes and made modifications as necessary. 4) The entire research team met to discuss the coding system, themes, and subthemes. 5) Lead authors concluded the analysis by identifying quotes that best represented each theme/subtheme. Social validity interviews were also conducted with 15 students who were able to provide meaningful feedback on the tool.

Results: Key themes identified indicate that parents/caregivers perceived TiME to: 1) support students' interactions with novel adults by reducing the burden of communication, 2) facilitate students' autonomy and independence, 3) personalize and humanize students, and 4) increase students' self-confidence and self-awareness. Preliminary analysis further suggests that parents who valued the self-advocacy of TiME were also likely to mention their intent to have students share TiME with potential employers, adult service providers, and/or other novel adults involved in students' post-school transition process.

Conclusions: This study enhances and supports prior literature by capturing parents/caregivers' perspectives on TiME's impact. Both parents and students were nearly unanimous in their enthusiasm for the tool's potential to promote self-advocacy and communicate key information about support needs and strategies using a strengths-based approach. Responses to TiME showcase the potential for assistive technologies to promote self-advocacy and more seamless transition.

401.014 A Quantitative Analysis of Clinician Evaluation Results Following Training on the Safety Planning Intervention Tailored for Autistic Individuals

J. Heiny¹, L. Morgan², D. Delgado^{1,3}, E. Venkatesh⁴, S. Bowers¹, D. S. Roubinov⁴, S. Jager-Hyman⁵ and B. B. Maddox¹, (1)TEACCH Autism Program, University of North Carolina at Chapel Hill, Carrboro, NC, (2)Autism and Suicide Prevention Workgroup, Kittery, ME, (3)Psychology, University of Georgia, Athens, GA, (4)Psychiatry, University of North Carolina at Chapel Hill, Chapel Hill, NC, (5)Psychiatry, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA

Background: A growing body of research dedicated to suicide risk screening, assessment, and interventions adapted for autistic people fills a critical knowledge gap to prevent premature death in this high-risk population. This is responsive to the autistic community's priorities for mental health research and practice (Benevides et al., 2020). Yet, clinicians have reported that the Safety Planning Intervention, effective for non-autistic people, feels less acceptable for use with their autistic clients (Jager-Hyman et al., 2020). Aligned with recommended adaptations (Schwartzman et al., 2021), the Safety Planning Intervention Tailored for Autistic Individuals (SPI-A) is designed to leverage autistic clients' strengths and preferences. To deliver the SPI-A, clinicians attend a training co-developed and co-led by autistic people, including those with lived experience of suicidality. Clinicians must then pass a competency evaluation consisting of open-ended questions about roleplay videos of a therapist and autistic client creating an SPI-A together.

Objectives: The present study measures the success of the SPI-A training by analyzing clinician pass rates for the evaluation.

Methods: The evaluation included a total of 11 questions, with the first eight questions scored separately from the last three. Questions assessed clinician knowledge of communication strategies for use with autistic clients (e.g., "What change could the clinician make to improve communication with Kai?") and application of SPI-A core components and considerations to increase the chances a client will use their safety plan (e.g., "Once Kai's safety plan is complete, what are three things Dr. Smith can do to maximize the likelihood that Kai will use their safety plan when needed?"). Team members independently scored deidentified responses using a standardized rubric that awarded up to two or three points, depending on the question, based on the inclusion of key words, phrases, and concepts specific to each question. A consensus scorer resolved any discrepancies.

Results: 277 clinicians that see autistic clients in neurodevelopmental diagnostic, outpatient mental health, primary care, and medical specialty clinics in four United States healthcare systems completed the evaluation. To pass, clinicians had to score at least 13 out of 16 points on Part 1 and at least 6 out of 7 points on Part 2. About 84% of clinicians passed on their first attempt ($n = 233$). On average, clinicians scored 14.01 points ($SD = 2.03$), or 88% ($SD = 12.70$), on Part 1 and 6.38 points ($SD = 0.88$), or 91% ($SD = 12.50$), on Part 2. The pass rate for Part 1 was 85.6%, slightly lower than the 89.2% pass rate for Part 2.

Conclusions: The results suggest that most clinicians successfully integrated the strategies for communication with autistic clients with the steps to create an SPI-A that the client is likely to use. This is a core tenet of the training – the importance of the clinician and client collaborating to ensure the safety plan is relevant and useful when clients are in crisis. In combination with prior analyses demonstrating improved clinician attitudes, self-efficacy, and knowledge from pre- to post- SPI-A training, this is suggestive of the training's success.

401.015 A Strength-Based Review of Current Autism Research

G. Rey¹, A. Gazith² and A. F. Boatswain-Jacques³, (1)McGill University, Montreal, QC, Canada, (2)Educational & Counselling Psychology, McGill University, Montreal, QC, (3)Educational & Counselling Psychology, McGill University, Montreal, QC, Canada

Background: The neurodiversity movement has led to a shift in how autism is understood, emphasizing differences as unique strengths rather than deficits (Bottema-Beutel et al., 2021). Despite increased societal acceptance, autism research often continues to describe autistic individuals from a deficit-based perspective. This review aims to assess the extent to which contemporary research aligns with a strength-based approach, focusing on the representation of autistic individuals, the terminology used for comparison groups, and the relevance of research findings to autistic people's quality of life (Happé & Frith, 2020).

Objectives: This review aims to evaluate how current autism research integrates a strength-based perspective by examining the descriptions of autism, the labels used for comparison groups, and how findings are discussed in relation to autistic individuals' quality of life. It also seeks to determine how often researchers focus on individual strengths, motivational styles, and differences relevant to the daily lives of autistic individuals.

Methods: A scoping review framework guided by the JBI Scoping Review template was used to conduct this study. A systematic search of articles published in 2023 was conducted using articles published in the Autism Research Journal Issue of 2023 (16). Studies were included if they were empirical, published in peer-reviewed journals, and focused on participants with an autism diagnosis. Each article was rated on three dimensions: Life Improvement, Comparison Group Description, and Pathologizing Autism, using a 0-1 scale, with 1 aligning with strength-based approaches and 0 meaning the absence of strengths approaches/leaning towards deficit. Rayyan software was used for data management.

Results: Preliminary findings from eight studies indicate limited adoption of a strength-based perspective in autism research. The average scores were as follows: Life Improvement ($M = 0.22$, $SD = 0.41$), Comparison Group Description ($M = 0.66$, $SD = 0.38$), and Pathologizing Autism ($M = 0.31$, $SD = 0.44$). These results show that while most research is shifting towards a strength-based perspective, implementing specific necessities that make up strength-based research, such as how research can impact the quality of life of autistic individuals, needs to be improved.

Conclusions: The findings underscore the need for a paradigm shift in autism research towards a more strength-based approach. While some studies show progress in using respectful terminology and focusing on the quality of life, many still rely on deficit-based frameworks. Future research should prioritize interventions that aim to improve life satisfaction for autistic individuals and use language that reflects autism as a difference, not a deficit.

401.016 A Survey on Sensitive Language Use in the Autism Community in Singapore

S. Suhumaran¹, R. Aishworiya² and C. M. Wong³, (1)Department of Child Development, KK Women's and Children's Hospital / Singhealth, Singapore, Singapore, Singapore, (2)Paediatrics, National University Hospital, Singapore, Singapore, (3)Department of Child Development, KK Women's and Children's Hospital, Singapore, Singapore, Singapore

Background: The language we use in describing autism has an integral role in shaping its social perception and understanding. International literature, primarily from western countries, has illustrated diverse preferences for language including that for identity-first language (IFL) (e.g. autistic person) versus person-first language (PFL) (e.g. person with autism). The ongoing debate between PFL and IFL is shaped by cultural, medical, and advocacy perspectives. While PFL continues to be widely used in formal settings, there is a discernible shift toward IFL, particularly among autistic individuals and advocacy groups who view autism as an integral part of their identity rather than a condition. Singapore is a developed small city-island nation located in Southeast Asia with a multicultural population of 6.03 million people. The ethnic composition of Singapore residents comprises 74.2% Chinese, 13.7% Malays, 8.9% Indians, and 3.2% Others. English is the official language used in schools and at the workplace. Given the country's multicultural background and Asian cultural setting, coupled with English fluency, we postulated that there would be a preference for PFL among caregivers and medical professionals and an IFL preference among autistic individuals. **Objectives:** The primary aim of this study was to understand preferences regarding language use within the autism community in Singapore. **Methods:** An anonymous online survey was sent out to adults on the autism spectrum, their caregivers, and professionals working in the field of autism. The survey comprised questions related to terms to describe autism, its symptoms, and areas of need. Respondents were asked to rate each term/phrase from 1 (uncomfortable/I do not like this term) to 7 (very comfortable/this would be my preference). **Results:** 229 individuals answered the survey (185 (80.7%) females, ethnic distribution reflective of national distribution). Respondent types comprised 29 (12.7%) autistic individuals (AI), 63 (27.5%) caregivers/relatives (CR), and 137 (59.8%) professionals (P). Examples of preferred terms (mean $\pm$ SD Likert score) when describing autism included autism rather than autism spectrum condition/disorder (5.82 $\pm$ 1.51 vs 3.96 $\pm$ 2.02, $p<0.001$), special interests rather than obsessions (5.54 $\pm$ 1.67 vs 3.01 $\pm$ 1.99, $p<0.001$), and challenging behaviours rather than problem behaviours (4.45 $\pm$ 1.91 vs 2.63 $\pm$ 1.77, $p<0.001$). There were multiple significant differences in language preferences between respondent types (AI, CR or P), but much less so between respondent gender, ethnic group, or age group. For example, AI did not prefer 'symptoms' of autism, or 'person with autism/ASD', whereas CR/P rated them much higher. **Conclusions:** While some language preferences in the Singapore population appear similar to those in Western populations, we need to be particularly cognizant of and sensitive to varying preferences between those with lived experience versus professionals. Improved use of terminology by considering cultural and demographic factors can facilitate better inclusion and acceptance of neurodiversity. Future research can deepen our understanding of the impact of language on identity, inclusion, and mental health in the autism community. Broadening the scope of respondents to include more children, non-verbal/speaking autistic individuals, and those from diverse racial, ethnic, and socio-economic backgrounds which are often underrepresented is critical in fully understanding the implications of language use.

401.017 A Synthesis of Caregiver-Implemented Ndbis for Culturally and Linguistically Diverse Children on Autism Spectrum
Y. Noh¹ and **L. H. Hampton²**, (1)Early Childhood Special Education, University of Texas at Austin, Austin, TX, (2)The University of Texas at Austin, Austin, TX

Background: Caregiver-implemented Naturalistic Developmental Behavioral Interventions (NDBIs) have proven effective in enhancing social communication skills in autistic children. However, the majority of research focuses on English-speaking, moderate-high income, and white caregivers, highlighting the need to address cultural and linguistic diversity in these interventions. **Objectives:** The purpose of this synthesis is to examine the effectiveness of caregiver-implemented NDBIs (CI-NDBIs) for autistic children from various cultural and linguistic backgrounds. To understand NDBI implementation by caregivers of autistic children, this synthesis aims to address the following research questions. **Research Question 1:** Are culturally adapted CI-NDBIs effective for improving caregiver implementation of core strategies? **Research Question 2:** What cultural adaptations have been implemented to address the needs of families from diverse cultural and linguistic backgrounds, and do these align with the recommendations for culturally adapting interventions? **Methods:** A systematic literature search was conducted that included several methods. First, an electronic database search was conducted using the following four databases: Education Source, ERIC, MEDLINE, and PsycINFO. The cultural adaptation checklist was derived from Lee et al. (2023) to examine seven domains: language, persons, content, goals, methods, context, and process to see whether the studies met the cultural needs of participants from diverse cultural and linguistic backgrounds. **Results:** The synthesis includes 10 studies from six countries, showing that these interventions improve autistic children's social engagement and communication, reduce parental stress, and enhance intervention fidelity and validity. **Conclusions:** While efforts have been made to study culturally adapted interventions for autistic children, much progress is still needed. The findings highlighted the importance of further research on cultural adaptations to improve the effectiveness of NDBIs for diverse populations. Specifically, the discussion emphasized the need for developing diverse assessment tools and integrating NDBI skills into daily routines, rather than focusing solely on play-based activities. Future research on caregiver-implemented NDBIs should prioritize cultural adaptations that consider the linguistic, contextual, and cultural backgrounds of participants, with an emphasis on collaboration with community partners. Moreover, comparing culturally adapted interventions with traditional implementations is essential for identifying the specific elements of cultural adaptations that contribute to more significant outcomes.

401.018 A Systematic Review of Psychosocial Interventions to Reduce Parenting Stress and Strain Among Caregivers of Autistic Children
S. M. Brunt¹, **M. Menezes²**, **J. E. Pappagianopoulos³**, **J. V. Smith⁴**, **M. Howard⁵**, **E. Sadikova²**, **M. Mazurek²** and **L. Witte²**, (1)University of Virginia School of Education and Human Development, Charlottesville, VA, (2)University of Virginia, Charlottesville, VA, (3)Clinical and School Psychology, School of Education and Human Development, University of Virginia, Charlottesville, VA, (4)Children's National Hospital, Rockville, MD, (5)Department of Human Services, University of Virginia, Charlottesville, VA

Background: Parents of autistic children experience high levels of parenting stress, which has a maladaptive transactional relationship with child emotional and behavioral problems. Most autism-specific interventions focus on modifying child behaviors, with parenting stress included as a secondary outcome, if at all. Previous research on interventions to specifically reduce parenting stress is mixed, and wide heterogeneity in study design and intervention modalities makes it difficult to parse apart which elements of interventions are effective at reducing parental stress.

Objectives: The aims of the review were to: a) examine the specific intervention ingredients that have been utilized in interventions aimed at reducing parenting stress/strain, and b) determine the efficacy of parent-focused interventions in reducing parenting stress/strain and discuss factors that may impact the efficacy of interventions.

Methods: A thorough database search of empirical articles evaluating parent-focused interventions designed to reduce parenting stress or strain among parents of autistic children was conducted. Inclusion criteria included a) publication in a peer-reviewed scientific journal, b) an intervention was implemented and tested, c) participants were parents of autistic children up through age 18, and d) parent stress/strain/burden was a primary outcome and was evaluated using a validated measure during the pretest and posttest timepoints (at minimum). Studies that included direct therapeutic involvement with the child by a professional and studies that had parent variables as a secondary outcome were excluded. Articles that met the inclusion criteria were reviewed and relevant data was extracted. Data extracted included demographics, study design, session format (in-person/virtual/hybrid), intervention modality (group/individual/mix), length of sessions and overall intervention duration, intervention components, measures used, analytic plan, and results.

Results: The search yielded 37 articles which met inclusion criteria and were included in the review. The interventions varied widely in terms of format, study design, and the therapeutic elements included. Group-based interventions were most common (19), followed by individual (13) and interventions with a mix of group and individual sessions (5). The most commonly used therapeutic element was psychoeducation (used in 21 interventions), followed by behavior management strategies (16), cognitive/coping strategies (15), relaxation/mindfulness/stress reduction techniques (14) and support/discussion with other parents (14). Thirty-one of the 37 interventions reported at least a partially significant reduction in parent stress/strain. Study settings were diverse, with 16 countries represented.

Conclusions: Due to heterogeneity in study settings, it is difficult to draw broad conclusions about the effectiveness of specific intervention components. The pattern of results suggests a potential hierarchy of needs based on the existing resources, where parents are in their journey, and areas of need in the community in which the intervention is implemented. For example, psychoeducation and social support may be more impactful for parents from low-resource areas or parents of newly diagnosed children, whereas cognitive/coping strategies or relaxation/mindfulness training may be more appropriate for parents who have already had those more basic needs met. Researchers and clinicians providing interventions should consider the culture and needs of the community of interest and work with parents to determine whether an offered intervention will fit with their unique needs.

401.019 A Vignette Based Study of the Effect of Dehumanizing Autism Research on Neurotypical Peoples Attitudes Towards Autistic People

M. Botha¹, C. Rutledge², T. M. Burns³ and A. Pearson⁴, (1)Psychology, Durham University, Durham, Durham, United Kingdom, (2)Psychology, University of Stirling, Stirling, North Lanarkshire, (3)University of Stirling, Stirling, United Kingdom, (4)Psychology, University of Durham, Durham, United Kingdom

Background: Dehumanization can involve a denial of human unique traits (those which separate us from robots) and human nature traits (those which are said to separate us from other non-human animals) (Haslam, 2006), infrahumanization (the denial of more complex emotional states (Leyens, 2002)), or overt dehumanization whereby a group of people are considered literally less evolved (Kteily, et al 2017).

Autism research has been said to be dehumanizing (Botha, 2021; Gernsbacher, 2007; Rose, 2020), and previous mixed-method research showed that autism researchers have a propensity towards dehumanizing autistic people, in particular denying agency, subjectivity, action, and complex emotion. Non-autistic adults have been shown a propensity towards denying autistic people human unique traits, thus displaying an animalistic dehumanization of autistic people. Little research to date, has focus on research as a potential source of this dehumanization which helps to form or sustain these negative attitudes.

Objectives: Considering this, the aim of this research was to identify whether dehumanizing rhetoric in autism research influences the attitudes of non-autistic adults towards autistic people.

Methods: Vignettes were created based on peer-reviewed autism research, with a particular aim towards creating a vignette based on dehumanizing autism research, and a vignette based on more humanizing peer-reviewed research and administered to 149 neurotypical people in the US and the UK, who were 18+ with participants recruited through prolific. Participants were paid roughly £9 an hour. Any mentions of autistic people or autism were redacted from the vignettes to prevent triggering pre-existing biases. These vignettes were administered in a repeated measures design, and participants were asked to rate measures of human uniqueness, human nature, infrahumanization, and overt dehumanization. We included a manipulation check to identify if anyone could identify the group. The study was pre-registered. The study was piloted with 10 participants to ensure the vignettes were interpretable.

Results: The targets in the dehumanizing vignette were rated as having lower human nature traits ($t(148) = -4.02, p < .001$), lower human unique traits ($t(148) = -1.92, p < .02$), lower down the ascent of human scale demonstrating overt dehumanization ($t(140) = -13.3, p < .001$), lower complex secondary emotion capability compared to both primary emotion capability ($t(148) = 6.10, < .001$), and the secondary emotion capability of the humanizing vignette ($t(148) = -9.35, p < .001$) – an effect that was not seen in the humanizing vignette for differences between primary and secondary emotions ($t(148) = .178, p > .05$). Most participants did not guess who the vignettes were about, but content analysis of the manipulation control check further illustrates the dehumanization, with participants wondering whether the information in the dehumanizing vignette was “even human”.

Conclusions: These results point towards there been a potential translation dehumanization from research to public attitudes. Future research should replicate the study newspaper mention of autism research which tend to be the translation tool between the academy and the public.

401.020 Achieving Competitive Integrated Employment through Industry-Aligned Robot Operator Training and Certification for Adults with ASD Receiving Lanterman Act Services in California

O. Solomon^{1,2}, S. K. Gupta³, A. Deavenport-Saman^{2,4}, J. Gregor⁵, I. Rosenberg⁶, M. Bastine⁶, A. O. Martin⁴, I. Franklin⁴, C. Ashe⁴, J. Morrow⁷ and L. Yin^{2,4}, (1)CHLA USC UCEDD, Los Angeles, CA, (2)Keck School of Medicine of USC, Los Angeles, CA, (3)Aerospace and Mechanical Engineering; Thomas Lord Department of Computer Science, University of Southern California, Viterbi School of Engineering, Los Angeles, CA, (4)Children's Hospital Los Angeles, University Center for Excellence in Developmental Disabilities, Los Angeles, CA, (5)Workforce and Economic Advancement, College of the Canyons, Santa Clarita, CA, (6)Uniquely Abled Project, Valley Village, CA, (7)Jay Nolan Community Services, Mission Hills, CA

Background: Successfully deploying robots in automation and advanced manufacturing is critical for the U.S. economy, yet it experiences a shortage of skilled workers. Individuals with ASD have not been sufficiently employed in robotics despite possessing skills such as attention to detail and tolerance of repetition.

Objectives: A 6-week industry-aligned training program was developed and pilot-tested at a community college to prepare fourteen (14) adults with ASD ages 18 to 40 years old who had a high school diploma or a GED certificate for entry level robot operator jobs.

Methods: North Los Angeles County Regional Center facilitated outreach and recruitment, and provided employment support to the participating Lanterman Act services-eligible adults with ASD. Based upon the Uniquely Abled Project's model (<https://uniquelyabledproject.org>), a technical training program for adults with ASD was developed and carried out at College of the Canyons (COC), a community college in north Los Angeles County. The training consisted of the robotics curriculum in two modes of presentation, standard and in 'plain language'. A comprehensive industry-aligned robotics curriculum combined the Tooling U / Society of Manufacturing Engineers (SME) and Universal Robots (UR) content and provided an entry-level foundation for jobs in automation and advanced manufacturing. A soft-skills training and professional preparation component taught by an employment services agency was also part of the program. Prior to the full implementation at COC, elements of the curriculum were piloted with five participants with ASD who learned to carry out increasingly complex hands-on programming tasks with a UR10e robotic arm. Family support groups were held twice during the training to share family members' experiences and discuss strategies to support the trainees.

Results: All 14 trainees completed the program and 13 (93%) achieved industry-standard certification in Tooling U / SME and UR content and hands-on skills. Despite securing certifications, 5 trainees who sought employment and job placement services post-program did not secure employment due to geographic distance from available jobs and limited number of local companies offering entry-level robot operator jobs. Nine remaining trainees chose to participate in an additional 12-week training course in computer numerical control (CNC) machining. Of these, 7 (78%) secured a position: 5 were hired in full-time entry-level jobs and 2 gained an apprenticeship placement anticipated to lead to permanent employment. Post-program, the trainees who secured employment or apprenticeships developed new friendships and gained confidence in their abilities, leading to an improved quality of life.

Conclusions: Adults with ASD have significant capabilities to learn and be certified in comprehensive industry-standard knowledge base in robotics, with 13 out 14 trainees completing the program with Tooling U / SME and UR certifications. Having completed the fast-track robot operator training and additional CNC machining training, 7 (50%) trainees gained full-time employment or apprenticeship positions in advanced manufacturing. The employed trainees developed social skills that resulted in friendships and increased social confidence. Adults with ASD have demonstrated a significant potential for competitive integrated employment in automation and advanced manufacturing. Industry collaboration is needed to increase access to high-wage jobs for adults with ASD.

401.021 Adaptation and Piloting the Caregiver Skills Training (CST) Program in Western Province, Sri Lanka

P. Dolawaththa¹, H. Yasora¹, V. S. Thebuwana¹, R. Haggapola Arachchi¹, B. Fernando², D. V. Vipulaguna³ and **A. Hewamalage**⁴, (1)Sri Lanka College of Paediatricians, Colombo, Western, Sri Lanka, (2)Sri Lanka College of Paediatricians, Colombo, Western, Sri Lanka, (3)Ministry of Health, Sri Lanka, Colombo, Western, Sri Lanka, (4)Namaste Sri Lanka, Colombo, Western, Sri Lanka

Background:

The World Health Organization launched the WHO Caregiver Skills Training (WHO CST) program, designed for caregivers of children aged 2 to 9 years. Initially developed in English, the CST includes evidence-based interventions to support both children's behavior and caregiver skills. The CST needed to be translated and adapted to local languages for implementation during the NAMASTE project in Sri Lanka (www.namastesl.com), and we developed a Sri Lanka-specific CST package based on this requirement. The adaptation goals are to ensure the program content is understandable, culturally acceptable, and relevant to regional participants.

Objectives:

To describe the process of adaptation and piloting to assess the feasibility of the CST program in Western Province, Sri Lanka

Methods:

Adaptation and piloting were done as an iterative process: the adaptation process began with the translation of CST materials by a panel of experts in both language and technical aspects, followed by a review by a Translation Committee. The translated documents were used in focus group discussions carried out with the participation of 12 caregivers of children with developmental delays and 45 healthcare professionals involved in the care of children with autism and Neurodevelopmental conditions (NDDs). The participant guides were modified based on input from caregivers, while facilitator and home visit guides were adapted using feedback from the healthcare professionals. The developed guides were piloted in a group including 10 caregivers, 2 facilitators, and 2 observers. The guides were finalized using data from the focus group discussions, the pilot phase, and the observer notes from the CST master trainer and special facilitators. We used deductive thematic analysis based on the Bernal theoretical framework (Bernal et al., 1995).

Results:

Feedback from caregivers and other stakeholders highlighted the need for several enhancements such as the lack of appropriate Sinhala words for certain English words (ex: feedback) and some symbols being unfamiliar in the Sri Lankan context (ex: a teacher would usually be shown wearing a sari in Sri Lanka). Pilot results indicated that participants found the CST program acceptable and relevant to their needs. However, they suggested specific improvements, including shortening the duration of group sessions, increasing the frequency of home visits, and incorporating more practical sessions. Caregivers noted that the delivery of the CST pre-pilot was satisfactory, but stressed the importance of selecting a specialized trainer for CST delivery—preferably someone with maturity and knowledge about children.

Conclusions:

The findings of this study suggest that the CST program in lower- and middle-income countries should be expanded and subjected to additional evaluation in realistic community environments.

401.022 Adapting the City to the Specific Sensory Needs of Autistic People: A Participatory Research Approach

M. Pieron¹, F. Berland², A. Lacroix³, G. Widmer⁴, M. H. Audier⁵, N. Dollion⁶ and S. Chokron⁷, (1)INCC UMR8002, CNRS, Université de Paris, Paris, Ile-de-France, France, (2)Campus Urbain Grand Orly Seine Bièvre, Ivry-sur-Seine, Ile-de-France, France, (3)Campbell Family Mental Health Research Institute, Centre for Addiction and Mental Health, Toronto, ON, Canada, (4)Self-advocate, Tours, Centre-Val-de-Loire, France, (5)APESA, Saint-Paul-trois-Châteaux, Rhone-Alpes, France, (6)C2S UR6291, Université de Reims Champagne-Ardenne, Reims, Grand-Est, France, (7)Hôpital Fondation Adolphe de Rothschild, Paris, Ile-de-France, France

Background:

Cities are spaces in which our senses are particularly engaged: vehicle noise, light reflections on glass surfaces, illuminated signs, food odors and more.... For people with atypical neurological or sensory functioning, such as autistic individuals, the intense sensory stimulation present in urban environments can make cities overwhelming, limiting their autonomy and quality of life.

Objectives:

The aim of this study is to identify the micro-designs of public space that are favorable and unfavorable to people with autism, based on their experiential knowledge.

Methods:

During the initial phase, this participatory project was designed by a consortium of researchers, autistic people, clinicians, and local authority representatives, all of whom were involved in decision-making throughout the project's stages. After receiving ethical approval, the first stage consisted of semi-structured interviews conducted with 20 autistic adults and 20 professionals who work with them on a daily basis (e.g., specialized educators, psychologists). Participants were asked to express their experience of the city, based on photographs of the urban environment (streets, crosswalks, benches). In the second stage, five design thinking workshops were held with local authority staff (road planning, accessibility), organizations, and autistic people, to present the results and foster the collaborative development of solutions, using the various expertise, to make the city more accessible.

Results:

Overall, urban designs of cities are often a significant source of fatigue, physical discomfort or pain, anxiety, and even distress for autistic people. However, micro-designs modifications in public spaces can improve their experience autonomy. Findings showed that sidewalks should be sufficiently wide, with clear traffic-flow rules and indicators, visually-defined boundaries with the roadway, shaded, and not cluttered on the ground. Crosswalks should follow a standardized structure to facilitate identification and use. Vehicles and bicycles' speeds should be reduced. Finally, the incorporation of quiet areas, plants, or water features (fountains, streams) can improve the urban experience for autistic people. The presence of dogs was also identified as an area of interest for some autistic people and warrants further exploration.

Conclusions:

Reducing sensory stimuli to those useful for interaction with urban environments can help limit sensory overload. Physically structuring public spaces to account for visual function deficits and vestibular particularities, along with the creation of recuperation areas through increased natural elements, and clearly defined public space usage rules would improve the autonomy of autistic people. Only a participatory approach involving the voices of autistic people and professionals can gather this type of information, which comes under the heading of user expertise. Future perspectives include testing the effect of these micro-adaptations on the behavior and well-being of autistic people during their regular walk but also better characterizing the neurovisual and vestibular disorders that have an impact on the urban experience of autistic people.

Cities are rich in stimuli that are often poorly adapted to the atypical functioning of autistic people. However, simple solutions can be implemented to enhance walkability, autonomy and overall well-being for neurodivergent individuals in urban environments

401.023 Addressing Latino Disparities in Autism Via Culturally Responsive Support Groups

K. Guerra¹, K. Pickard², S. Valladares Ortiz³, M. Sarith Valdivia Acosta² and M. DuBay⁴, (1)CHOA- Marcus Autism center, Atlanta, GA, (2)Emory University School of Medicine, Marcus Autism Center, Atlanta, GA, (3)Marcus Autism Center, Children's Healthcare of Atlanta and Emory University School of Medicine, Atlanta, GA, (4)University of Virginia, Charlottesville, VA

Background: Persistent racial and ethnic disparities in obtaining an autism spectrum disorder (ASD) diagnosis and services have been documented for Spanish Speaking (SS) Latino children and other racial/ethnic minorities (Luelmo, Kasari, & Fiesta Educativa Inc., 2021). SS Latino children with ASD from Spanish-speaking homes face a myriad of unique challenges and inequities in education and healthcare. For example, when SS Latino children are diagnosed, they are more likely to have co-occurring intellectual disability. Following diagnosis, SS Latino children and their parents receive fewer evidence-based treatments and less medical specialty care than non-Latino White counterparts (Zuckerman, 2020). The goal of this abstract is to describe the outcomes of a research project that developed and evaluated autism support groups for SS Latino parents of autistic children when delivered by culturally and linguistically responsive facilitators.

Objectives: 1) Examine feasibility and acceptability of SS facilitator led autism support groups 2) Identify parental benefits and perceived barriers of autism support groups 3) Understand parents' experiences in participating in autism support groups via exit interviews

Methods: 13 SS Latino parents of children with ASD (ages 2-19) were recruited from two ongoing Spanish-language autism support groups. Families participated in virtual support groups facilitated by a SS Latina speech-language pathologist and SS Latina parent facilitator. One support group met weekly for 60-minute sessions over the span of 2 ½ months (10 sessions). A second support group met once a month for 60-minute sessions, for a total of 10 months (10 sessions). Both groups provided parents with education on autism basics, service navigation, developing routines, sleep, bilingualism, and self-care. Parents completed empowerment and social support measures at pre and post time points with the option of completing an exit interview regarding their experiences in the support group. Paired samples t-tests were used to evaluate changes in parents' self-efficacy and social support during group participation. Exit interviews were transcribed and coded by bilingual speakers using thematic analysis.

Results: Parents reported high satisfaction with the virtual caregiver groups (M=94.6%). Additionally, parents indicated significantly higher self-efficacy supporting their child after participation in group (p=0.08). Qualitatively, participants noted that the presence of a SS Latina facilitator and other SS Latino parents was important and fostered cultural identity and support. Parents revealed that having sessions in Spanish facilitated their learning and connection to other parents. Despite having children with different needs, parents found shared experiences helpful in anticipating future challenges, navigating institutional systems, and advocating for appropriate autism related services.

Conclusions: This study highlights the need to address disparities in autism care for SS Latino families by developing culturally responsive autism support groups. Findings following exit interviews and post study measures revealed parental increased knowledge regarding ASD service navigation and accessibility. Additionally, parents reported high satisfaction with virtual Spanish led groups and emphasized the need for more accessible and culturally responsive care in other settings and across the autism lifespan.

401.025 All Stakeholders Engaged in Research Together (ASSERT): Envisioning Future Research

S. N. Brasher¹, M. Johnson¹, L. S. Coleman², S. Furukawa³, K. Fitzpatrick³ and B. A. Malow⁴, (1)Nell Hodgson Woodruff School of Nursing, Emory University, Atlanta, GA, (2)Marcus Autism Center, Children's Healthcare of Atlanta & Emory School of Medicine, Atlanta, GA, (3)Vanderbilt University Medical Center, Nashville, TN, (4)Sleep Disorders Division, Department of Neurology, Vanderbilt University Medical Center, Nashville, TN

Background: Too often in the autism and intellectual and/or developmental disabilities (IDD) community is research being done for them, but without them. This is particularly more common for those with higher support needs. Recently, a paradigm shift has begun to occur that calls for the intentional and equitable engagement of all stakeholders to be involved in research. However, tailored approaches are needed to ensure equitable engagement and collaboration among different stakeholders, most importantly individuals themselves in the autism and/or IDD community.

Objectives: The objective of this study was to build capacity within the autism and more broadly IDD community to foster engagement and knowledge on patient-centered outcomes research (PCOR) and develop future research responsive to the needs of a diverse community.

Methods: Stakeholders (n=52), including autistic adults, individuals with IDD not on the spectrum (e.g. Trisomy 21, Spina Bifida, Tourette Syndrome), clinicians, caregivers, and researchers, engaged in an online bidirectional learning community (All StakeholderS Engaged in Research Together/ASSERT) twice monthly for six months through the Project Extension for Community Healthcare Outcomes (Project ECHO) model. Sessions lasted 90 minutes and included: Introductions, Topic overview, Small group breakout sessions, Larger group share, and Lightbulb moments. Anonymous baseline surveys were completed by all participants (n=52) to determine previous experiences in research and the extent to which they felt valued, heard, and trusted in the research process. Following each of the twelve sessions, participants completed an anonymous survey to assess changes over time. Pre/post results were matched on an individual and stakeholder level. A regional advisory board (n=15) consisting of autistic and/or IDD individuals, as well as other stakeholders met quarterly to provide oversight to the project. Participants were recruited using snowball sampling through national networks.

Results: Results of the twelve pre- and post-session surveys were analyzed using R statistical software. Due to the non-parametric nature of Likert scale surveys and the relatively small sample, a Wilcoxon signed-rank test with continuity correction was employed to assess overall significance of pre/post session survey responses based on paired observations. Further Wilcoxon tests were conducted to compare significance between groups (researchers or non-researchers). Significance was observed (< .05) for each of the questions from pre/post session surveys. Pre-session results showed "slight confidence" and "very little confidence", whereas participants after undergoing the ASSERT online community shifted towards "very confident" and "highly confident" responses. Survey constructs targeted concepts such as "understanding informed consent", "identifying types of research", "knowing ways to share (disseminate) research", "Understanding what patient-centered means", and "co-creating research together", among others. Other survey metrics showed stakeholders felt heard (99.4%, N=329), valued (99.4%, N=329), and meaningfully engaged (96%, N=329).

Conclusions: Outcomes of this project included enhanced capacity building among autistic and IDD individuals and other stakeholders through multidirectional learning using an ECHO model. As a result, all individuals expanded knowledge and awareness of ways to build inclusive research that can position our team of patients and stakeholders towards future research to improve outcomes for autistic and IDD individuals.

401.026 An Example of Co- Developing Tools to Support Neurodivergent Needs and Promote Person- Centred Approaches in Autism Research: The Intellectual Disabilities and Autism Working Group

K. Van den Bosch¹, M. L. Law², A. San Jose Caceres³, S. Douglas⁴, M. Doherty⁵, E. Tilkin-Franssens⁶, A. Ghosh⁷, R. Holt⁸, A. Lautarescu⁹, J. R. D. Plas¹⁰ and J. Cooke¹¹, (1)AIMS-2-Trials Autism Representative, Vigo, Pontevedra, Spain, (2)Forensic and Neurodevelopmental Sciences, King's College London, London, United Kingdom, (3)Hospital General Universitario Gregorio Marañón, Madrid, Spain, (4)Autistic contributor, Bristol, UK, (5)Neuroscience, Brighton & Sussex Medical School, Brighton, United Kingdom, (6)KU Leuven, Leuven, Belgium, (7)Department of Child and Adolescent Psychiatry and Psychotherapy, Central Institute of Mental Health, Mannheim, Mannheim, Germany, (8)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, United Kingdom, (9)King's College London, London, United Kingdom, (10)AIMS-2-TRIALS A-Rep, University of Cambridge, Cambridge, United Kingdom, (11)Forensic and Neurodevelopmental Sciences, Kings College London, Insititue of Psychiatry, Psychology & Neuroscience, London, United Kingdom

Background:

Only 6% of UK research participants have an Intellectual Disability (ID), despite 9 in 10 autistic people and their families expressing they want to take part in research (Autistica. (2020); Autistica, n.d.). Participating in research can be a frightening experience for neurodivergent people with different communication and sensory needs that are not well accommodated for by traditional research practices. Therefore, more should be done to cater for these specific needs of neurodivergent participants in research settings, thus addressing current gaps in representation. We have established a participatory working group (WG) known as the ID & autism WG (IDA WG), which brings together stakeholders and researchers with the goal of co-producing tools to better support neurodivergent needs in research.

Objectives:

To address communication barriers that may prevent research engagement, we have co-developed a Research Passport specifically targeted at autistic persons with ID. The objective of the Passport is to allow the participant to communicate his/her needs and preferences prior to their research visit. Researchers can then effectively plan the visit as well as engage in open supportive discussions with the family, caretakers or participant around comfort and involvement. Implementation of the Passport in research settings moves us towards a more person-centred research approach for people with complex support needs. In this way, their needs are prioritised to enhance engagement and promote superior data quality.

Methods:

An initial version of the Research Passport was co-created by a sub-group of members from the IDA WG, combining aspects of existing available resources in autism and ID respectively (Ashworth et al. 2020, Kidney & McDonald, 2014). We then shared a draft version with the wider IDA WG for feedback on content and structure before a beta version was ready for piloting with research participants. The beta version of the Research Passport was subsequently translated into Spanish for use by colleagues in Madrid. Autism representatives were included in every stage of the design and piloting of the passport, ensuring this project was co-produced from start to finish.

Results:

The Research Passport is currently being piloted within studies at King's College London and The Instituto de Investigación Sanitaria Gregorio Marañón, Madrid. Researchers are collating open-ended feedback from participants and families/caretakers on the content, structure, utility, and perceived helpfulness of the Passport. Anecdotal feedback from researchers on the same aspects are also being recorded. Over the next few months, we hope to collate this information to further refine the tool.

Conclusions:

Our Research Passport for persons with autism and ID is currently available online as a printable document for researchers or allied professionals. Tools such as this, can provide valuable support not only for participants and their families/caretakers, but also for researchers who want to accommodate a more diverse range of needs in their research studies. We hope that by designing and distributing tools such as the Passport, we can promote a more person-centred approach to conducting research that enables those with complex support needs to be better represented in research settings.

401.027 An Exploratory Study of Inclusive Practices within the Scottish Police Force

C. Ballantyne¹ and K. Gillespie-Smith², (1)Department of Psychology, University of the West of Scotland, Paisley, United Kingdom, (2)Department of Clinical Psychology, University of Edinburgh, Edinburgh, United Kingdom

Background: It is not uncommon for an autistic person to come into contact with the criminal justice system (CJS), either as a victim (eg Lindblad & Lainpelto, 2011) or a suspect (Woodbury-Smith & Dein, 2014). Therefore it is necessary that the Police have relevant training, knowledge and awareness of autism and the associated behaviours to allow for inclusive practices and work under an appropriate neurodivergent framework. There is a dearth of research about the interactions which Scottish police currently have with autistic people, and international findings cannot be generalised to police forces with different training and organisation (Gibbs & Haas, 2020; Slokan, 2019).

Objectives: The present study builds on the survey method used by Crane et al. (2016) within the Scottish policing service. Additionally, it elevates the autistic voice in the production of knowledge by appreciating the experience of both autistic people and police officers (Bagatell, 2010; Milton, 2014a).

Methods: Three online surveys (one for police, one for autistic adults, and one for caregivers) were produced to elicit data about experiences of autism and policing. Most questions had forced multiple-choice options but open-ended text boxes were included throughout for participants to elaborate on their responses. The content of the surveys was similar, but questions differed where appropriate to match the participant group (e.g. only autism community members had to confirm their clinical diagnosis and only police were asked for their perspectives on training needs). The surveys probed the following topics: (1) Demographic Information, (2) Nature of Police/ Autistic Encounters, (3) Autism Diagnosis Disclosure, (4) Meeting Autistic Individuals' Needs.

Results: 44% of officers found that meeting the communication needs of autistic individuals difficult when conducting interviews, with little knowledge of aspects such as sensory difficulties. Overall, only 35 % of officers were satisfied with how they had worked with autistic individuals. Officers cited lack of skills, training, which is often only given to those who are high ranking, and awareness as barriers to inclusive practice, along with inappropriate facilities and time constraints. When a disclosure of the individual's autism diagnosis was made to a police officer, 100% of officers reported that this 'always' or 'sometimes' happened prior to, or during, first contact. The autistic individual's diagnosis was most frequently disclosed by the autistic individual's parent/ caregiver (always = 21.9%; sometimes = 78.1%) or by themselves (always = 6.7%; sometimes = 80%). Autistic adults and caregivers were most unsatisfied with treatment on first encounter (41.2% and 70%) and the explanation they received about the investigation process (41.6% and 72.8%), but autistic adults were mostly satisfied with their treatment by police interviewers (57.1%). A thematic analysis of the open text data revealed themes of Identifying & understanding autism, Catering for needs, Adequacy of training and Mistrust of Police.

Conclusions: The study highlighted a need for appropriate training to be given to all Scottish Police Officers regardless of rank in order for the development of police strategies for effective engagement and inclusion of autistic individuals within the Scottish CJS.

401.028 An Investigation of the Views of Parents of Autistic Students Who Have Experienced School Exclusion

T. Zeltic¹, F. Happe² and L. Crane³, (1)Institute of Psychiatry, Psychology and Neuroscience, Kings College London, London, United Kingdom, (2)Social, Genetic and Developmental Psychiatry Centre, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, UNITED KINGDOM, (3)University of Birmingham, Birmingham, Birmingham, United Kingdom

Background:

Autistic students experience higher levels of school exclusion than their neurotypical peers (Adams, 2022; Guldberg, Wallace, Bradley, Perpa, Ellis & MacLead, 2021). School exclusion has an adverse impact on autistic students' future educational and social outcomes, rendering them disempowered and isolated.

Objectives:

The aim of the current study is to explore the views of the parents of autistic students who have experienced school exclusion in secondary schools in the UK.

Methods:

We conducted semi-structured interviews with 16 parents of autistic students (aged 12-17 years) regarding their children's school experience which led to school exclusion and other forms of school non-attendance. Using Frasier's (2004) seven phases of narrative analysis, we found seven subthemes that dominated through 80 narratives that we constructed.

Results:

Seven subthemes were compared for commonalities and grouped into four categories: Downward Spiral, Breakdown of the School placement; School non-attendance, and Positive Outlooks. Through narrative analysis, we found that despite the struggles their children experienced in secondary schools, the parents recognized their children's strengths and were hopeful regarding their children's futures.

Conclusions:

This study has found that inflexibility of school environments and school staff often leads to school exclusion of autistic children. The complexities of secondary school social and academic expectations contribute to deterioration of mental health of autistic students. In addition, late diagnosis was recognized as another contributing factor that made the school life of autistic students exceptionally difficult. This study has important implications for educators and policy makers regarding listening to autistic community to better engage autistic students in education which will positively impact their future prospects.

401.029 Analyzing and Studying Videos from an Autistic Infancy during Autistic Adulthood

J. M. Williams, Wisconsin's Community of Practice on Autism Spectrum Disorders and Developmental Disabilities, Northbrook, IL

Background: I am an autistic adult who was born in 1988. From birth to 18 months of age, I was a participant in a research study that was conducted by Mitchell Batavia, who was a graduate student at the time (who would eventually obtain a Ph.D. in Physical Therapy/Pathokinesiology) studying typical infant development. Using myself as a case study, I was filmed from 1988 to 1990 as a part of his research, which chronicled my development in infancy, and included interviews with my parents, who shared observations about my development with Mr. Batavia while he conducted his research. When Mr. Batavia was studying my development, he was under the impression that he was studying a typically developing infant. Unbeknownst to him, I was actually displaying telltale signs of autism from birth (though to be fair, those signs were not widely known by autism professionals back then). Two years later, I was formally diagnosed with autism at the age of 3. 28 years later, in adulthood, I converted the video footage that was filmed by Mr. Batavia into a digital format. When viewing this footage with today's knowledge of autism development in early childhood, it clearly shows that I was displaying telltale signs of autism from birth.

Objectives: To share clips from this footage, display how the symptoms I displayed in infancy were not acknowledged by my parents and the researcher at the time of filming, and describe how the symptoms displayed foreshadowed many issues I have lived with as an autistic person throughout my life. My ultimate goal is to continue to share this video footage in order to support further autism research in early childhood. This presentation will present the footage in the style of the TV show "The Wonder Years."

Methods: I have shown these videos to professionals and researchers in the field of autism, while at autism conferences across the United States, via formal presentations, networking events, and personal communications while at those autism conferences. I have also shared copies of these videos to autism professionals, with the hopes they can be studied further.

Results: Every professional and researcher in the field of autism I have shown clips of this video footage to, in the present day, has been able to identify telltale symptoms of autism, from the first video that was filmed shortly after birth to the final video that was filmed when I was 18 months old.

Conclusions: Although diagnosticians are currently not encouraged to diagnose autism in children until they are at least 2 years old, a growing amount of research has proven that many autistic individuals start displaying symptoms of autism and/or telltale signs of developing autism from birth. Many of these symptoms can predict the issues autistic people may face later in life, and video footage of infants who were diagnosed with autism later in life routinely demonstrate that telltale signs of autism often occurred at birth or in infancy.

401.030 Applying the Principles of Health Literacy and Social Media Literacy to Autism and Neurodiversity Messages on X (Formerly Twitter)

C. E. Freden¹, J. A. Choi² and E. Kang¹, (1)Department of Psychology, Montclair State University, Montclair, NJ, (2)School of Communication and Media, Montclair State University, Montclair, NJ

Background: Social media is a powerful means by which “real-time” data can be collected to gauge what people are talking about (Ohme et al., 2023), especially when it comes to “hot topics” like autism and neurodiversity. Autism is a lifelong neurodevelopmental condition which the Neurodiversity Movement recognizes as an essential byproduct of the neurological differences inherent in humanity (Kapp, 2020). Health literacy describes how people understand, utilize, and disseminate health information in basic, interactive, and critical ways (Nutbeam, 2000). Social media literacy (SoMeLit) is a recently developed framework that describes the requisite content and competencies for making sense of one’s social media engagement (Cho et al., 2024). Adding to emerging research examining autism-related discussion topics on social media (Edwards et al., 2024; Kim et al., 2022), this study applies the principles of health literacy and SoMeLit to the examination of messages pertaining to autism and neurodiversity on “X” (formerly Twitter).

Objectives: This study sought to explore what X users are talking about regarding autism and neurodiversity, and to interpret these findings through the lenses of health literacy and SoMeLit.

Methods: A total of 11,978 messages were collected from X between January-March 2024 using the Postman Twitter API v2 Recent Search “Get” endpoint (Postman & X, 2024). Keywords were a combination of “autism” or “autistic” or “asd” and “neurodiversity” or “neurodivergent” or “neurodiverse.” After data cleaning, 10,653 messages were analyzed using SAS Text Miner 15.3 (SAS Institute Inc., 2023) for topic modeling, resulting in four, five-word strings. Each string was manually inspected to translate the findings into user-friendly topics.

Results: The four topics generated by SAS are delineated in Table 1. The most prolific topic pertained to 1.) making sense of what “neurodivergent” means and how this relates to autism, including general statements about what neurodivergent and autistic people are like and allusions to experienced stigma. The other topics were 2.) hashtag campaigns, 3.) merchandise advertising (with a subset of messages discussing autistic children, not merchandise), and 4.) attempts to spread disinformation and obtain deceptive charity funds via “news” headlines.

Conclusions: Topic 1 messages and the Topic 3 subset of messages about autistic children suggest users’ attempts to understand autism and neurodiversity through questions, statements, and the sharing of lived experiences, actions that reflect interactive health literacy (Nutbeam, 2000) and SoMeLit’s “Evaluation” competency (Cho et al., 2024). Likewise, Topic 2 hashtag campaigns and Topic 3 merchandise advertising messages represent other ways to promote the visibility of autism and neurodiversity, reflecting critical health literacy (Nutbeam, 2000) and SoMeLit’s “Contribution” competency (Cho et al., 2024). The disinformation of Topic 4 could be viewed as a “test” of users’ functional health literacy (Nutbeam, 2000) and SoMeLit’s “Analysis” competency (Cho et al., 2024). Importantly, this study did not measure the accuracy or impact of messages, or users’ awareness of SoMeLit content domains (Self, Medium, Reality; Cho et al., 2024). It is essential that practitioners and researchers aim to equip the public with knowledge about autism and neurodiversity to foster individuals’ health and social media literacy.

401.031 Are Child Social-Emotional Competencies Protective in the Relation between Social-Emotional Behavior Problems and Parenting Stress in Children with Autism Characteristics?

S. Heath¹, A. S. Carter², L. B. Cunningham³, S. Broder-Fingert⁴, W. L. Stone⁵, R. C. Sheldrick⁶, B. R. Ingersoll⁷ and A. Wainer⁸, (1)University of Massachusetts Boston, Boston, MA, (2)Department of Psychology, University of Massachusetts Boston, Boston, MA, (3)Psychology, University of Massachusetts, Boston, Boston, MA, (4)UMASS Medical School, Boston, MA, (5)Psychology, University of Washington, Seattle, WA, (6)University of Massachusetts Chan Medical School, Worcester, MA, (7)Psychology, Michigan State University, East Lansing, MI, (8)Department of Psychiatry and Behavioral Sciences, Rush University Medical Center, Chicago, IL

Background:

Caregivers of autistic toddlers report greater parenting stress and mental health challenges than those raising non-autistic toddlers (Barroso et al., 2018; Schnabel, 2020). Further, autistic toddlers demonstrate elevated social-emotional behavior (SEB) problems and delays in SEB competencies compared to non-autistic toddlers (Reid et al., 2020). Caregiver parenting stress is associated with elevated SEB problems and delays in SEB competencies (Baker et al., 2003; Davis & Carter, 2008). Among caregivers raising autistic toddlers, SEB competencies can act as a protective factor in the relation between SEB problems and parenting stress (Huang et al., 2014). We examine the contributions of SEB problems and competencies to caregiver distress and caregivers' stress about interactions with their toddlers.

Objectives:

We hypothesize that SEB competencies will moderate the relation between BITSEA problem scores and parent distress and caregiver relational stress among caregivers and toddlers with autistic characteristics.

Methods:

Children (16-32 months) in Part C Early Intervention (EI) with social communication delays and their caregivers (n=208) participated in an ongoing community-based Hybrid Type I implementation/effectiveness trial of Caregiver Implemented Reciprocal Imitation Teaching. Caregivers identified children as non-Hispanic White (n=73), Black (n=39), Asian (n=11), Multi-racial (n=28), Hispanic White (n=32), or unknown (n=25). At baseline, caregivers completed the Brief Infant-Toddler Social and Emotional Assessment (BITSEA; Briggs-Gowan & Carter, 2006), a nationally normed screening tool for 12–36-month-olds, which was administered to assess SEB problems and SEB competencies. The Parenting Stress Index (PSI) (Abidin, 1990) is a widely used measure of parenting stress. Two scales are included in this report: Parenting Distress subscale (e.g., "I feel trapped by my responsibilities as a parent") and the Parent-Child Dysfunctional Interaction subscale (e.g., "my child smiles at me much less than I expected").

Results:

Results of a linear regression predicting to PSI relational stress indicated significant unique main effects for SEB problems and SEB competencies as well a significant interaction effect ($R^2 = 0.27$, $F(204) = 5.23$ $p = .23$). The model predicting to PSI parent distress indicated a significant main effect for SEB problems, no main effect for SEB competence, and a significant interaction effect ($R^2 = 0.11$, $F(204) = 8.74$ $p = .03$). To understand the clinical significance of the interaction, the levels of the two parenting stress measures were examined across four groups: No "Of Concern" BITSEA scores, "Of Concern" for problems only, "Of Concern" for competence only, "Of Concern" for both problems and competence. Caregivers with no "Of Concern" and "Of Concern" problem scores only showed similar levels of caregiver relational stress; however, "Of Concern" competencies and "Of Concern" scores for both impacted caregiver relational stress. In the model predicting to caregiver distress, SEB problems only appeared to increase distress when SEB competencies were also "Of Concern." (See Figure). Findings were replicated among toddlers who received an ASD diagnosis.

Conclusions:

As hypothesized, SEB competencies moderated the relation between SEB problems and both parenting distress and caregiver relational stress. These findings are consistent with competencies playing a protective role in the relation between child behavior problems and parenting distress, and relational distress.

**401.032 Asert: A Promising Model for Advancing Support for the Autism Community**

A. Layton¹, M. Sadowsky², M. Lubetsky³, R. Cramer⁴ and E. L. Saich¹, (1)Penn State College of Medicine, Hershey, PA, (2)A.J. Drexel Autism Institute, Philadelphia, PA, (3)WPIC of UPMC, Pittsburgh, PA, (4)UPMC, Pittsburgh, PA

Background: There are a range of adverse outcomes across the life course associated with an autism diagnosis, including lower quality of life scores, higher rates of comorbid physical and mental health conditions, and a significantly reduced life expectancy among autistic individuals compared to those without autism. Increasing community support and engagement, including access to resources, services, and employment and training opportunities may mitigate these adverse outcomes. For the past fifteen years, the Autism Services, Education, Resources, and Training (ASERT) Collaborative has been working to identify the needs of autistic individuals across Pennsylvania and improve access to quality resources, services, and data to support the autism community across the state. ASERT is a unique collaboration that brings together academic institutions and state government to develop practical research projects and community-focused efforts to support people on the autism spectrum, their families, and providers.

Objectives: To support the diverse needs of the autism community, their families, and support staff by implementing a diverse array of strategic goals, evaluation efforts, and major initiatives across Pennsylvania, with the potential for ASERT to serve as a model program for other countries or states.

Methods: ASERT collects and analyzes data through a variety of methods. First, ASERT maintains a statewide Resource Center that provides direct connections with the autism community and responds to inquiries in real time. Age, county of residence, role, and reason for inquiry are recorded on an ongoing basis and satisfaction surveys are collected from individuals who contact the Resource Center. Second, the ASERT website is continuously updated with the latest news, events, and training opportunities. Website analytics, including number of visitors, pageviews, sources, location, and top pages, allow for constant monitoring and quality improvement. Third, ASERT provides a variety of trainings for self-advocates, parents/caregivers, professionals, and the general community. Data is collected on reach and satisfaction with trainings.

Results: Since September 2019, over 6,000 people have been assisted through the ASERT Resource Center, including individuals from all counties within Pennsylvania, and over 470 individuals residing outside of the state. Of the 218 respondents to the satisfaction survey, over 90% agreed or strongly agreed that the Resource Center staff and resources were helpful, and they were likely to call the Resource Center again. Since September 2019, over 1.1 million unique ASERT website visitors have viewed resource pages over 2.4 million times. Visitors to the website have come from over 200 countries and territories across the world, and all 50 US states. Since 2015, ASERT has trained over 30,234 people across Pennsylvania and conducted over 260 virtual and 616 in-person training events.

Conclusions: ASERT has reached thousands of autistic Pennsylvanians, families, and support professionals through ongoing programming, resources, and training opportunities. Results indicate a promising practice model with the potential to be replicated and adapted in other states to fit unique needs for the broader intellectual and developmental disability (IDD) community. Future evaluation efforts could be focused on understanding the impact of this model on knowledge, attitudes, and beliefs among individuals, families, and providers.

401.033 Ask Me What I Think: Exploring Autistic Middle and High School Student's Satisfaction with School Services

O. Michael¹, M. Thirion², K. S. Dickson³, A. Drahota⁴ and J. Locke⁵, (1)University of Miami, Seattle, WA, (2)University of Washington, Seattle, WA, (3)San Diego State University, San Diego, CA, (4)Department of Psychology, Michigan State University, East Lansing, MI, (5)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA

Background: Given the increasing number of autistic students served in schools (OSEP, 2024) and documented challenges for students in middle and high school (Hedges et al., 2014), there have been increased efforts to understand the quality of services for this age group (Kraemmer et al., 2019). Despite initiatives to increase access to high quality services (Roberts & Webster, 2020), few researchers have focused on the development of methods to understand autistic students' perspective on the services they receive in school and their overall satisfaction with services.

Objectives: We aim to provide insights from the community informed co-design of a student-specific assessment and present autistic middle and high school students' reflections on satisfaction with school services.

Methods: We engaged in a community-partnered iterative co-design process to develop a student-specific assessment including two focus groups with autistic teens (n=7) and their caregivers (n=2) and advisory board consisting of autistic young adults (n=2). Autistic youth co-designed definitions, developed visual representations of the constructs, renamed the survey to "How Can We Support You?" and tested the tool to evaluate usability. Participants were compensated \$200. Then, autistic middle and high school students (n=34) participated in pilot testing of the survey. Participants were 67% male and 79% white (average age=13.1, average grade=7.4). The survey took approximately 15 minutes to complete, and participants were compensated \$20 for their completion. Although the "How Can We Support You?" survey has questions related to support received in school and areas of need, this presentation will focus on the autistic youth's response to seven questions related to satisfaction with school services.

Results: The seven satisfaction questions used a Likert scale from 1 (Strongly Disagree) to 5 (Strongly Agree). The item with the highest mean score was "I think my teachers listen to my needs" (M=4.12). This was closely followed by "I am satisfied with the teachers who provide supports for me at school" (M=4.00). The statements "I think my teachers are qualified to help students like me," "I think my teachers know how to work with me," and "I think my teachers know how to support me" were rated with mean scores of 3.97, 3.76, and 3.74, respectively. The two lowest-rated items were "The different types of supports offered at my school have helped me," and "I am satisfied with how many different types of supports are offered at my school for me," which received mean scores of 3.68 and 3.59, respectively. Overall, the average satisfaction score across all seven items was 3.84 which indicates general agreement with the statements.

Conclusions: Providing opportunities for autistic students to voice feedback on the services they receive in school is essential to ensure the relevance and impact of these supports. Lower scores related to the effectiveness and variety of available support suggest that continued work is needed in the ongoing assessment of student needs and implementation of practices that effectively address these areas. The co-design and pilot findings point to the utility of the "How Can We Support You" survey for assessing student satisfaction.

401.034 Associations between Autistic Traits and Parental Differential Treatment

A. Jensen¹ and M. Bennett², (1)Brigham Young University, Provo, UT, (2)School of Family Life, Brigham Young University, Provo, UT

Background:

Numerous studies have shown that parental differential treatment (PDT), or parental favoritism, has negative implications for healthy development including depressive symptoms, challenges in sibling relationships (Jensen et al., 2013), and externalizing behaviors (Rolan & Marceau, 2018). While PDT has been studied as a whole, much is still unknown about why parents may favor their children in specific ways (Jensen et al., 2023).

Objectives:

The current study sought to identify autistic traits that may elicit parental differential treatment (PDT). Because of the multifaceted nature of autism, findings from this study have the potential to provide insights to parents about how they may be treating their children differently, based on their child's unique set of autistic traits/behaviors.

Methods:

Participants (recruited via Amazon Mechanical Turk) completed a survey assessing their experiences of parental differential treatment and their own autistic traits using the Autism Quotient (AQ) measure (Baron-Cohen et al., 2001). Participants were young adults ages 18-29 (*M age* = 25.4; 57% Female, 43% Male; 73% White, *n* = 739) who resided in the U.S. and had at least one living sibling.

Results:

Using regression analysis, we examined PDT across six domains (conflict, time, affection, perceived favoritism, communication, and financial support). Independent variables included five domains of autistic traits (deficiencies in social skill, communication, attention switching, attention to detail, and imagination) and demographic controls. Results revealed that participants lower in social skills or higher in attention to detail, per the AQ measure, received less favored treatment in comparison to a sibling in some domains (conflict). In contrast, participants with more challenges with imagination received relatively favored treatment in other domains (affection, financial support, being liked more, and communication).

Conclusions:

Our findings suggest that certain autistic traits are correlated with specific types of parental favoritism. Discussion will focus on these trends and their implications for familial relationships. As there is growing evidence for the significance of autistic behaviors and identifying as autistic, over a clinical autism diagnosis, our study provides evidence that these behaviors do influence family relationships in different ways. As autism is a spectrum and can present itself in many ways, using our findings parents may be able to identify their autistic child's autism profile and how they may be prone to favor/disfavor that child according to it.

401.035 Attitudes Toward Medicinal or Recreational Marijuana Use in the Autism Community

M. Mitchell¹, R. Tayrien¹, N. Wonders², F. Solop² and C. J. Smith¹, (1)Southwest Autism Research & Resource Center, Phoenix, AZ, (2)GloboLocal Vision, Flagstaff, AZ

Background: In preparation for a clinical trial investigating the safety and efficacy of marijuana to reduce anxiety in adults with autism, we conducted three stakeholder focus groups to learn more about attitudes related to marijuana as a potential treatment. Marijuana is generally perceived as harmless and is currently available without restriction. However, negative health effects of chronic usage are well documented (Bedillion et al., 2022). Marijuana use has escalated dramatically with legalization, making it second only to alcohol in abused drugs (SAMHSA, 2022). As marijuana is easily obtained by adults and can be used as a method to self-medicate, it is important to learn the thoughts of key stakeholders representing the autism community.

Objectives: This is an observational study to explore the attitudes of key stakeholder groups representing the autism community on marijuana recreational use and as a treatment.

Methods: To avoid possible bias introduced by knowledge of the autism research center that is conducting the clinical trial, an independent research group recruited and conducted informed consent for participants in three stakeholder focus groups: 1) Caregivers of people diagnosed with autism (n=15); 2) Young Adults aged 18-30 diagnosed with autism (n=11); and 3) Healthcare Providers (licensed psychologists, BCBA's, Occupational Therapists, Aesthetic Technician, SLP's, and founders/managers of agencies) who regularly serve people with autism (n=15). Stakeholder groups were split in half and two focus groups were conducted for each stakeholder group. The independent research group worked collaboratively with the autism center to develop a list of questions to address: 1) challenges associated with ASD, 2) medication and treatment options, 3) marijuana and 4) marijuana as a treatment option.

Results: Participants in all groups expressed favorable or neutral opinions about the legalization of marijuana, indicating calming effects, potential to reduce anxiety, improve quality of sleep, and appetite, favoring natural treatments over synthetic, pharmaceutical treatments. They also believe these positive effects can increase quality of life. Groups also expressed concern about the limited research on long-term effects (on cognition and overall health) as well as limited evidence for therapeutic benefits. They were also concerned about limited quality control of marijuana products (THC percentage, strains, dosage). Caregivers also expressed a concern related to autism-related communication challenges because it may be difficult to report undesirable side effects. Quotes in Table 1.

Conclusions: Stakeholders are in favor of natural treatments vs. synthetic treatments and believe that marijuana-based products have the potential to be beneficial, but more research and regulatory control of ingredients are needed. Unique insight from the caregiver group was that it is difficult to find medical professionals willing to work with autistic individuals, and that commonly professionals try to treat various symptoms without considering the person's greater needs. The health care professionals group also shared insight that they see in their fields that professionals refuse to work with those in the autism community, which shows the need to bridge this gap to better treat individuals with autism.

401.036 Autism ALERT: Exploring the Experiences of Families Working Toward Autism Evaluation and Diagnosis with Family Navigator Assistance

J. Junqua¹, M. Solgi², A. Feryn³, M. O. Reinitz⁴, P. Cavanaugh⁵, J. Raja-Vora⁶, M. Tae³ and K. Zuckerman⁶, (1)Oregon Health and Science University, Portland, OR, (2)School of Medicine, Oregon Health and Science University, Portland, OR, (3)Biostatistics and Design Program, Oregon Health and Science University, Portland, OR, (4)Division of General Pediatrics, Oregon Health & Science University - CDRC, Portland, OR, (5)Providence Oregon Help Me Grow, Portland, OR, (6)Division of General Pediatrics, Oregon Health & Science University, Portland, OR

Background: Family navigation holds promise for reducing stressors and facilitating early autism diagnosis; however, little is known about how navigation impacts families' experiences of autism diagnostic assessment.

Objectives: To understand the family experience of telehealth autism navigation, and to explore mechanisms by which navigation improves access to care.

Methods: This project evaluated Autism ALERT, a pilot site-randomized trial of family navigation for children with autism symptoms. 50 families participated from 7 Oregon primary care clinics: 30 families were assigned to telehealth family navigation as the intervention arm, and 20 families were assigned to information-only as the control arm. Families in both arms completed 2 self-administered surveys: on enrollment (baseline) and after 6 months. Surveys consisted of standardized scales used to assess Family Centered Care (FCC), Care Coordination (CC), Shared Decision Making (SDM), Autism Knowledge, Family Empowerment, Family Stress, and Parenting Stress, and (in the intervention arm) Navigator Satisfaction. For data analysis, we summarized the change in each score from baseline to 6 months (change in mean/change in proportion) using intention to treat, comparing intervention vs. control arms. We calculated p-values using the Generalized Estimating Equation (GEE) difference-in-difference models. Finally, we summarized Navigator Satisfaction with descriptive statistics.

Results: Of the 50 families enrolled in Autism ALERT, 48 completed the baseline survey (96%) and 36 (72%) completed the 6-month survey. Child participants were 17% female, 39.6% Latino, 85.1% English speaking and 56.3% White. Families in the intervention arm experienced non-significant increases in FCC (14.3% increase in the intervention vs 1.7% increase in the control arm; $p = 0.56$), CC (2.4% increase vs. -5% in the control arm), SDM (19% increase vs. 11.7% increase in control arm; $p = 0.743$), and Autism Knowledge (61% increase vs. 50% increase in the control arm; $p = 0.49$). Changes in family empowerment (-1.41 in the intervention arm vs. -1.23 in the control arm; $p = 0.849$) family stress (-0.66 in the intervention arm vs. -0.45 in control; $p = 0.802$), and parenting stress (2.09 in the intervention arm vs. 1.83 in control arm; $p = 0.80$) were similar in both groups. Finally, 70% of intervention families felt satisfied or highly satisfied with all aspects of family navigation.

Conclusions: A majority of families had high satisfaction with family navigation and non-significant positive effects were observed for FCC, CC, SDM, and autism knowledge for families engaged in family navigation compared to the information-only control group. Although results are limited due to sample size and self-reported nature of survey-based data collection, this pilot study suggests beneficial aspects of telehealth navigation for families. Interestingly, family navigation did not seem to decrease family/parenting stress or family empowerment during the journey to an autism diagnosis. This suggests other factors contributing to stress and empowerment not directly addressed by family navigation. Future larger studies could provide more information on mechanisms which contribute to the success of family navigation for families seeking an autism diagnosis.

401.037 Feasibility & Acceptability of UC Leadership Academy for Emerging Disability Rights Leaders: Review of Pilot Program
E. Cincione¹, J. A. Estabillo², B. Warner³, E. A. Laugeson⁴, B. Stoffmacher⁵, K. Weller⁶, A. Kuo⁷, Y. Bolourian⁸ and K. Rosenau⁹, (1)Psychiatry, UCLA Semel Institute, Los Angeles, CA, (2)Psychiatry, UCLA Semel Institute for Neuroscience & Human Behavior, Los Angeles, CA, (3)UCLA, Los Angeles, CA, (4)UCLA Semel Institute for Neuroscience and Human Behavior, UCLA PEERS® Clinic, Los Angeles, CA, (5)UCLA Semel Institute for Neuroscience & Human Behavior, Los Angeles, CA, (6)David Geffen School of Medicine at UCLA, Los Angeles, CA, (7)UCLA Tarjan Center, Los Angeles, CA, (8)UCLA Department of Medicine, Los Angeles, CA

Background: Recent appeals for targeted research and training in self-advocacy and policy skills underscore the necessity of elevating the voices of individuals with intellectual and developmental disabilities (IWIDD), including autism, as required by the Developmental Disabilities Assistance and Bill of Rights Act of 2000 (DD Act; Public Law 106-402, 106th Congress). In response to this need, UCLA Tarjan Center UCEDD and UC-LEND held their inaugural UC Leadership Academy for Emerging Disability Rights Leaders (“Leadership Academy”) in Spring 2024.

Objectives: This study assessed the feasibility and acceptability of a novel Leadership Academy to teach IWIDD skills related to disability policy and self-advocacy.

Methods: The Leadership Academy was a 10-week program in which 10 IWIDD met virtually for two-hour weekly sessions. Based on a previous needs assessment and feedback from IWIDD, curriculum focused on disability policy (e.g., history of disability rights in America, introduction to government) and self-advocacy skills (e.g., advocacy and testifying, storytelling). The program culminated in a leadership showcase in which fellows presented on their advocacy topic. Upon completion of the program, participants answered questions related to each session’s curriculum and provided ratings for the content and skills taught. Feasibility was evaluated based on retention rates, attendance, and survey completion.

Acceptability was measured through participant satisfaction surveys and qualitative responses in their application and showcase presentation.

Results: Nine fellows graduated the program, including six who self-identified as autistic (mean age = 27, SD = 7.4). Results indicated high feasibility, with 90% retention rate and 66% survey response rate. Moreover, 77% of participants attended greater than 80% of the sessions. Participants reported positive experiences with the program, with 100% of respondents indicating they *agreed* or *strongly agreed* that they gained knowledge about relevant advocacy topics, improved in their introductory self-advocacy skills, and that the structure and presentations of the program were effective and helpful.

Additionally, qualitative review of the autistic fellow’s applications suggested that 45% of respondents were interested in *self-advocacy in the workplace or classroom* and 36% of respondents were interested in *learning leadership skills as a means of supporting their community*. In survey responses of autistic graduates, 50% expressed interest in learning more about *current disability rights activities and opportunities* and 50% reported interest in *self-advocacy in the workplace or classroom*. Moreover, the session *Advocacy in Practice* was ranked “most helpful” by 83% of respondents.

Conclusions: Findings suggest that the pilot Leadership Academy is both feasible and acceptable, providing a strong foundation for future programming. Results highlight the importance of teaching IWIDD skills related to disability policy and self-advocacy. Future programs should consider including additional topics related to *current/ongoing advocacy events* and/or *advocacy in practice: self-advocacy in the workplace and classroom* which may enhance the program’s effectiveness in meeting self-advocates’ needs.

401.038 Autism Diagnosis: Where Is It Happening, with Whom, and Why?

V. I. Underwood Carrasco^{1,2}, C. Charlesworth³, K. Watson³, O. J. Lindly⁴ and K. Zuckerman¹, (1)Division of General Pediatrics, Oregon Health & Science University, Portland, OR, (2)OHSU-PSU School of Public Health, Portland, OR, (3)Oregon Health & Science University, Portland, OR, (4)Health Sciences, Northern Arizona University, Health Sciences Department, Flagstaff, AZ

Background: In the US, a formal autism diagnosis by specialty mental health (SMH) clinicians trained in autism assessment is needed for access to condition-specific services. However, there are long waitlists for SMH diagnostic evaluations, reflecting limited SMH workforce availability. The American Academy of Pediatrics supports primary care provider (PCP) autism diagnosis as a means of accelerating access to autism care; however, it is unclear how widespread this practice is in the US, or whether access to PCP diagnosis is equitable.

Objectives: Use a national dataset of Medicaid/CHIP insurance claims to assess the frequency of PCP versus SMH diagnosis of autism in early childhood, the association of child sociodemographic and neighborhood factors with PCP versus SMH diagnosis, and whether the COVID-19 pandemic impacted rates of PCP diagnosis.

Methods: Using Transformed Medicaid Statistical Information System Analytic Files (TAF) from 14 states with sufficient claims volume and complete data, we conducted an exploratory retrospective cohort analysis of children ages 1-5 who were first diagnosed with autism between 2017 and mid-2020. Taxonomy codes and claims for well-child visits captured different provider types. Diagnosis by provider type (i.e., PCP vs. SMH) before and during the COVID-19 pandemic was compared according to patient (i.e., age, sex, race and ethnicity) and geographic characteristics (urbanicity, state). Restricting to pre-COVID data, we then explored factors associated with a PCP diagnosis using Ordinary Least Squares (OLS) regression models including state-fixed effects.

Results: PCP diagnosis varied by state, ranging from 14.5% in North Dakota to 49.8% in Nevada, and by race and ethnicity, ranging from 22.3% for Black children to 32.9% for Hispanic children (Figure 1). Among children who received an autism diagnosis before (n=21,368) and during (n=1,883) COVID, 25.7% and 22.9% were diagnosed by a PCP as opposed to a SMH provider, respectively. The first few months of COVID show early signs of a negative diagnosis trend for both PCPs and SMH providers, but more data is needed to understand diagnosis patterns and variation since the start of COVID. In an adjusted OLS model (Figure 2), we found that compared to white children, children with Hispanic ethnicity were more likely to be diagnosed by a PCP versus an SMH provider (4.65 percentage points, 95% C.I. 2.1p.p. - 7.21p.p., p < 0.001).

Conclusions: This study suggests that over 1/5 of Medicaid- and CHIP-enrolled children ages 1-5 receive an autism diagnosis from a PCP rather than a specialty provider. Even so, there is substantial variability in PCP diagnosis rates by state. We also observed that Hispanic children were significantly more likely than white children to be diagnosed by a PCP versus a SMH provider. Additional research will include TAF data from 2020-2021 to better understand diagnosis trends before and during COVID and describe how to reach children who need an autism diagnosis more equitably.

401.039 Autism Intervention in Mexico-U.S. Border Cities: Examining Providers' Training, Challenges, and Services.

C. Orendain Soto¹, K. Valdez Lopez², F. A. Castellon³, J. Rocha⁴, M. Valladares⁴, L. Rocha⁴ and A. D. Duenas⁵, (1)*Child and Adolescent Services Research Center, San Diego, CA*, (2)*Psychology, California State University Long Beach, Long Beach, CA*, (3)*University of California Los Angeles, Los Angeles, CA*, (4)*Special Education, SDSU, San Diego, CA*, (5)*Counseling, Educational Psychology, and Special Education, SDSU, East Lansing, PA*

Background:

Autism varies globally, with significant differences in identification, access to intervention, and policies across countries (de Leeuw et al., 2020). In Mexico, the prevalence of autism remains uncertain, given that the most recent data is a decade old (Fombonne et al., 2016). Existing studies have shown that caregivers are typically the first to raise concerns with professionals when seeking diagnosis and services (Montenegro et al., 2022). However, there is a gap in understanding the training of Mexican professionals to work with autistic children and provide services in a Mexico-U.S. border city.

Objectives:

This study aims to explore 1) the educational background and professional experience of early intervention autism providers in Mexican border cities, 2) challenges these providers face when supporting families, and 3) the scope of service provided and interactions with transborder populations.

Methods:

Participants included Mexican psychologists (n=9), child psychologists (n=1), special education teacher (n=1), and school psychologist (n = 1; N = 12, Mean age = 29) through purposeful and snowball sampling. Inclusion criteria included 1) working in a Mexican border city and 2) working with at least one autistic child. Participants completed a consent form, a demographic form, and a semi-structured interview via Qualtrics. Inductive thematic analysis was performed using the Dedoose software.

Results:

Using a convergent parallel design, the study evaluated providers' experiences using surveys and semi-structured interviews (Creswell, 2014). The analysis generated four main themes: 1) Notable gap in autism-focused training in university-level education in Mexico. Ten participants reported not receiving specialized autism training during their undergraduate and graduate studies, and all sought additional certifications from international sources such as Europe, the U.S., or other Latin American countries. 2) Providers highlight the challenges faced by the Mexican government and mental health systems, such as the high costs and waiting periods ranging from 1 week to 6 months for services. Providers complete a socioeconomic assessment to offer families free therapy sessions, psychoeducation, school support, and materials. 3) A range of both evidence-based practices (EBP) and non-EBP were provided, including ABA, play therapy, speech therapy, occupational therapy, sensory therapy, art therapy, recreational therapy, equine therapy, and music therapy. All providers reported working with American families, adapting to caregivers' cross-border travel needs, and offering English-language resources. However, providers expressed frustration with the U.S. health system's lack of flexibility, particularly in allowing Mexican providers to complete school rotations to better support their clients.

Conclusions:

There is a critical need for autism-specific training in Mexico. Access to services is heavily influenced by socioeconomic factors, creating disparities in service delivery. Despite these challenges, autism providers in Mexico are highly motivated to meet their clients' needs by adapting their therapy practices. The services provided in a border city reflect a mix of EBP and non-EBP, shaped by resource limitations but also highlighting innovative approaches in binational settings.

401.040 Autism Terminology Preferences in a Large United States Sample

P. Dwyer¹, Z. J. Williams^{2,3,4,5}, J. E. Markfeld³ and T. G. Woynaroski¹, (1)*Olga Tennison Autism Research Centre, La Trobe University - OTARC, Melbourne, VIC, Australia*, (2)*Medical Scientist Training Program, Vanderbilt University School of Medicine, Nashville, TN*, (3)*Department of Hearing and Speech Sciences, Vanderbilt University Medical Center, Nashville, TN*, (4)*Frist Center for Autism and Innovation, Vanderbilt University, Nashville, TN*, (5)*Vanderbilt Brain Institute, Vanderbilt University, Nashville, TN*

Background:

How researchers should talk about autism and its diversity is controversial. Numerous studies investigate community preferences regarding English-language autism terms, but results are inconsistent, possibly reflecting sampling differences (Archibald et al., 2024).

Objectives:

To examine autism terminology preferences in a large USA sample.

Methods:

5382 autistic people and parents of autistic people (464 autistic parents, 1683 autistic non-parents, and 3235 non-autistic parents, from 4724 families; 1616 male, 3534 female, 232 nonbinary/nonconforming/other; $M_{age}=41.24$), recruited from SPARK Research Match, rated liking and offensiveness of autism terms (e.g., “autism”), heterogeneity terms (e.g., functioning levels), and person terms (e.g., “person with autism”). Bayesian probit multilevel models analyzed group- and term-based rating differences, accounting for nesting within families. Marginal predictions were compared across items/groups, based on 95% highest-density credible intervals.

Results:

Autism (Fig. 1): “Autism” was more liked and less offensive than other terms. The term “autism spectrum development” was liked least, but “autism spectrum condition” was most offensive. “Autism spectrum disorder” and “...development” were less liked by and more offensive to autistic parents and autistic non-parents than to non-autistics.

Heterogeneity (Fig. 1): “Autism with low/high support needs” was relatively well liked and offensive compared to alternatives. “Profound autism” was least liked and most offensive. Heterogeneity terms were usually liked more, and always statistically rated as less offensive, by non-autistic parents relative to both autistic groups. However, “autism with high/low support needs” was liked more by autistic and non-autistic parents compared to autistic non-parents, and “autism with/without intellectual disability” was liked more by non-autistic parents than autistic people who were not parents. Most heterogeneity terms, except references to support needs or intellectual disability, were more offensive to autistic parents than autistic non-parents.

Person (Fig. 2): “Person on the autism spectrum” and “person with autism” were statistically most liked overall, and the former was least offensive; however, both autistic groups rated them as less liked and more offensive than non-autistic parents. “Person diagnosed with autism,” “person who has autism,” “person with autism spectrum disorder,” “person who is autistic,” and “autistic person” were slightly less liked overall, but “autistic person” was more liked and less offensive in both autistic groups than among non-autistic parents; non-autistic parents preferred the three terms including “with.” “Person suffering from autism” was least liked and most offensive.

Conclusions:

Participants showed varied preferences, but they – especially autistic participants – apparently disliked many clinical terms and heterogeneity terms, with simple and neutral-valanced terms such as “autism” and references to support needs. The terms “profound autism” and “person suffering from autism” were especially disliked. These results provide insight into terms that should be avoided by researchers/clinicians, but although the sample is large, it is not representative of the autism community in the USA or internationally. Only 107 participants reported intellectual disability diagnoses, and only 1113 were Hispanic/Latine/Spanish, non-White, or mixed-race. Further directions include investigating diversity of terminology views and their relation to sociodemographic factors and neurodiversity movement awareness/support, which will provide more nuanced insights.

401.041 Autistic Adults and Caregivers' Perceptions and Usage of Cannabis: A Mixed Methods Qualitative Study

H. R. Steinberg¹, K. Ardeleanu² and T. Garfield³, (1)AJ Drexel Autism Institute, Philadelphia, PA, (2)A.J. Drexel Autism Institute, Philadelphia, PA, (3)A.J. Drexel Autism Institute, Drexel University, Philadelphia, PA

Background:

In the United States, cannabis was initially identified as medicinal. The criminalization and stigmatization of cannabis, beginning in the 20th century, resulted in limiting access to illicit channels and relatively little research on the use and impacts of cannabis. With legal access to cannabis expanding through state medical and recreational policies, autism been identified as a qualifying condition for medicinal cannabis in some states, including Pennsylvania. Little is known about how cannabis is perceived, used, and accessed in the autism community. In Pennsylvania, despite parental advocacy in 2017 to make autism a qualifying condition, less than one percent of medical cannabis patients use the diagnosis to access cannabis.

Objectives:

This study used surveys and interviews to 1. describe autistic adults' and caregivers' opinions and perceptions of cannabis, 2. characterize behaviors, decisions, and usage around cannabis within this population, and 3. better understand this population's motivations and barriers to accessing medical cannabis.

Methods:

A total of 119 autistic adults, 52 caregivers of autistic individuals, and 9 autistic caregivers completed a survey that included questions about attitudes and behaviors related to cannabis, as well as demographic information. All participants were Pennsylvania residents. From this sample, a subset of 19 participants who were actively using cannabis were selected to participate in follow-up interviews to better understand their experiences with and perspectives on cannabis use.

Results:

We found that caregivers generally believed that cannabis was age-inappropriate for their minor children. Participants reported that few medical providers addressed potential risks or benefits of cannabis use. Most autistic adults (82%) had used cannabis at least once. Preliminary findings from the interviews indicated that participants generally had positive impressions of cannabis. They used cannabis to help with common co-occurring conditions, such as anxiety and chronic pain. Some participants said they used cannabis for autism-specific challenges, such as to help them cope with sensory sensitivity and overstimulation. For some participants, cannabis use supported functioning in daily activities, including eating, sleeping, socializing, and focusing on tasks. Most participants did not use autism as their qualifying condition for receiving medical cannabis, instead often opting to use anxiety or PTSD. Race and class also shaped access and use – many low income and/or participants of color used informal means, such as dealers or friends, to obtain cannabis, or they purchased cannabis from neighboring states where recreational cannabis use is legal.

Conclusions:

Recommendations related to cannabis policies and legalization, cannabis programs, and the need for clinical trials involving autistic individuals are discussed.

401.042 Autistic Psychiatrists' Experiences of Recognising Themselves and Others As Autistic: A Qualitative Study

M. Doherty^{1,2,3}, N. Chown², N. Martin² and S. Shaw⁴, (1)Neuroscience, Brighton & Sussex Medical School, Brighton, United Kingdom, (2)London South Bank University, London, United Kingdom, (3)School of Medicine, University College Dublin, Dublin, Dublin, Ireland, (4)Brighton & Sussex Medical School, Brighton, United Kingdom

Background: Diagnosis of autism falls under the remit of psychiatry and is currently based on externally observed differences from a perceived norm. Recognition that psychiatrists could be autistic is recent. Embodying such differences may inhibit recognition that one is actually different from the majority. Alternatively, autistic strengths such as enhanced pattern recognition may aid self-recognition. Psychiatrists are the second largest specialty group in Autistic Doctors International (ADI), an online community of autistic doctors.

Objectives: To explore experiences of autistic psychiatrists in relation to recognising themselves and others as autistic.

Methods: A qualitative study using loosely structured interviews and interpretive phenomenological analysis.

Results: Eight autistic, senior psychiatrists based in the United Kingdom were recruited from "ADI Psych" a psychiatry specific subgroup of ADI. One had a childhood diagnosis, two were diagnosed as adults; the remainder self-identified as autistic. Three themes were identified.

Theme 1: Recognising oneself as autistic. Recognition of autism followed diagnosis of their children or encounters with autistic patients, with one participant reporting that "*these are my people*". Barriers to self-recognition included lack of autism training, deficit-based diagnostic criteria and stereotypical views of autism.

Theme 2: Recognising autistic colleagues. Recognising that they were autistic led to the realisation that many colleagues were also likely autistic, particularly those in neurodevelopmental psychiatry.

"Looking around psychiatrists there are those that are clearly autistic and... usually pretty involved in neurodevelopmental disorder."

Theme 3: Not recognising autistic patients. All participants reported the ability to quickly recognise autistic patients, and to develop good rapport easily, once aware of their own autistic identity. Difficulties recognising patients as autistic occurred prior to self-recognition when they shared autistic characteristics and experiences.

"Well, we all do that don't we, meaning I do that so therefore obviously everybody else does... my benchmark for what's 'normal' is me."

One participant reflected on a long career in academic clinical practice, and involvement in development of diagnostic tools still used today. His lack of awareness had potential implications for the validity of instruments developed, as some items apparently lacked specificity.

"I remember arguing about rating scales... this question seemed quite inappropriate because.. someone like myself could say 'yes that's me' therefore it wasn't really a good one for picking up autism."

Conclusions: Autistic psychiatrists face multiple barriers to recognising that they are autistic. Lack of such self-recognition may have negative implications for the validity of assessment processes and may impede diagnostic accuracy with autistic patients. We acknowledge that a minority of our participants had an official autism diagnosis. The accuracy of self-identification in psychiatry is a contentious area, particularly in relation to autism. However, our participants were psychiatrists whose clinical roles involve autism diagnosis. Membership of "ADI Psych" involves scrutiny by other psychiatrists and acceptance within the group offers community confirmation when the group consists of psychiatrists who regularly diagnose autism. Self-recognition and disclosure by autistic psychiatrists may be facilitated by reframing the traditional deficit-based view of autism towards a neurodiversity-affirmative approach, with consequent benefits for autistic patients.

401.043 Autistic Student-Driven Priorities for Belonging in Higher Education.

A. Wang¹, C. Bendevis², E. Coombs³, C. Devlin⁴, P. Dwyer⁵, N. Pogue⁶, M. Pabia¹, J. Ryan⁷, H. Santilli⁸, I. Weigel-Mohamed¹, H. Ma¹, T. Connolly⁹, B. Di Rezze¹⁰, D. B. Nicholas¹¹, S. Thompson-Hodgetts¹² and **H. M. Brown⁸**, (1)University of Alberta, Edmonton, AB, Canada, (2)First Nations Technical Institute, Elphin, ON, Canada, (3)Counselling Psychology, University of Alberta, Calgary, AB, Canada, (4)Ryerson University, London, ON, Canada, (5)Olga Tennison Autism Research Centre, La Trobe University - OTARC, Melbourne, VIC, Australia, (6)Vancouver Island University, Nanaimo, BC, Canada, (7)Rehabilitation Medicine, University of Alberta, Edmonton, AB, Canada, (8)Educational Psychology, University of Alberta, Edmonton, AB, Canada, (9)Carleton University, Ottawa, ON, Canada, (10)McMaster University, Hamilton, ON, Canada, (11)University of Calgary, Edmonton, AB, Canada, (12)Occupational Therapy, University of Alberta, Edmonton, AB, Canada

Background: Increasing research investigates belonging in Autistic post-secondary (PS) students, exploring facilitators and barriers, experiences of belonging, and the impact of specific support services.^{1,2,3} However, many Autistic students report feeling a lack of belonging, which is associated with poorer academic and social outcomes in PS settings. *Belonging*, characterized by acceptance and value from others across social contexts, is argued as imperative for maintaining academic success and motivation.⁴ Evidently, PS institutions must make systemic changes to address prevailing inequities and promote Autistic student belonging, as highlighted by Neurodiversity advocates and allies.⁵ However, few researchers have asked Autistic students for their perspectives on institutional changes to promote their belonging, despite increasing calls for the importance of participatory autism research and utilizing this knowledge to serve Autistic communities.⁶

Objectives: This qualitative analysis aims to amplify Autistic PS students' perspectives in shaping institutional change to enhance their sense of belonging on campus. Specifically, it seeks to answer: (1) What changes do Autistic students identify as essential for fostering a greater sense of belonging at their institutions? (2) What priorities should institutions focus on to create more inclusive and supportive environments for Autistic students?

Methods: The Belonging Questionnaire (TBQ) was developed using a participatory approach and included short and long-answer questions to explore the university experiences of Autistic students. Nine long-answer questions provided in-depth insights into belonging on campus, emphasizing social, environmental, and accessibility factors. Eligible participants were self-identified Autistic individuals who had completed at least six months of PS education in Canada. This study focused on responses to the prompt: "What do you think universities should be doing to identify and build environments in which autistic students are welcomed?" Using reflexive thematic analysis⁷, responses were inductively coded into emerging priorities, then defined, refined, and organized into five key themes.

Results: The study included 27 Autistic adults with diverse racial, ethnic, gender, and sexual identities. We identified five priorities within their responses: (i) *Tailored Autism-specific services* to meet their unique needs, (ii) *Neuro-affirming Autism education* for faculty, staff, and students to foster understanding of Autistic ways of being, (iii) *Building an inclusive culture* through policy and outreach, with meaningful involvement of Autistic students, (iv) *Developing and supporting student groups*, both identity- and interest-based, to encourage social connections, and (v) *Ensuring sensory safety on campus*, including access to sensory rooms and regulation tools to create a more welcoming environment and enhance their sense of belonging.

Conclusions: This study emphasizes a disability justice-informed approach to amplify Autistic students' perspectives in shaping institutional change for greater belonging, aligning with calls for participatory research.⁸ The identified priorities - tailored services, neuro-affirming education, inclusive culture through policy and outreach, support for student groups, and sensory safety - reflect existing literature on the need for inclusive practices.⁹ However, a gap remains between advocacy and action. Closing this gap through genuine collaboration with Autistic students is key to creating supportive academic environments.

401.044 Autistic Women and Sustained Employment: Navigating Gender and Neurotypical Norms in Workplaces

Y. Hamdani¹, W. Deschamps², A. Dussault³, A. Tint⁴, M. Spoelstra⁵, A. Jetha⁶, M. Gignac⁶, M. C. Lai⁷, F. Niles-Williams⁸, B. Mistry⁸ and C. Hollemeyer⁹, (1)Azrieli Adult Neurodevelopmental Centre, University of Toronto, Toronto, ON, Canada, (2)Liberty Co, Waterloo, ON, Canada, (3)Auticon, Toronto, ON, Canada, (4)University of Calgary, Calgary, AB, Canada, (5)Autism Ontario, Toronto, ON, Canada, (6)Institute of Work and Health, Toronto, ON, Canada, (7)Campbell Family Mental Health Research Institute, Centre for Addiction and Mental Health, Toronto, ON, Canada, (8)University of Toronto, Toronto, ON, Canada, (9)Fielding Graduate University, Santa Barbara, CA

Background: Employment participation is promoted as a social determinant of health in prevailing public health discourses. However, sustaining paid work can be challenging for autistic women compared to non-autistic people and autistic men, even when they are highly qualified for the work. Many autistic women experience adverse social and mental health consequences as they 'work' to sustain employment. Little research exists about autistic women's workplace experiences.

Objectives: Our study examined how autism and gender intersect and impact on employment participation and workplace supports for autistic women in Ontario, Canada. We aimed to:

1. explore how work is experienced by autistic women from the perspectives of autistic women, employers, and employment support professionals;
2. examine the intersectionality of gender and autism and its impact on their workplace experiences and sustained employment; and,
3. explore what workplace accommodations and supports they found helpful and what were the implementation challenges and opportunities.

Methods: This qualitative study involved in-depth interviews with two groups of participants: 1) autistic women with paid work experience, and 2) employers or employment support professionals who had arranged workplace supports for autistic women. Reflexive thematic analysis methods (Braun & Clarke, 2021) were used to identify patterns in the data related to 1) gender, autism, workplace experiences and sustained employment, and 2) workplace accommodations and supports. Data sources were interview transcripts and the interviewer's post-interview reflective memos. Transcripts and memos were read and discussed by a subset of the research team to develop a coding scheme, then coded by a research assistant using NVivo software. Key themes were generated, reviewed and refined at regular intervals with the larger research team, which included researchers, trainees, autistic women advisors, and representatives from organizations supporting/employing autistic people.

Results: Ten autistic women and eight disability employment support/human resource professionals participated in the study. Navigating gender and neurotypical norms for workplace behaviours had consequences for sustained employment and the wellbeing of autistic women. Participants across groups discussed workplace challenges for autistic women including: navigating stereotypes and assumptions about autism based on child and male presentations, navigating expectations and conventions for gendered social behaviours, adapting to shifts in job roles and responsibilities; not noticing or engaging in cultural workplace practices; communicating with male supervisors; experiencing discomfort from physical and sensory environments; feeling overlooked in Equity, Diversity, Inclusion and Accessibility (EDIA) workplace initiatives; and experiencing marginalization and micro-aggressions by colleagues and superiors. Autistic women participants also discussed undergoing formal reviews and conflict management processes, taking leave-of-absences, being fired and leaving employment. Collective ideas for supportive workplaces included: structured, predictable tasks and responsibilities, clear expectations for roles and deliverables, access to mental health supports and formal mentors, accessible workspaces, and employer training on autism and neurodiversity-affirming workplaces.

Conclusions: Our research provides insights into autistic women's employment experiences, and highlights areas where improvements in workplace policies and practices can be made. These included greater attention to making workspaces gender- and neuro-inclusive and explicitly discussing gender, neurodiversity and mitigation of challenges and inequities experienced by autistic women in EDIA initiatives.

401.045 Filipino Generation Z College Students' Autism Knowledge Lack of Effect on Autism Stigma

J. A. P. Dacumos, L. B. F. Tan, C. J. S. Dela Peña, Y. J. M. Poblete and P. A. Catan, Department of Psychology, De La Salle University - Manila, Manila, Metro Manila, Philippines

Background: Initiatives to reduce stigma included increasing people's knowledge of Autism, adhering to a segment of Turnock's theory (2022) of Autism Stigma which suggests that individuals with higher knowledge of Autism have lower stigmatization. Multiple studies conferred with this idea (Golson et al., 2022; Jones et al., 2021; Kitchin et al., 2021; Kuzminski et al., 2019; Sasson & Morrison, 2017; Underhill et al., 2019), while other studies challenged it, presenting alternative variables that might bear a more substantial influence (Gillespie-Lynch et al., 2017; Underhill et al., 2019; White et al., 2019). Further complicating debates on the relationship, even if awareness and knowledge of Autism is increasing especially in younger populations (Stronach et al., 2018; White et al., 2016), Autistic individuals and children still experience Autism Stigma today (Botha, 2021; Botha et al., 2020; Catubigan et al., 2023; Joseph & Delariarte, 2023; Lasco et al., 2022; Pascua & Dizon, 2022). While these findings provided valuable insights to the discussion, they were primarily derived from Western settings. With this, multiple gaps in the topic exist, namely the unclear relationship between Autism Knowledge and Autism Stigma, especially in younger populations, and information that considers non-Western contexts.

Objectives: Responding to the inconsistent findings regarding an individual's Autism Knowledge and its effect on their endorsed Autism Stigma, this study investigated whether Filipino Gen-Z College Students who had a better grasp of Autism endorsed less stigma against autistic individuals. Additionally, this study investigated whether Filipino Gen-Z College Students who were affiliated with autistic individuals presented an even greater grasp of Autism endorsed lesser stigma or not.

Methods: 126 respondents completed a survey disseminated through social media for this Cross-Sectional Explanatory study (Johnson, 2001). The survey asked Filipino Gen Z College Students, between the ages of 18 to 27 years old, to disclose their affiliation status and accomplish the Autism Spectrum Knowledge Scale General Population Version, Social Attitudes Towards ASD Scale, and Marlowe-Crowne Social Desirability Scale (Form C). Respondents with high social desirability were omitted. Data was analyzed through a Linear Regression and Moderation Analysis

Results: Findings suggested that respondents who were knowledgeable about Autism did not necessarily endorse lower stigma, $t = -1.46$, $\beta = 0.18$, $95\%CI: -0.63, 0.09$, $p = .14$. Likewise, respondents affiliated with an autistic individual did not present lower stigma, $t = -0.58$, $\beta = 1.31$, $95\%CI: -3.37, 1.83$, $p = .56$. Respondents also reported higher Autism Knowledge and Autism Stigma compared to past samples.

Conclusions: Results indicated that even with the understanding of Autism heightened, stigma remains a concern. This may reflect shared Autism-related information's technical symptomatology-base. The approach may have inadvertently highlighted disruptions and maladaptivity which may further endorse negative reactions and stigma towards Autistic individuals. With this, approaches to Autism inclusion do not necessarily need to anchor strictly on sharing technicalities. Instead, they can focus on a more holistic and nuanced presentation

401.046 Awareness and Stigma of Autism in Chinese Parents of Autistic Children

H. W. Lam¹, X. Zhang² and W. C. So³, (1)Educational Psychology, The Chinese University of Hong Kong, Hong Kong, Hong Kong, (2)Educational Psychology, The Chinese University of Hong Kong, Hong Kong, Hong Kong, China, (3)Educational Psychology, The Chinese University of Hong Kong, Hong Kong, NA, Hong Kong (China)

Background:

Autism prevalence is on the rise in China (Sun et al., 2019). However, previous research around the globe has found that public in China have poorer knowledge about autism, including its causes, symptoms, and long-term consequences, than those in the Western countries (Harrison et al., 2023; Wei et al., 2022; Yu et al., 2020). Little is known about the level of autism knowledge among Chinese parents of autistic children specifically, although Leung et al. (2023) commented that Chinese parents may not be as sophisticated as their Western counterparts in recognizing the features of autism. Lack of autism knowledge may result in delayed diagnosis, elevated parental stress and poor psychological well-being (e.g., Zaki et al, 2016). Thus, it is crucial to understand the autism knowledge in Chinese parents of autistic children and the underlying demographic factors influence the level of such knowledge. Our findings can shed light on the direction of intervention for Chinese parents of autistic individuals (e.g., provision of workshops to enhance autism knowledge).

Objectives:

The current study aimed to examine the level of autism knowledge in Chinese parents of autistic children and compared it to the standard of adequate autism knowledge established in Harrison et al. (2017) and to identify factors that contributed to autism knowledge. We hypothesized that Chinese parents of autistic children have lower level of autism knowledge than the public in western societies, but their knowledge may vary with family demographics.

Methods: 98 parents of autistic children (88 females; Mean age=40.80; SD=5.12) completed the demographic questionnaire and Autism Stigma and Knowledge Questionnaire (ASK-Q; Harrison et al., 2017) which includes four sub-scales: Diagnosis, etiology, treatment, and stigma. On average they earned USD3800- 6400/month and attained sub-degrees.

Results: Chinese parents of autistic children, on average, demonstrated adequate autism knowledge on all four sub-scales (Table 1). Parents' age was negatively correlated with treatment scores ($r=-0.241, p=0.019$). Children's chronological age and age of autism diagnosis were negatively correlated with parents' diagnosis scores ($r=-0.238, p=0.018$; $r=-0.333, p=0.002$; respectively). There was no significant difference in autism knowledge between mothers and fathers. Non-working parents scored lower in the stigma sub-scale than working parents ($F=6.26, p=0.014$). There were significant and positive associations between levels of education and scores on treatment as well as stigma ($F=4.03, p=0.005$; $F=5.76, p<0.001$; respectively). Similarly, family income showed positive correlations with scores on diagnosis, etiology and stigma ($F=2.72, p=0.035$; $F=3.11, p=0.019$; $F=3.025, p=0.022$; respectively). Figure 1 displays ASK-Q across various levels of education and different family income brackets.

Conclusions: Chinese parents in general score higher than those of participants in Harrison et al. (2017). However, there are individual variations in the parents' knowledge about and stigma toward autism and those variations can be accounted for by some of the family demographics. Workshops on enhancing autism knowledge are particularly useful for parents with lower income and education level.

**401.047 Battle of the Bots in Autistic College Student Survey Research**

B. E. Cox¹, B. R. Nachman² and Y. Jiang¹, (1)Michigan State University, East Lansing, MI, (2)University of Pittsburgh, Pittsburgh, PA

Background:

Fraudulent responses which intentionally provide false, irrelevant, or inaccurate data (Meade & Craig, 2012; Nichols, 1989) have become an increasing problem in autism research -- particularly for studies with public recruitment, financial compensation for participants, and/or online data collection. The nascent body of literature on fraudulence offers few suggestions for implementing piecemeal countermeasures of unmeasured effectiveness that struggle to keep pace with the digital and methodological evolutions that have accelerated the infiltration of fraudulent data.

Objectives:

In this paper, we introduce a multidimensional typology of countermeasures and outline ways to streamline their implementation. We then reference three successive waves of data collection in an ongoing study about autistic undergraduates to: demonstrate the scale of the threat potentially posed by bots and frauds; provide explicit examples of how dozens of countermeasures can be deployed; and present initial evidence of their effectiveness.

Methods:

Following wide-ranging recruitment for our Wave 1 survey (e.g., websites, newsletters, social media) we quickly detected an influx of responses, many of which were completed within five minutes and had fake email addresses. We began implementing rudimentary countermeasures thereafter (e.g., required ".edu" email addresses, reverse coded items, ReCaptcha challenges). After 3 months, 6,477 surveys were started and 1,437 were completed. We ultimately concluded only 6.6% of started surveys and 31.9% of completed surveys were legitimate (n=430).

For Wave 2 a year later, we deployed 21 distinct types of countermeasures (e.g., screener, URL tracking, "honey pot" item) across 4 domains: Deter, Prevent, Track, and Detect. Our eventual fraud detection spreadsheet included 44 individual indicators of potential fraud, 38 of which were automatically calculated and aggregated into 4 summary scores which in turn yielded a provisional assessment of legitimacy [auto-reject, presumed-legit, or unclear] based on a 12-branch decision tree. All except the auto-rejected cases received an additional one or two rounds of human review by members of our research team before any final determination of legitimacy was made.

Results:

Although our survey link was clicked approximately 4,000 times, our preventative efforts brought the number of started surveys down from 6,477 in Wave 1 to only 1,526 in Wave 2; 334 of those failed the screener and 287 did not make it through the main survey, yielding 904 completed surveys. Ultimately, 33.4% of started surveys and 56.3% of completed surveys were deemed legitimate (n=509), a dramatic improvement over the prior year.

Wave 3 data collection is occurring in fall 2024 with even more countermeasures in place; results from this wave will be ready to present by conference time.

Conclusions:

Combating the threat of bots and frauds is fraught with challenges, complications, and compromises as researchers navigate tensions between ethics, equity, effort, and evidence. Implementation of countermeasures is limited by various types of capacity: technological, researcher knowledge and skill, time, and resource requirements (Godinho et al., 2020). However, our study demonstrates that proactive, coordinated, and comprehensive efforts to combat fraud can improve efficiency and accuracy in autism research.

401.048 Beyond the Surface: Investigating Ptss in Caregivers of Adults with Ndd

J. M. Lim¹, J. Barlas² and D. Kaur², (1)Institute of Mental Health Singapore, Singapore, Singapore, Singapore, (2)James Cook University, Singapore, Singapore, Singapore, Singapore

Background:

Caregivers of adults with neurodevelopmental disorders (NDD), particularly in Singapore, experience significant emotional and psychological distress, often exhibiting posttraumatic stress symptoms (PTSS). This study builds on prior research, exploring how the caregiving environment, behaviors of individuals with NDD, and cognitive responses contribute to the development of PTSS in caregivers. There is a gap in research regarding caregivers in multicultural, non-Western settings, which this study seeks to address.

Objectives:

The study aims to quantify the occurrence of PTSS in caregivers of adults with NDD in Singapore. Specific objectives include investigating the relationship between caregiver burden, coping strategies, and PTSS, while examining the moderating roles of cultural beliefs and caregiver burden. It also explores the mediating role of caregiver cognition in the development of PTSS.

Methods:

A quantitative, exploratory research design was employed. Participants were 45 primary caregivers of adults (aged 19 years and older) with NDD receiving treatment at Singapore's Institute of Mental Health. Data were collected via validated self-report questionnaires, including the PTSD Checklist for DSM-5 (PCL-5), Modified Overt Aggression Scale (MOAS), and Coping Strategies Inventory-S (CSI-S). Descriptive statistics, correlation, regression, moderation, and mediation analyses were conducted using SPSS version 29.

Results:

Preliminary data indicated that 11.1% of caregivers met DSM-5 criteria for PTSD, with 6.7% meeting the PCL-5 cutoff for PTSS. The most reported PTSS symptom was intrusive thoughts (82.2%), followed by arousal and reactivity (77.8%), while avoidance was least reported (42.2%). Aggressive behaviors of NDD individuals correlated significantly with caregiver PTSS ($p < 0.05$). The caregivers' adult children exhibited significant behavioral challenges, with 53.3% of caregivers identifying physical aggression as the most traumatic caregiving event, followed by verbal aggression (22.2%). Event rumination and intrusive cognition significantly mediated the relationship between aggressive behaviors and PTSS, explaining 53.3% of the variance. Coping strategies were also examined, with disengagement coping (e.g., avoidance, denial) found to significantly predict both trauma symptoms and caregiver burden ($p < 0.01$), while engagement coping (e.g., problem-solving, seeking support) did not significantly mitigate these outcomes. Disengagement coping strategies were associated with higher PTSS and greater caregiver burden. Caregiver burden moderated the impact of aggressive behaviors on PTSS, with higher burden levels exacerbating the trauma impact.

Conclusions:

This exploratory study highlights the significant psychological impact on caregivers of adults with NDD in Singapore, particularly regarding aggressive behaviors and PTSS. Cognitive processes, such as intrusive rumination, play a crucial mediating role, suggesting the need for targeted cognitive-behavioral interventions. The moderating effect of caregiver burden underscores the importance of support structures to alleviate burden and mitigate trauma impact. Future research should expand sample sizes and explore the cultural and societal influences on caregivers, and the coping mechanisms employed to manage the stressors associated with their roles to understand caregivers in non-Western settings.

401.049 Biology, Language, and Ethics: Insights on Autism Genetics Research from Diverse Perspectives

B. Life¹, J. Phan², H. Natri³ and C. van der Merwe⁴, (1)University of British Columbia, Vancouver, BC, Canada, (2)George Mason University, Fairfax, VA, (3)The Translational Genomics Research Institute, Phoenix, AZ, (4)Stanley Center for Psychiatric Research, Broad Institute of MIT and Harvard, Cambridge, MA

Background:

With the advancing understanding of autism genetics, there is a clear and pressing need for consultation with autistic constituents. The establishment of a dialogue allowing bidirectional information flow between autistic individuals, family members, and genetic researchers is anticipated to address ethical concerns, improve research quality, and ensure research goals are in alignment with community values. This is the mission of HEARD (Healthy Engagement in Autism Research Dialogue). By engaging experts in the field, we have aimed to clarify misconceptions and promote a nuanced understanding of genetic influences on autism. By bringing together diverse perspectives, we are equipped to answer the question: What does this research mean for the autistic community?

Objectives:

To report results from the first year of HEARD discussions and engage the INSAR genetics research community in a dialogue about constituent priorities, the risks and benefits of current approaches in autism genetics research, and future research directions.

Methods:

Each structured monthly meeting begins with a presentation on a topic in autism genetics by a field expert, followed by a discussion that brings together diverse perspectives to contextualize the genetic findings. Recordings of the discussions were made and subsequently analyzed to identify common themes and key findings. Where relevant, primary literature is reviewed and integrated to support results.

Results:

Analyses yielded three categories of discussion topics: those pertaining to the biology of autism genetics, communication of genetic findings, and the ethical implications of this field of research. From the summaries of biological-focused discussions, we report contemporary insights into the roles of rare and common variation in autism genetics, the relationship between autism and co-occurring conditions, and the influence of common models of autism (discrete, continuous, composite, social construct) on genetic research. Areas of disagreement, such as the definition of autism and the utility of polygenic risk scores as a predictive tool in autism diagnosis, are highlighted. How autism research is communicated in research, media, and clinical settings is found to have profound impacts on the autistic community, including negative health outcomes, misinterpretation/misapplication of results, and negative self-perception. Consequently, we provide recommendations for value-neutral, inclusive language substitutes for commonly used value-negative terminology in autism genetics research. Lastly, we integrate perspectives of autistic individuals and family members to describe ethical concerns in autism genetics research, including perceived negative impacts on the autistic community and disparities between research objectives and community priorities.

Conclusions: From a year of structured discussions with experts and constituents, we have identified discordant perceptions of the biology, language, and ethical interpretations of autism genetics research. Here, we summarize the key findings and present specific recommendations for terminology and research objectives. We aim to engage the autism genetics research community in a respectful and informative dialogue. By challenging traditional models in autism genetics, we hope to facilitate autism genetics research that is inclusive of the diversity of autistic experiences.

401.050 COVID-19 Disruptions to Autism Care: A Brief Report on Unmet Needs and Access Barriers

N. H. Zhong, Ferkauf Graduate School of Psychology, Yeshiva University, BRONX, NY

Background: Autism spectrum disorder (ASD) is a neurodevelopmental condition characterized by social communication and social interaction deficits, along with patterns of restricted and repetitive behaviors. To address these skill deficits and improve overall functioning, children with ASD require comprehensive services, including diagnostic assessments (Monteiro et al., 2016), early intervention (Choi et al. 2021; Gitimoghaddam et al. 2022), and a variety of behavioral and social interventions (Makrygianni et al. 2018; Wolstencroft et al. 2018). The COVID-19 pandemic had a profound impact on the delivery of services for children with ASD in the United States. Families reported difficulty accessing the services they needed (Srinivasan et al. 2021), heightened stress levels (Ferguson et al. 2021; White et al. 2021), and challenges obtaining educational support (Hurwitz et al. 2021). Additionally, it forced a shift towards telehealth, with mixed results regarding efficacy and accessibility (Ellison et al. 2021).

Objectives: To better understand how the pandemic exacerbated existing disparities in access to services, affecting an already vulnerable population, a needs assessment was critical for identifying the specific services required by children with ASD and their caregivers during the pandemic, as well as the barriers to accessing these services.

Methods: This study utilized a needs assessment to identify services sought by families with children with ASD under the age of 18, as well as the barriers they faced in accessing these services during the pandemic. A total of 27 caregivers of children with ASD ($M_{age} = 47.37$, $SD_{age} = 10.49$) participated in this study. A mixed method approach was utilized to while considering this small research sample size. First, descriptive statistics, including means, frequencies, and percentages, were generated to summarize findings for an overview of the responses. Second, the frequencies of services needed and the barriers were analyzed using descriptive statistics and content analysis for open-ended responses. Lastly, the relationships between the total number of services needed and the characteristics of both the caregivers and the children were analyzed quantitatively, using correlations, independent t tests and power analysis, and multiple linear regression with 1,000 bootstrapping repetitions.

Results: The most sought-after service for children with ASD was social skills training, needed by 59.3% of the families. Other frequently required services included speech therapy (51.9%), applied behavior analysis (ABA) therapy (48.2%), occupational therapy (48.2%), parent training and consultation (44.4%), and child psychotherapy (40.7%). In addition, the most frequently reported barriers to accessing services were preference for face-to-face interactions over online services ($n = 29$), limited availability of providers with expertise in ASD ($n = 19$), and child challenging behavior ($n = 18$). Lastly, multiple linear regression analyses revealed that child anger was a significant predictor of the number of services sought.

Conclusions: This study highlights the significant unmet needs for various essential services among children with ASD during the COVID-19 pandemic. The findings underscore the importance of addressing barriers to access, such as the limited availability of ASD-specialized providers and the challenges posed by child anger, to ensure that families receive the necessary support during times of crisis.

401.051 Caregiver Experiences with Autism Diagnosis in Children with Down Syndrome

G. Anzueto¹, J. Atanasova², R. Banihani^{3,4} and O. Kraus De Camargo⁵, (1)Pediatrics/McGovern Medical School at the University of Texas Health Science Center at Houston, Developmental and Behavioral Pediatrics Program at the Dan L Duncan Children's Neurodevelopmental Center at The Children's Learning Institute, Houston, TX, (2)Child Health Evaluative Sciences, SickKids Research Institute, The Hospital for Sick Children, Toronto, ON, Canada, (3)Department of Newborn & Developmental Pediatrics, Sunnybrook Health Sciences Centre, Toronto, ON, Canada, (4)Department of Pediatrics, University of Toronto, Toronto, ON, Canada, (5)CanChild Centre, McMaster University, Hamilton, ON, Canada

Background: The co-occurrence of Autism Spectrum Disorder (ASD) in children with Down Syndrome (DS) creates significant diagnostic challenges, with ASD symptoms often misattributed to DS, leading to delays in diagnosis and early interventions. While research on ASD in individuals with DS has largely focused on clinical and basic science perspectives, little attention has been given to caregivers' experiences, their interactions with healthcare systems, and the factors prompting further ASD evaluations. In Canada, research on ASD in children with DS and their families is limited. This study is among the first to explore caregiver perspectives on navigating the diagnostic process.

Objectives: Explore the experiences of caregivers whose children with DS have been diagnosed with ASD, focusing on the diagnostic journey, how they adapt to their changed lives and engage with healthcare systems.

Methods: Using a convergent parallel mixed-methods design, quantitative data were gathered through structured surveys ($n=21$), and qualitative insights were collected from semi-structured interviews ($n=11$). Participants were caregivers of children under 18 with confirmed DS-ASD diagnoses, recruited through Down syndrome associations, limiting the experiences by excluding families not connected to these groups. Those awaiting ASD assessments were excluded. Data was collected from March to June 2024, following approval from the University of Toronto's Research Ethics Board. Descriptive statistics were used to analyze survey data, while interviews underwent inductive thematic analysis.

Results: Participants were primarily from Ontario (86%), with smaller groups from British Columbia and Alberta. Caregivers described **confusion throughout the diagnostic process**, feeling "lost in the system" and "repeatedly dismissed" by healthcare professionals. Most shared that their concerns were "not taken seriously," with behaviors frequently attributed as "normal" or "typical" for a child with DS. ASD assessments were often delayed by years due to **reluctance among providers**, who felt "signs of autism could be similar to that of children with DS." For most, receiving ASD diagnosis brought emotional relief, helping them understand their child's behaviors and reframe expectations. Caregivers coped by building informal support networks, educating themselves through workshops and conferences, and establishing routines that minimized transition challenges. However, they faced ongoing challenges accessing tailored interventions and managing fragmented care. Quantitative data showed the **mean age of ASD symptom onset was 2.76 years** ($SD = 1.73$). Diagnoses occurred between **3 and 12 years**, with a **median diagnosis age** of 6 years. While most diagnoses were delayed - by about four years - a few children were diagnosed by age 4, these had a family history of ASD or intellectual disability, early regression, and access to specialized centers. Frequently reported early symptoms included repetitive behaviors (100%), speech delays/regression (90.5%), and sensory sensitivities (62%).

Conclusions: Children with DS face diagnostic delays for ASD, even though caregivers often recognize early developmental differences. Families experience emotional strain from fragmented care and highlight the need for tailored interventions, as current approaches rarely address DS and ASD together. These findings highlight the need for improved diagnostic frameworks and integrated care models that address dual diagnosis DS-ASD, with potential to shape clinical guidelines, interventions and healthcare policies.

401.052 Caregiver Psychiatric Symptoms, Assessment Delay, and Access to Supports for Children with Neurodevelopmental Conditions

K. A. Boulton¹, A. Hodge², N. Ong³, C. Middeldorp⁴, D. C. Coghill⁵, N. Silove⁶ and A. J. Guastella⁷, (1)Brain and Mind Centre, Children's Hospital Westmead Clinical School, Faculty of Medicine and Health, University of Sydney, Sydney, NSW, Australia, (2)Sydney Children's Hospital Network, Sydney, NSW, Australia, (3)The Children's Hospital at Westmead, Sydney, NSW, Australia, (4)University of Queensland, Brisbane, QLD, Australia, (5)University of Melbourne, Melbourne, VIC, Australia, (6)Sydney Children's Hospital Network, Sydney, Australia, (7)Faculty of Medicine and Health, University of Sydney, Sydney, NSW, Australia

Background: Children with neurodevelopmental conditions, such as autism, typically present with many transdiagnostic needs which extend to the broader family unit. Caregivers of these children frequently encounter substantial barriers when seeking interventions and support services, which can lead to increased stress and negatively impact their mental health and well-being. There is also evidence that caregivers with poorer mental health may also experience longer delays in accessing services for their child, which may further impact their mental health. However, the mental health of caregivers is not typically assessed as part of standard clinical practice, despite recommendations and growing evidence advocating for such assessments. Additionally, there has been little research exploring the relationship between caregiver psychiatric symptoms and their assessment and support needs during a child's neurodevelopmental assessment.

Objectives: The aim of this study was to explore the relationship between caregiver psychiatric symptoms and child diagnostic assessment delays, as well as access and needs for supports at the time of diagnostic assessment.

Methods: This cross-sectional study reports on data from the Sydney Child Neurodevelopment Research Registry. Participants were caregivers of children attending a tertiary-level assessment service for a multi-disciplinary neurodevelopmental and diagnostic assessment, commonly for autism. Caregivers completed questionnaires asking about their current psychiatric symptoms (depression, anxiety, caregiver strain). Caregivers also provided information about intervention history and use of support services, for both the child receiving assessment, and for caregivers themselves. **Results:** Participants were caregivers of 187 children aged 1.63 – 16.58 years ($M=6.97$, $SD=3.76$, 72% male). Overall, 71% of children received a diagnosis of autism. Results showed that caregivers with elevated psychiatric symptoms had a one-year delay in accessing developmental assessments, compared to children of caregivers without elevated symptoms. This was despite there being no significant difference in the age at which caregivers first detected a developmental delay in children. Caregivers with elevated psychiatric symptoms also reported a greater desire for interventions and support services for themselves and their child, and increased difficulties when attempting to access these supports. Further, caregivers with elevated psychiatric symptoms reported more barriers when accessing services compared to caregivers without elevated symptoms. Caregivers with elevated psychiatric symptoms were significantly more likely to report problems with transport, increased time to coordinate care and a lack of knowledge about where to go or who to contact, as barriers which impacted their ability to access interventions.

Conclusions: These results highlight an important and likely complex relationship between caregiver psychiatric symptoms and access to assessment and support services for children with neurodevelopmental conditions, the most prevalent of which was autism. Caregivers with psychiatric symptoms have greater service needs for themselves and their child and report more barriers when trying to access these services. Results suggest elevated caregiver psychiatric symptoms provide a useful indicator for enhanced support pathways and specialised care.

401.054 Caregiver-Reported Character Strengths of Youth on the Autism Spectrum

P. Burnham Riosa, K. Yu and S. D'Angelo, Brock University, St. Catharines, ON, Canada

Background: Historically, autism research emphasizes the deficits and challenges of autistic people. However, more recent studies aim to highlight the strengths of people on the spectrum. While strengths-focused autism research continues to develop, existing literature on strengths and positive traits of people on the spectrum is still in its early stages. Character strengths are positive traits that influence thoughts, feelings, and behaviours and allow one to think about one's life more positively. The Values in Action (VIA) Classification of Strengths is the most widely known measure of character strengths, which identifies 24 character strengths grouped into six overarching values. Although the VIA classification has been widely used among a general population of parents to help identify their children's strengths, its use in autism research remains limited. While some studies have examined character strengths in autistic people using the VIA framework, no studies to our knowledge have directly used it to measure parent-reported strengths of youth on the spectrum.

Objectives: We administered a caregiver-rated version of the VIA Youth Survey (VIA-Youth) to explore caregiver-reported strengths of youth on the autism spectrum.

Methods: Twenty-five caregivers (M age = 42.4 years; 60% female) of youth on the autism spectrum ages 10 to 17 (M age = 11.9 years; nine identified as male, 15 identified as female, and one youth identified as non-binary) participated. Our cross-sectional survey included demographic questions, a measure of daily living skills (i.e., The Waisman Activities of Daily Living Scale [WAD-L]), and an adapted version of the 96-item version of the VIA-Youth Classification of Strengths. Data analysis involved calculating descriptive statistics, including total W-ADL scores and mean scores for the VIA-Youth's 24 strengths and six virtues. We conducted additional exploratory subgroup analyses to identify the top three character strengths for youth with different support needs and youth with communication differences.

Results: Overall, caregivers' top-rated VIA character strengths were Humility (i.e., accurately evaluates accomplishments; thinks well of themselves, but is aware of their mistakes) and Appreciation of Beauty and Excellence (i.e., notices beauty and/or skilled performance in the physical environment, skills and talents, or moral goodness); the lowest-rated character strength among their children was Leadership. Of the six overarching VIA values, Courage (i.e., can face adversity), Humanity (i.e., has caring relationships with others), Temperance (i.e., engages in habits in healthy ways, manages excess consumption), and Transcendence (i.e., finds meaning in life, feels connected to the larger universe) had the highest mean scores, while Wisdom and Justice had lower mean scores.

Conclusions: The findings of our study have important implications for autistic youth, their family members, and allies. Espousing a strengths-focused orientation that highlights positive traits is essential to fostering growth, opportunity, and flourishing among youth on the spectrum. Additionally, this work may encourage researchers and practitioners to prioritize character strengths to enhance services and supports for autistic youth and their families.

401.055 Challenges and Empowerment: Autistic Mothers' Experiences with Parenting and Societal Reactions

E. M. Blijd-Hoogewys, *Psychiatrie Noord, Groningen, Netherlands*

Background:

Parenthood presents significant challenges, and for autistic mothers, these are compounded by a lack of support and societal misconceptions (McDonnell & DeLucia, 2021; Pohl et al., 2020). Autistic mothers frequently face prejudice, unsolicited advice, and ableism, complicating their parenting experience. Despite studies showing that 85% of autistic mothers find motherhood rewarding - experiencing similar levels of satisfaction, effectiveness, and parental stress as non-autistic (allistic) mothers (Lau et al., 2021; Adams et al., 2021) - they continue to face stigma and judgment. In response, the Female Autism Network of the Netherlands (FANN), a collaborative group of practitioners, researchers, and autistic women, sought to investigate the societal reactions faced by autistic mothers.

Objectives:

The objective of this study is to deepen understanding of the challenges autistic mothers face and advocate for a more inclusive and supportive parenting environment. By examining societal reactions, the study aims to raise awareness and encourage a shift toward empowerment and acceptance.

Methods:

FANN conducted an online survey to gather insights from 97 autistic mothers, all of whom had a formal ASD diagnosis. The participants had a mean age of 42.16 years (SD = 8.23), with an average age of autism diagnosis at 36.70 years (SD = 10.38). Only six mothers were diagnosed before the age of 18. The average number of children was 1.98 (SD = 0.96), with eight mothers having four or more children. A thematic content analysis was conducted to analyze the responses.

Results:

Autistic mothers reported that their children were a significant source of sensory stimuli, often leading to extreme fatigue. Many expressed fears about motherhood, including concerns about failing as a parent. Additionally, mothers frequently engaged in masking - concealing their fears and discomfort to cope, which often led to avoiding social situations.

Regarding societal reactions, many mothers noted a lack of response, largely attributed to their late autism diagnosis or reluctance to disclose their diagnosis. Dismissive remarks such as, "I don't think you have autism," or "Having a young family is tough for everyone," were common. Some mothers experienced judgment about their decision to have children, often being labeled as irresponsible, with comments like, "Do you even know what you're getting into?" Despite these challenges, some mothers did report receiving positive reactions alongside the unsolicited advice they encountered.

Conclusions:

Autistic mothers delivered a strong message about their lived experiences, emphasizing the need for increased awareness: "Most people don't understand what autism means in daily life." They also called for broader recognition that "Autism is not wrong or limited; it's just a different way of thinking." Moreover, they underscored their capability as parents, stating, "We are perfectly capable of raising children, especially autistic children."

The findings underscore the importance of listening to the needs of autistic parents, promoting greater understanding, and focusing on empowerment rather than condescension to support their parenting journey.

401.056 Family Support As a Protective Factor for Parenting Stress

S. Scott¹, H. Brown² and L. L. McIntyre³, (1)*The University of Oregon, Seattle, WA*, (2)*University of Oregon, Eugene, OR*, (3)*Special Education and Clinical Sciences, University of Oregon, Eugene, OR*

Background:

Many parents of young children with developmental delays report clinically high levels of parenting stress (Postorino et al., 2019). Importantly, higher rates of child behavior problems are correlated with increased parenting stress (Staunton et al., 2023). Early intervention often targets child challenging behavior in hopes of collateral effects on parenting stress (Kurtz et al., 2021). However, associations between parent-level and child-level demographic variables and parenting stress are not well understood. This study investigated the relationship between child challenging behavior, parent confidence, family support, child adaptive behavior, demographic information, and parenting stress in a sample of families with preschool-aged children with delays who were enrolled in a larger longitudinal randomized control trial of a parenting intervention.

Objectives:

1. Describe the relationship between child challenging behavior and parenting stress, after accounting for parent-level demographic information (e.g., income, maternal education, employment, family support), child diagnosis, and parent confidence in managing child challenging behavior.
2. Examine the role of family support in predicting parenting stress after accounting for parent-level demographic information (e.g., income, maternal education, employment), child challenging behavior, and parent confidence in managing child challenging behavior.

Methods:

Participants in this study included 181 caregivers (91% female, mean age= 32, $SD=7$) of children aged 30–36 months with developmental delay or disabilities (DD) enrolled in Oregon Parent Project: An RCT of Parent Training for Preschoolers with Delays (R01 HD059838; McIntyre, PI). Eligible children received early intervention services, had delays in adaptive behavior (standard scores between 45 and 75 on Vineland Adaptive Behavior Composite), were ambulatory, and did not experience major sensory impairments (e.g., deafness, blindness). Caregivers completed measures of parenting stress (Parenting Stress Index Short Form), parent confidence in handling child challenging behavior (Parenting Tasks Checklist), child behavior problems (Child Behavior Checklist), social support (Family Support Scale), and demographic information. Descriptive statistics and multiple regressions were used to analyze data.

Results:

Multiple linear regression was used to test if child challenging behavior, parent confidence in managing child challenging behavior, and family support significantly predicted parenting stress after accounting for demographic variables. The overall regression was statistically significant ($R^2 = 0.50$, $F(5, 169) = 35.42$, $p < 0.01$). It was found that child challenging behavior significantly predicted higher parent stress ($\beta = 0.39$, $p < 0.01$). It was found that parent ratings of support significantly predicted lower parent stress ($\beta = -0.16$, $p < 0.05$).

Conclusions:

Results suggest that for caregivers of young children with developmental delay or disabilities, there is a significant positive relationship between child challenging behavior and parenting stress. The key finding from this study was that after accounting for relevant demographic variables and child challenging behavior, parent ratings of support predicted lower parenting stress. Limitations include that all measures were parent self-report, and the Parenting Stress Index measures some overlapping information with the child behavior checklist. Future analyses will explore differences in intervention outcomes based on these baseline predictors of lower parenting stress.

401.057 Chinese American Parents' Experiences of Autism Diagnosis Process during COVID-19 and Their Family's Perceptions about Their Children's Disabilities: A Qualitative Study

J. Zhu¹ and **W. A. Machalicek²**, (1)*Texas Center for disability studies, The University of Texas at Austin, Austin, TX*, (2)*University of Oregon, Springfield, OR*

Background: Early diagnosis is crucial for early intervention in children with autism spectrum disorder (ASD); however, significant racial, ethnic, socioeconomic, and linguistic disparities persist in autism identification and access to services. Although existing studies highlight these disparities, there is a notable lack of research exploring the experiences and perceptions of Chinese parents regarding the ASD diagnostic process. The Chinese population is often underrepresented in autism research and frequently groups diverse Asian subgroups together, however, all Asians do not have the same cultural practices. The differences in autism history and the uniqueness of each Asian ethnic group provide a compelling reason to attempt to better understand Chinese American caregivers' perceptions and experience of the ASD diagnostic process.

Objectives: This study aims to examine: 1) the experiences of Chinese immigrant parents during the autism diagnosis process, and 2) their family's perceptions about their child's disabilities.

Methods: Six Chinese immigrant mothers of children with autism residing in the United States participated in 1 to 1.5-hour interviews conducted via Zoom.

Results: Five mothers noted that they first noticed their child's abnormal behavior through a lack of response to their name, while one noticed avoidance of eye contact. Initially, all six mothers attributed these concerns to limited social interactions due to COVID-19, delaying their decision to seek help. Language delay was the primary motivation for pursuing medical evaluation, with diagnoses typically occurring before age 3.

COVID-19 resulted in long wait times for a diagnosis, with one mother waiting up to a year. Some diagnoses were conducted online, raising concerns about their accuracy. None of the parents received explanations about autism, forcing them to research on their own, which further delayed access to services. One mother even sought a second diagnosis in China for confirmation. When discussing their children's conditions, all parents described their children's condition in terms of specific behavioral traits such as difficulty making eye contact, poor attention span, delayed language development, and extreme sensitivity to certain sounds. Four mothers acknowledged the unknown cause of autism, while one blamed environmental factors and another hoped for a cure. All mothers identified themselves as the primary caregivers for their autistic children and expressed feelings of being misunderstood by the children's grandparents and fathers regarding their caregiving efforts. They faced blame for not adequately caring for or educating the child, which they believed contributed to the child's autism or worsening issues. One mother mentioned that her husband and mother-in-law wished for another healthy son to carry on the family name.

Conclusions: This study offered valuable insights into the unique experiences, perceptions, and challenges faced by Chinese immigrant families. It highlighted how cultural beliefs and values shape Chinese immigrant parents' understanding of autism and their diagnostic journeys. The parents' varied emotional reactions to the diagnosis—ranging from disbelief and anger to rapid acceptance—underscore the need for tailored communication strategies that respect cultural sensitivities. Furthermore, the study identified the significant pressures experienced by mothers, informing service providers on how to better support parental well-being and improve family quality of life.

401.058 Clinician Conceptualization of Camouflaging (Social Coping) across Neurotypes and Mental Health Conditions

L. Man¹, C. H. J. Lee², A. Li³, M. Alexandrovsky⁴, W. Ai¹ and M. C. Lai⁵, (1)Centre for Addiction & Mental Health (CAMH), Toronto, ON, Canada, (2)Ministry of Health and Welfare Tsao-Tun Psychiatric Center, Tsao-Tun, Nan-Tou County, Taiwan, (3)Centre for Addiction and Mental Health, Toronto, ON, Canada, (4)Department of Psychology, University of Toronto, Toronto, ON, Canada, (5)Campbell Family Mental Health Research Institute, Centre for Addiction and Mental Health, Toronto, ON, Canada

Background:

Camouflaging (a.k.a. masking or social coping) is described as hiding neurodivergent characteristics (e.g., stimming behaviours) or adopting neurotypical social behaviours (e.g., adjusting eye contact). Little is known about how this concept is integrated into assessment and therapy delivered by clinicians, especially in the context of different neurotypes and mental health conditions with differences in social behaviour (e.g., Social Anxiety Disorder, SAD), sensorimotor behaviours (e.g., Tourette's Syndrome, TS; Attention-Deficit/Hyperactivity Disorder, ADHD), academic concerns (e.g., Learning Disabilities, LD), and emotional distress with social implications (e.g., SAD; Major Depressive Disorder, MDD).

Objectives:

Identify clinician conceptualization of camouflaging within assessment and therapy contexts across neurotypes (i.e., autism, ADHD, TS, LD) and mental health conditions (i.e., SAD, MDD) that show social differences.

Methods:

A mixed-methods survey comprising open-ended questions, multiple choice questions, and visual Likert scales was used to capture a) examples of camouflaging across neurotypes and mental health conditions and b) examples, tools and challenges of understanding camouflaging within clinical practice. Qualitative responses were analysed using thematic analysis.

Data collection is ongoing. So far, 27 clinicians participated. A majority (56%) of respondents were clinical psychologists (amongst social workers, registered psychotherapists, psychiatrists, pediatricians, behavioural therapists, and nurses) who have worked an average of 6.48 ± 7.51 years (range: 0-33). Most clinicians identified as women (88%) and were assigned-female-at-birth (85%), white (56%) and located in Canada (59%). This sample included neurodivergent clinicians, including those self-identified/diagnosed as autistic (15%, $n = 4$) or as having ADHD (33%, $n = 9$).

Results:

Among participants so far, 96% of clinicians have heard about the concept of camouflaging, endorsing a strong understanding of the concept (71 ± 22 out of 100, range 0-94). Bolded terms below indicate emerging themes from qualitative synthesis. Regarding autism, clinicians define camouflaging through examples of **adopted behaviour** (e.g., adjusting for social differences) and **hiding autism-related differences** (e.g., sensorimotor or social differences). It often has the purpose of **fitting into neurotypical environments**, can be **conscious** or **unconscious**, and has mental health **costs** (e.g., burnout). Clinicians also recognized camouflaging in the context of ADHD (63%), SAD (59%), LD (30%), MDD (30%), and TS (15%). Here, camouflaging is defined in terms of general and neurotype/condition-specific strategies (Figure 1).

Over 85% of clinicians were at least 50/100 confident in spotting camouflaging in assessment (64 ± 26 , range: 0-95) and therapy (64 ± 25 , range: 0-100). Clinicians commonly use a mixture of observation, direct inquiry, self-report measures (e.g., Camouflaging Autistic Traits Questionnaire), or building space for clients to self-report camouflaging in assessment and therapy. Accurate and direct measurement remains a key challenge in supporting clients who camouflage (Table 1).

Conclusions:

This ongoing mixed-methods study has identified camouflaging as an emerging construct which is partially integrated into current clinical practice but remains lacking in measurement and conceptual clarity. Limitations include self-selection bias from highly interested/neurodivergent clinicians. Future efforts include refining operationalization and measurement of camouflaging to facilitate clinical care across different neurotypes and mental health conditions.

401.059 Fragile Knowledge: A Computational Discourse and Sentiment Analysis of a Corpus of 60'000 Autism Research Abstracts

M. Botha¹, T. M. Burns² and C. Rutledge³, (1)Psychology, Durham University, Durham, Durham, United Kingdom, (2)University of Stirling, Stirling, United Kingdom, (3)Psychology, University of Stirling, Stirling, North Lanarkshire

Background: Autism research has been a rapidly changing field that has grown exponentially in the last few decades (Carmona-Serrano et al., 2021). Alongside a general increase in the volume of autism research there has been a growing scrutiny of autism research, for both quality and rigor. For example, autism research has said to have an issue with dehumanization of autistic people (Gernsbacher, 2007), questionable research practices (Poole, 2023), and the lack of harm measurement in intervention studies (Bottema-Beutel et al., 2021). However, its hard to get a full picture of the field given its rapid growth, fast-moving nature, and the density of the literature. Computational textual analysis, and computational discourse analysis has been used to understand attitudes towards autistic people in news media, by analysing large quantities of text in systematic ways – computationally. This type of analysis takes large amounts of information and operationalizes it using a mix of machine learning and human driven analysis. The ability to process hundreds of thousands of words makes it ideal for gaining an overarching understanding of the discourse, rhetoric, and linguistic framing of topics. Its important to understand rhetoric and discourse because the consequences of such construction are material and inform the reality of how minority groups are treated, including autistic people.

Objectives: Thus, the aim of this study was to use a computational textual analysis to model an overview of the field, to explore the rhetoric and conceptualization of autistic people, compared to non-autistic people, and to understand the sentiment with which autistic people are written about.

Methods: In this study we used computational textual analysis methods on a corpus of autism research abstracts ($N = 56829$). First, we conducted a sentiment analysis to identify the valence of the abstracts in how they talked about autistic people and whether this has shifted over time. Next, we used a Natural Language Processing method of identifying the most common Bigrams and Trigrams (which are commonly collocations of teams. These were hand-refined for meaningfulness by removing redundant collocations.

Results: Sentiment was predominantly negative and has not meaningfully changed over time. The collocations of words show a pervasive and particular focus that associates autism with childhood, and pathologizes it as disorder, dysfunction, focuses on co-occurring conditions and prioritizes biological research. Topic modelling supports this focus. Furthermore, non-autistic people were associated with more positive adjectives than autistic people, as well as more agency and power (for example with active verbs, instead of passively). Sentiment analysis between autistic and non-autistic people showed that autistic people were discuss with significantly higher disgust ($p < .01$), fear ($p < .01$), and anger ($p < .01$).

Conclusions: Meta-science about the field is important, including in how we as researchers construct and discuss autistic people. Computational methods are an ideal way for understanding the overview of the field, as well as for paying particular attention to linguistic and rhetorical constructions of autistic people and how it might shape the field.

401.060 Co-Regulation Among Hispanic and Non-Hispanic Mothers of Children with Autism Spectrum Disorder

S. Guadarrama¹, S. I. Diaz² and J. N. Phung², (1)California State University San Marcos, San Marcos, CA, (2)Psychology, California State University San Marcos, San Marcos, CA

Background:

Co-regulation is an interactive process that occurs when parents assist their children in regulating emotional distress (Lobo & Lunkenheimer, 2020). Strategies used during parent-child interactions may influence a child's later ability to effectively regulate their emotional distress on their own (Robson et al., 2020). Children with Autism Spectrum Disorder (ASD) have more difficulties with emotional regulation, thus making successful co-regulation challenging (Valentovich et al., 2018). Studies evaluating interventions to optimize co-regulation between dyads are heavily based on non-Hispanic samples, rooted in Western cultural values.

Objectives:

Given that there may be co-regulation differences as a function of cultural values, the present study aimed to build on existing research by examining the relationship between co-regulation and cultural values of Hispanic mothers raising children with ASD. Specifically, this study explored *marianismo* (i.e., feminine gender role) and *familismo* (i.e., prioritizing family needs) and the quality of mother-child co-regulation.

Methods:

Twenty mothers completed the study questionnaire, which included demographics and the following measures: the Social Communication Questionnaire (Rutter et al., 2003) to assess ASD symptoms; the *Marianismo* Beliefs Scale (Castillo et al., 2010) to assess endorsement of traditional gender role expectations; Sabogal's Familism Scale (Sabogal et al., 1987) to assess familism values; and the Parent Stress Index – Short Form (Abidin, 1995) to measure parenting stress. Eighteen of the 20 mother-child dyads participated in a video recorded observational play-session, which involved three timed phases separated by untimed clean-up transitions (Figure 1). Mutual engagement states were coded so that higher scores of positive engagement indicated good co-regulation (e.g., dyadic enjoyment and attunement) and higher scores of negative engagement indicated poor co-regulation (e.g., dyadic negative affect and less attunement).

Results:

Results demonstrated that there were no significant differences in adherence to Hispanic cultural values between Hispanic and non-Hispanic mothers. *Familismo* did not predict lower parenting stress, but Hispanic mothers had higher parenting stress than non-Hispanic mothers. Hispanic mothers also had higher scores on the 'Family as a Pillar' subscale in the *Marianismo* Beliefs Scale compared to non-Hispanic mothers, suggesting that Hispanic mothers agreed more with beliefs that women are the main source of strength of the family. Although cultural values did not significantly predict co-regulation patterns, trending findings indicated a positive relationship between *marianismo* and positive engagement, and a negative relationship between *familismo* and positive engagement. Negative relationships were also indicated between *marianismo* and negative engagement, and between *familismo* and negative engagement. Possibly, *marianismo* and *familismo* scores may differentially predict mothers' interactions with their children.

Conclusions:

The present study contributed to existing research on co-regulation among minority families by examining co-regulation in a diverse sample of mothers of children with ASD and exploring its potential association with Hispanic cultural values (i.e., *marianismo* and *familismo*). Future directions include focusing on recent immigrants who may exhibit a heightened adherence to Hispanic cultural values compared to highly acculturated Hispanics. This work adds to the growing literature informing culturally sensitive practices when working with Hispanic families affected by ASD.

401.061 Collaborating for Change: Adapting an Autism Parent-Mediated Intervention for Spanish Speaking Latinos

A. Garrido¹, M. Montenegro¹, A. C. Ramirez², M. Ortiz³, G. Matheus⁴, V. L. Villarreal⁵, B. Villalobos⁶, N. Fresno Cañada⁷, G. Gonzalez Nuñez⁷, R. Calderon⁸, S. Perez⁹, M. Mares¹⁰ and C. Montiel-Nava², (1)University of Texas Rio Grande Valley, Edinburg, TX, (2)Department of Psychological Science, University of Texas Rio Grande Valley, Edinburg, TX, (3)Psychology, University of Texas Rio Grande Valley, Edinburg, TX, (4)The University of Texas Rio Grande Valley, Edinburg, TX, (5)Department of Psychological Science, University of Texas Rio Grande Valley, Edinburg, TX, (6)California State University, Northridge, Northridge, CA, (7)UTRGV, Edinburg, TX, (8)University of Texas Rio Grande Valley, Edinburg, TX, (9)Autismo en mi Vida Rio Grande Valley, Edinburg, TX, (10)United Way of South Texas, McAllen, TX

Background: Access to autism care is often challenging for Latino families due to barriers such as language disparities, stigma, limited availability of culturally competent providers, and socioeconomic factors. Research indicates that with appropriate support, parents can effectively implement intervention strategies and achieve positive outcomes. Involving parents as therapists enables cost-effective, individualized interventions that are easy to implement and generalize while also boosting parental efficacy. Additionally, parent-mediated interventions (PMIs) have been successfully utilized across various ethnic and minority groups, including Latinos. For low-income and marginalized populations, PMIs that are affordable, easy to implement, culturally adaptable, and not require a formal diagnosis help to close treatment gaps.

Objectives: The purpose of this study was to culturally and linguistically adapt the Spanish-version of the World Health Organization Caregiver Skills Training (WHO-CST) for a predominantly Spanish-speaking Latino-populated region in the United States.

Methods: The current study employed a community-based participatory research (CBPR) approach and utilized a phenomenological framework to assess the content and cultural relevance of the Spanish translation of the CST. Program materials were first forward translated to Spanish, then reviewed by four bilingual doctoral students, and finally revised by experienced translators. Once a harmonized Spanish translation was achieved, three 90-minute focus groups were held with Spanish-speaking and bilingual parents (n=18) of children diagnosed with autism spectrum disorder (ASD) to gather insights on potential modifications required to create a culturally responsive and linguistically suitable curriculum. Descriptive statistics were conducted to summarize participants' demographics. Data collected from the focus groups was analyzed using applied thematic analysis.

Results: 27.8% (n=5) of the children had co-occurring conditions, including Intellectual Disability (IDD) and Cerebral Palsy (CP). Of the children, 83.3% (n=15) were male, while 16.7% (n=3) were female. The children's ages ranged from 9 to 17 years ($\bar{x}$ =11.8; SD= 2.11). All caregivers in the study were mothers, and 72.2% (n=13) were bilingual, speaking both English and Spanish, while the remaining 27.8% (n=5) spoke only Spanish. Focus groups conducted resulted in significant adaptations to the Spanish translation of the CST, yielding different subthemes embedded in three main adaptations groups: linguistic, content and environmental adaptations. Findings highlighted the importance of verbiage use by professionals to avoid reinforcing negative stereotypes and to promote empathy and respect for how Spanish-speaking Latino parents perceive certain words. Furthermore, participants emphasized the value of *personalismo* which entails providers transmitting professionalism and warmth and highlights the importance of personalized attention and courtesy in interpersonal interactions.

Conclusions: Through community partnerships and consultations, the present study develops a culturally sensitive and linguistically appropriate version of the CST specifically for Spanish-speaking Latinos, enhancing the overall feasibility and accessibility of the program. Additionally, this study emphasizes the critical need to understand the linguistic and cultural backgrounds of end users before implementing or providing services within the autistic community. By highlighting the value of stakeholder input, the research demonstrates how collaborative efforts can lead to more effective interventions that resonate with unique experiences and needs of Latino families, ultimately promoting better outcomes for parents and children in autism care.

401.062 College Student Viewing and Ratings of Film and Television Representations of Autism

M. Dean¹, A. Kroll¹ and A. Nordahl-Hansen², (1)Education, California State University Channel Islands, Camarillo, CA, (2)Østfold University College, Halden, Norway

Background:

Film and television productions can increase viewers' knowledge of autism; as audiences learn about the lived experiences of autistic individuals based on the storyline enacted during the production (Nordahl-Hansen et al., 2018a). Fictional portrayals of autism have been used effectively as an educational tool in clinical and professional development settings (Jerrentrup et al., 2018; Nordahl-Hansen et al., 2018b; Stern & Barnes, 2019). In contrast, other portrayals have perpetuated stereotypes and misinformation about autism (Dean & Nordahl-Hansen, 2021; Jones et al., 2022b), which can negatively impact the lived experiences of autistic people (Jones, 2022a; Orm et al., 2023).

Objectives:

This study examines the extent to which college students a) view films and television shows with autistic characters, and b) rate the authenticity of autistic portrayals.

Methods:

University students (n=91) completed a three-part survey, including a demographic survey, the Social Distance Scale (Gillespie-Lynch et. al, 2015), and the Autism Representation Survey. The Autism Representation Survey was designed for this study and used a multiple choice format to ask participants if they had watched part or all of recent film and television shows featuring fictional autistic characters (*As We See It* (Amazon; 2022), *Atypical* (Netflix; 2017-2021), *Cha Cha Real Smooth* (2022), *Everything's Going to be Okay* (Hulu; 2020), *Extraordinary Attorney Woo* (Netflix; 2022), *Heartbreak High* (Netflix; 2022), *Sesame Street* (Max; 2017-2024), *The A Word* (BBC; 2016-2020), *The Good Doctor* (ABC; 2017-2024)).

Results:

On average, participants had watched about two and a half shows (m =2.52, SD =1.69). For each show, participants reported watching a) the entire show or series, b) part of the film or series, c) only one or two episodes, d) trailers or clips, e) never. The most widely viewed shows were *Atypical*, (19.80% watched the full series and 14.30% watched part of the series), *The Good Doctor* (7.70% watched the full series and 20.90% watched part of the film or series), and *Sesame Street* (4.40% watched the entire series and 18.76% watched the part of the series). Participants rated the authenticity by selecting the three they deemed the most authentic portrayals of autism. Shawn Murphy from *The Good Doctor* (49.5%), Sam Gardener from *Atypical* (23.3%), and Julia from *Sesame Street* (20.9%) were selected most frequently. To examine stigma patterns in relation to participant authenticity ratings, Social Distance Scale composite scores were divided into "High Stigma" and "Low Stigma" scores. Chi-square tests revealed a significant relationship between high stigma ratings and the authenticity ratings of two female characters (Matilda and Julia). Participants with high stigma scores rated these two characters as less authentic than participants with low sigma scores.

Conclusions:

Participant ratings of autistic characters who are white, male savants as being more believable suggests that media overrepresentation of common autism tropes influence audiences' perceptions of autism. Participants with high stigma rated the character of Matilda as less authentic, which is surprising given that the character is played by an autistic actress. These exploratory results highlight the need to examine a possible bias in audience-perceptions of female or gender diverse autistic characters.

401.063 College Students' Explicit Attitudes, Experiences, and Impressions of Autism

S. I. Diaz and J. N. Phung, Psychology, California State University San Marcos, San Marcos, CA

Background:

Academic success relies on interpersonal skills, such as assuming different roles, adjusting to social environments, and building social relationships (Hillier et al., 2017). Despite similar or higher academic engagement compared to their neurotypical (NT) peers (McLeod et al., 2019), autistic college students have lower graduation rates (Kitchin & Karlin, 2021). Autistic students are at risk for social stigma from non-autistic peers, leading to negative social interactions (Bailey et al., 2019). Hesitation to engage with autistic students may stem from a lack of awareness about ASD, influenced by personal attributes like experience with autistic people (White et al., 2016). Additionally, NT college students with more autistic traits themselves held more negative attitudes toward autistic students (Matthews et al., 2015; Wang et al., 2022).

Objectives:

NT students may perceive their autistic peers more positively when a diagnosis is disclosed (Wang et al., 2022). To better understand the predictive role of diagnosis disclosure and personal attributes, we utilized fictional vignettes to examine college student attitudes toward their autistic peers.

Methods:

Undergraduate students ($n = 438$; 74.2% women) at a public university read three vignettes about hypothetical college interactions. Two vignettes described a (labeled and unlabeled) autistic student; the third vignette described a NT student. Participants reported on their autism characteristics using the Broad Autism Phenotype Questionnaire (BAPQ; Hurley et al., 2006), their experiences with autism, and first impressions of the word “autism”. The questionnaires were scored per the scoring instructions, and the “first impressions” responses were qualitatively coded by two independent coders for positive, negative, and neutral valence.

Results:

Analyses revealed that women participants and those with more autism traits had more negative attitudes toward the unlabeled autistic student. Additionally, participants who had fewer autism traits as well as those who identified personally knowing someone with autism had less negative attitudes toward the labeled autistic student (Table 1). Valence analyses revealed participants who reported a negative statement when asked about the word “autism” had more negative affective attitudes toward the labeled autistic student compared to those who reported a positive statement whereas participants who reported a negative statement had more negative cognitive attitudes compared to those who reported a neutral statement (Figure 1).

Conclusions:

The present study expands on previous work examining attitudes and experiences of NT college students toward their autistic peers. Our results indicate the importance of experiences and diagnostic disclosure when considering college students’ perceptions of their autistic peers. Explicit impressions of autism were only related to attitudes when the participant was made aware of the character’s autism diagnosis. Supporting previous work, the fewer autism traits a participant had, the less negatively they felt toward both autistic students, and the less negatively they perceived the labeled autistic student. Future directions should further explore NT college students’ perceptions of autism in naturalistic settings, as participants’ responses to a fictional vignette may differ from their real-world beliefs and actions toward autistic people. Implications of this research include creating more inclusive college spaces for autistic students to succeed both academically and socially.

401.064 Community Perspectives of Sensory Underpinnings of Autistic Feeding Challenges

B. M. St John¹, C. M. Brown², C. Mosca³, M. Doblin⁴, G. Moschonis⁵, R. Belski⁶, A. Mudholkar⁶ and A. E. Lane⁷, (1)University of Washington, Seattle, WA, (2)Olga Tennison Autism Research Centre, La Trobe University, Bundoora, VIC, AUSTRALIA, (3)CSIRO, Werribe, VIC, Australia, (4)La Trobe University, Melbourne, VIC, Australia, (5)La Trobe University, Melbourne, VIC, Australia, (6)Olga Tennison Autism Research Centre, La Trobe University, Bundoora, VIC, Australia, (7)Olga Tennison Autism Research Centre, La Trobe University, Melbourne, VIC, Australia

Background:

Feeding challenges presenting as food refusal, restricted eating, avoidance of new or unfamiliar foods, and adverse mealtime behaviour are highly common in autism (up to 84%) and are nominated by caregivers of autistic children as amongst the most stressful of parenting issues (Leader et al., 2020). Sensory differences including over- or under-responding to common sensory stimuli may underpin autistic feeding challenges. In reports of autistic feeding challenges from families and clinicians, responses to the sensory quality of foods are often described as overly intense resulting in strong, aversive physical, emotional and/or behavioural reactions to foods. To date, however, there has been no comprehensive examination of the sensory underpinnings of autistic feeding challenges.

Grounding research on the lived experiences of the relevant community is an essential first step in any program of research. Understanding relevant lived experiences provides valuable insight into the expertise, capacity, and needs of the community. In this study, therefore, we sought the lived experience community perspectives on the contribution of sensory differences to autistic feeding challenges.

Objectives:

The objective of this research was to describe the perceptions of autistic adults and caregivers of autistic people (the lived experience community) of the significance of sensory contributions to autistic feeding challenges.

Methods:

Autistic adult (n=8) and carer (n=3) participants participated in one of three focus groups. All groups were run online and were facilitated by a member of the research team with at least one other member of the team in attendance. Community perceptions of the significance of sensory contributions to autistic feeding challenges were explored in the groups through sharing of summaries of literature and lived experiences. First, participants were encouraged to share their experiences via a semi-structure discussion guide. Second, a short presentation of the published literature to date on sensory underpinnings of autistic feeding challenges was given by the research team. This was followed by continued facilitated discussion to capture community reactions to presented literature and additional thoughts or priorities.

Each focus group was recorded, transcribed and thematically analyzed. Three members of the research team independently coded the transcripts for themes within and across participants. Final themes were developed through an iterative process of independent coding and group discussion until consensus was reached.

Results:

Sensory experiences were individualized across participants with many describing in detail their specific sensory responses. However, despite variability participants reported considerable overlap in their preferences and aversions in regard to the sensory properties of foods. Three primary themes were identified across participants: 1) consistency and predictability is essential for food acceptance, 2) sensory preferences drive food acceptance and refusal, and 3) autistic individuals adjust their eating and mealtime experiences to match their sensory preferences and daily regulation needs. Themes and subthemes will be covered in detail during this presentation.

Conclusions:

Findings from this study provide insight into the sensory underpinnings of autistic feeding challenges including both the individuality of sensory experiences and overlapping preferences related to the sensory properties of foods.

401.065 Conceptualizing and Measuring "Problem Behavior" in Early Intervention Autism Research: A Secondary Systematic Review and Evaluation

K. Bottema-Beutel¹, R. Guo², J. Hinson-Williams³, Y. Shen³, S. C. LaPointe⁴, T. G. Woynarowski⁵ and M. Sandbank⁶, (1)Lynch School of Education and Human Development, Boston College, Chestnut Hill, MA, (2)Teaching, Curriculum, and Society, Boston College, Boston, MA, (3)Teaching, Curriculum, and Society, Boston College, Chestnut Hill, MA, (4)University of North Carolina-Chapel Hill, TEACCH Autism Program, Carrboro, NC, (5)Department of Hearing and Speech Sciences, Vanderbilt University Medical Center, Nashville, TN, (6)The University of Texas at Austin, Austin, TX

Background: Some autistic children exhibit behavior that caregivers, clinicians, and researchers consider problematic, and that may negatively impact their quality of life (Sivathasan et al., 2024). However, there is little consensus about the types of behaviors that constitute a problem, and therefore should be reduced via intervention. In autism intervention research, behaviors labeled “problem behavior” range from inherently harmful behaviors such as aggression and self-injury, to non-normative but not harmful behaviors such as repetitive movements or adherence to routine. Reflecting the variety of ways that problem behavior is conceptualized, researchers also use a variety of measurement systems to assess this construct. Understanding how problem behaviors are conceptualized and measured in autism research is especially important because the presence of problem behavior is often used to justify intervention approaches that many autistic people find objectionable (e.g., punishment-based approaches) (Adams & Erevelles, 2017).

Objectives: We conducted a secondary systematic review of group-design, non-pharmacological intervention studies for autistic children up to age eight to explore researcher conceptualizations of problem behavior, and the measurement systems researchers use to assess problem behavior.

Methods: Studies were selected from a parent systematic review that included 289 intervention studies published prior to November of 2021, the most recent search date. For the secondary review, we located any study in our database in which specific behaviors were targeted for reduction or elimination; 102 studies met this criteria. A coding scheme was applied to these studies by two independent coders to determine: (a) whether reducing problem behavior was described as a purpose of the intervention, (b) the rationale for targeting behaviors for reduction, (c) how the behavior was conceptualized, and (d) how the behaviors were measured. We also consulted instrument manuals and relevant literature to summarize validity and reliability information for the ten most commonly used measures.

Results: Forty-seven percent of studies described reducing behavior as a primary or secondary purpose of the study and/or intervention, 33% gave a rationale for targeting behaviors for reduction, and 28% offered some conceptualization (i.e., gave a conceptual definition, listed examples, or described impacts) of the behavior(s) they targeted. Only 8% offered a conceptual definition. The most commonly used measurement systems were “off-the-shelf” instruments (i.e., at least some validation beyond inter-rater reliability), and were administered as parent reports. Of the ten most common instruments, only two were validated along six different validation dimensions in autistic populations. All but one full scale or subscale assessed behaviors that were either: (a) non-normative but not inherently harmful, or (b) a mix of inherently harmful and non-normative but not inherently harmful.

Conclusions: The construct of “problem behavior” is inadequately conceptualized in the context of intervention research for young autistic children, and assessed by instruments that are lacking across several dimensions of validity. Intervention researchers should provide clear definitions and rationales for targeting behaviors for reduction via intervention, and should develop refined measurement tools for assessing these behaviors in collaboration with the autistic community.

401.066 Consensus Recommendations for Usability and Acceptability of Mobile Health Autism Screening Tools

G. Tangkilisan¹, L. Rivas Vazquez², P. Fuch³, B. W. Sanders⁴, J. K. Dolata⁵, S. Bedrick⁶, E. Fombonne⁶, S. Broder-Fingert⁷ and K. Zuckerman⁸,
(1)Department of Pediatrics (Division of General Pediatrics), Oregon Health and Science University, Portland, OR, (2)Department of Pediatrics (Division of General Pediatrics), Oregon Health & Science University, Portland, OR, (3)University of Massachusetts Medical School, Worcester, MA, (4)Department of Medical Informatics and Clinical Epidemiology, Oregon Health & Science University, Portland, OR, (5)Department of Pediatrics, Oregon Health & Science University, Portland, OR, (6)Department of Psychiatry, Oregon Health & Science University, Portland, OR, (7)UMASS Medical School, Boston, MA, (8)Division of General Pediatrics, Oregon Health & Science University, Portland, OR

Background:

Parents who have developmental concerns about their child may find autism screening tools online. Healthcare providers may also encounter these tools in practice. Online screening tools may improve autism screening through advanced technologies and improved connection to services. However, language, cultural, and technological barriers may impede equitable access to care.

Objectives:

Create consensus recommendations amongst parents, health and educational providers, and autistic adults for equitable design of autism screening apps and websites.

Methods:

We used consensus methodology to develop recommendations for improved online autism screening tool design. There was a total of 14 panelists: 2 pediatricians, 1 child psychiatrist, 2 tool developers, 3 early intervention providers, 3 autistic adults, and 5 parents of children with autism participated in a Modified Delphi panel. Some participants had multiple roles.

The panel included 3 asynchronous rounds of online discussion and voting using Slack (a collaborative communication software), and one live online Zoom videoconference. Participants received a multimedia summary (written summaries, videos, interactive polls) of research on screening tool usability/accessibility, and a list of 28 preliminary design recommendations from our prior research. Each round, participants suggested alternative or additional recommendations, and voted for recommendations. The recommendation list was iteratively revised and reduced. In the final voting round, recommendations were grouped into categories. A final consensus guideline was developed based on the discussions from the videoconference.

Results:

The consensus panel produced 19 final recommendations (Table 1), in 5 conceptual categories: transparency, equity, access, product design and user experience, and development process. There was a total of 50, 70, and 45 comments/suggestions during each asynchronous voting round respectively.

The top three highest ranked statements were “tools should directly link to sources of information about autism and/or community resources, and should allow parents to directly refer the child to child development programs (e.g. Early Intervention)”, “tool’s reading level should be 5th grade or less and should be easily understandable for parents with elementary level math education,” and “tools should be developed for the wide range and variability of behaviors, needs, strengths, and individual experiences associated with autism, including both children with high support needs and children with subtle, atypical, or inconsistent behaviors and presentation.”

Panelists prioritized recommendations that supported family familiarity with autism and systems of autism care. In particular, panelists expressed that tools need linked resources to information about autism and community resources, with an emphasis on local interventions and reputable resources.

Conclusions:

A multidisciplinary panel can translate research findings to actionable recommendations for tool developers for equitable autism screening. Direct input from individuals impacted by current autism screening guidelines can help create guidelines that reflect stakeholder experience.

401.067 Coping and Social Support Among Caregivers of Children Diagnosed with ADHD, Autism, or ADHD+Autism

M. Howard¹, S. Anderson², M. Menezes³ and M. Mazurek³, (1)Department of Human Services, University of Virginia, Charlottesville, VA, (2)Child Study Center, Yale School of Medicine, New Haven, CT, (3)University of Virginia, Charlottesville, VA

Background: Caregivers of children with neurodevelopmental differences, such as attention-deficit/hyperactivity disorder (ADHD) and autism, face unique stressors that may affect coping and access to social support. The compounding effects of behavioral difficulties and the high need for support (e.g., therapies/services) of some children with neurodevelopmental conditions can lead parents to becoming fatigued, which may impact their ability to effectively cope with caregiving demands. Additionally, there are mixed findings on how caregivers of children with ADHD, autism, or ADHD+autism access social support compared to caregivers in the general population. To best meet the needs of caregivers of children with ADHD and/or autism in child-rearing responsibilities, a deeper understanding of their potential strengths or buffers to stressors, including caregiver coping and social support, is needed.

Objectives: This study explored whether there are differences in caregiver coping and social support among caregivers of children with ADHD, autism, and ADHD+autism.

Methods: Data were obtained from the 2022 National Survey of Children's Health, a nationally distributed caregiver-report survey of child health and well-being. Participants were limited to caregivers of children aged 3-17 years ($M = 11.51$ years; 67% male) with a current autism diagnosis ($n = 5,906$). Caregiver coping was operationalized as how well the caregiver was "handling the day-to-day demands of raising children." Responses were dichotomized to "very well" and "somewhat well/not very well/not very well at all." Social support was assessed with the question, "During the past 12 months, was there someone that you could turn to for day-to-day emotional support with parenting or raising children?" Responses were dichotomized into "yes" and "no." We ran multiple binary logistic regressions with caregiver coping as the outcome in one model and caregiver social support as the outcome in the other model. The substantive predictor was caregiver group (ADHD+autism as the referent, compared to ADHD only and autism only). Covariates included child age, race, sex, co-occurring intellectual disability, co-occurring behavior problems, family income, and single parent household.

Results: Results indicated that, accounting for covariates, diagnostic group (ADHD, autism, ADHD+autism) did not significantly predict caregiver coping. Nonetheless, having a child with ADHD only was significantly related to caregiver social support ($B = .27, p = .006$) as compared to having a child with ADHD+autism. Caregivers of children with ADHD reported 1.30 times the odds of having social support compared to caregivers of children with ADHD+autism.

Conclusions: Our findings revealed that having a child with ADHD+autism was associated with a lower likelihood of having social support than having a child with only ADHD. However, diagnostic group (i.e., ADHD, autism, ADHD+autism) was not significantly associated with how well caregivers were handling the day-to-day demands of raising children above and beyond other factors. The results highlight that caregivers of youth with ADHD+autism may be at particular risk for lacking needed social support. Social support is amenable to intervention, and results should inform policies (e.g., increasing access to care) and practices (e.g., incorporating wellness of parents into treatment planning for their children) to optimize supports and functioning of caregivers of children with these neurodevelopmental conditions.

401.068 Correlations between Support Network for Autistic People, Levels of Support and Hours of Therapy According to the Mapa Autismo Brazil.

I. Farias¹, D. Vieira², L. de Oliveira³, G. M. Souza³, L. H. Santana³, C. Vieira³, J. Mourão³, A. C. Steinkopf⁴ and V. R. D. Gomes¹, (1)Nacional Council of Science and Technology Development, Brasilia, Federal District, Brazil, (2)Steinkopf Institute, Brasilia, Federal District, Brazil, (3)Steinkopf Institute, Brasilia, Federal District, Brazil, (4)University of Brasilia, Brasilia, Federal District, Brazil

Background: The Mapa Autismo Brasil - MAB (Autism Map Brazil) is the first Brazilian non-governmental data survey whose objective is to map the profile and sociodemographic characteristics of people diagnosed with autism in the country. The first stage of the MAB took place in the Federal District in 2023.

Objectives: This study aims to correlate percentage data collected in MAB Stage I regarding the existence of support networks by level of support and compare this finding with the number of hours of therapy reported by respondents.

Methods: The study used non-probability convenience sampling, aiming for a minimum of 382 participants. Data collection was carried out through an online survey from July to September 2023, with responses collected from autistic individuals or their guardians in the administrative regions of the Federal District, Brazil. The survey covered demographics, support levels, educational experiences and other relevant topics. 1,699 valid responses were obtained.

Results: The results obtained indicate that, regarding the level of support reported by the respondents, 56.15% were diagnosed at Level 1, 31.08% at Level 2 and 7.65% at Level 3, denoting an inversely proportional relationship with data from average age of diagnosis: Support Level 3, 4 years; Level 2, 5 years and Level 1, 12 years. Regarding the existence of a support network for autistic people, they responded that they had a support network in times of crisis or similar: 70.55% of autistic people Support Level 1, 61.74% of autistic people Support Level 2 and 44.62% Level 3, also observing an inversely proportional relationship between these variables. The research does not present sufficient elements to infer the reasons for this finding. One hypothesis is that, due to the complexity of care, it is greater as the need for support increases, requiring, proportionally, greater preparation, familiarity and time allocation, it becomes more difficult to have an effective support network for people with greater need for support. It was also found that autistic Support Level 3 people were the population group that had the highest percentage of 'not currently undergoing therapies', at 32.31%. Of those who undergo therapy and are classified as Level 3 of Support, only 13.85% do so for more than 10 hours per week and 20.77% between 5 and 10 hours per week. Would this reality be linked to the lower percentage of existence of a support network (44.62%) or the reasons for the lower number of hours of therapy in a population group that would need greater intensity and therapeutic density would be linked to other difficulties, such as issues financial?

Conclusions: The data obtained in the 1st stage of the MAB show greater vulnerability of Support Level 3 autistic individuals in relation to the support network, completion and length of therapy. The study provided an information-rich portrait of the population profile of autism and raised other questions relevant to understanding the fundamental singularities in autism related to support networks and the implications of their existence or not.

401.069 Creating a Caregiver Education Program with Chinese Caregivers of Autistic Children: A Community Engaged Process

Y. Yang¹, **Q. Pan²**, **Y. Xin³**, **X. Liu⁴**, **H. Qiu⁵**, **M. Y. S. Bak⁶**, **A. D. Duenas⁶**, **A. M. Reilly⁷** and **N. Dumas²**, (1)Special Education, Lingnan Normal University, Zhanjiang, Guangdong, China, (2)Educational Psychology, University of Minnesota - Twin Cities, Minneapolis, MN, (3)Department of Special Education & Counseling, Education University of Hong Kong, Hong Kong, New Territory, Hong Kong, (4)Educational Psychology, University of Minnesota, Minneapolis, MN, (5)Psychology, University of Minnesota - Twin Cities, Minneapolis, MN, (6)Counseling, Educational Psychology, and Special Education, SDSU, East Lansing, PA, (7)Educational Psychology, University Of Minnesota - Twin Cities, Minneapolis, MN

Background: Chinese caregivers face unique challenges when providing support for their autistic children. Despite a growing body of research highlighting the advantages of caregiver education for both autistic individuals and their caregivers, little is known about what Chinese caregivers of autistic children may want and need within caregiver education. If caregiver education were to be utilized to its full potential to mitigate service disparities; accessibility, sustainability, and acceptance decided by caregivers are critical. However, in many of the extant literature investigating effectiveness of caregiver education, caregivers are typically relegated to the role of passive recipients (i.e., study participants) rather than active contributors; and crucial aspects of caregiver education programs, such as content, modality, duration, and accessibility are determined by researchers. Furthermore, research emphasizes the development and utilization of culturally appropriate education materials for caregivers from diverse backgrounds

Objectives: This preliminary study aimed to address this gap by gathering perspectives and insights into the specific needs and preferences of Chinese caregivers of autistic children in the *pre-development stages* of creating a caregiver education program using a community-engaged approach. We conducted two-stages of focus group discussions with Chinese caregivers of autistic children: 1) before development of the caregiver education content using an interview guide and 2) after we had built two prototype video modules based on the first focus group discussions.

Methods: We invited 14 Chinese caregivers of autistic children to share their needs and perspectives on the content and delivery of a caregiver education program. The study employed a qualitative design, utilizing focus group discussions as the data collection strategy. Focus Group 1 was focused on the content participants would like to see in a comprehensive caregiver education program. After Focus Group 1 was completed, we analyzed the results and created two prototype education videos based on participant feedback. The prototype videos served as topic guides for the Focus Group 2 and focused on the delivery method the participants would like for a comprehensive caregiver education program.

Results: Three themes were identified from Focus Group 1: a) understanding autism from cause to intervention, b) learning behavioral principles and techniques, and c) support for caregiver mental health. Two themes were identified from Focus Group 2: considerations for accessible language and cognitive load, and the importance of case examples and modeling.

Conclusions: We integrated caregivers into the pre-development process of caregiver education materials and attempted to equalize the power imbalance between researchers/professionals and caregivers. The three identified themes related to the content of online caregiver education programs serve as a window reflecting a preliminary view of current services for autistic children and their families. Accessibility of information also emerged as a crucial factor for caregivers. This underscores the need to provide caregivers with definitions and the historical backgrounds of some of the medical or Western-originated terms to increase caregiver self-efficacy. Another notable finding was that the participants asked for increased modeling emphasized by the shortage of quality practitioners in autism intervention.

**401.070** Creating a Community of Support for Black Parents of Autistic Individuals

H. Onovbiona¹, **P. Moreno²**, **E. A. S. del Rosario³** and **L. B. Quetsch¹**, (1)University of Arkansas - Fayetteville, AR, Fayetteville, AR, (2)University of Arkansas, 72701, AR, (3)University of Arkansas, Fayetteville, AR

Background: To date, autism literature has narrated the many barriers experienced by Black caregivers of autistic individuals as they navigate receiving care for their child. Some of these barriers include the stress and racial trauma that families face, including racial microaggressions from providers, racial discrimination, and challenges accessing resources and services (Onovbiona et al., 2023; Weitlauf et al., 2023). In addition, Black caregivers also report experiencing poor support from families and community members due to differences in beliefs about autism in their community (Drame et al., 2020; Onovbiona et al., 2023). Few interventions and services have leveraged Black cultural strengths, including social support, story-telling, and collective activities (Johnson & Carter, 2020; Kaiser et al., 2022). Indeed, Black caregivers of autistic youth call for more support: "I think we do need more of our own support groups because a lot of times when you get the diagnosis, your family isn't gonna rally around you" (Onovbiona et al., 2023; p.10).

Objectives: The present study explored if participation in a culturally-informed support group led to changes in caregiver empowerment and stress.

Methods: To address this gap, we piloted a 5-session virtual support group for caregivers raising Black autistic individuals ($N=7$) that incorporated storytelling, communalism, and collectivistic service-driven activities centered around better care for Black autistic individuals. Surveys and interviews were used to assess for changes in parental stress, empowerment, healing of racial trauma, and satisfaction of the support group.

Results: By the end of the support group, caregivers demonstrated significant reductions in parental stress, ($t(5) = 4.716, p = .003$) and gains in perceived empowerment ($t(6) = -2.230, p = .034$). Qualitative findings highlighted the areas of the support group that contributed to caregiver satisfaction (e.g., connection, solution-focused components). Time was noted as a prominent barrier.

Conclusions: The study provided preliminary evidence that utilizing a culturally responsive support group could reduce caregiver stress, increase empowerment, and promote racial trauma resilience among caregivers raising Black autistic youth.

401.071 Depressive and Anxiety Symptoms Among Parents of Autistic Children: Results from a Large Cohort in China

T. Ren¹ and **F. Li²**, (1)Developmental and Behavioral Pediatric Department & Child Primary Care Department, Brain and Behavioral Research Unit of Shanghai Institute for Pediatric Research and MOE Shanghai Key Laboratory for Children's Environmental Health, Xinhua Hospital, Shanghai, Shanghai, China, (2)Department of Developmental and Behavioral Pediatric and Child Primary Care & Ministry of Education-Shanghai Key Laboratory for Children's Environmental Health, Xinhua Hospital, Shanghai Jiao Tong University School of Medicine, Shanghai, 200092, China, Shanghai, Shanghai, China

Background:

Parents of autistic children are at an increased risk for depression and anxiety, with variations in risk observed across regions and cultures. However, evidence on the prevalence and correlates of these symptoms in parents of autistic children in China remains scarce.

Objectives:

This study aims to describe the prevalence and correlates of depressive and anxiety symptoms in parents of autistic children within a large Chinese ASD cohort.

Methods:

Children diagnosed with ASD were drawn from the Shanghai Autism Early Development study (2015–2023). Diagnoses were made according to the DSM-5 criteria and confirmed via the Autism Diagnostic Observation Schedule (ADOS). Depressive symptoms in parents were measured using the Patient Health Questionnaire-9 (PHQ-9), and anxiety symptoms were measured using the Generalized Anxiety Disorder 7-item (GAD-7) scale. A total score >4 on either scale indicated the presence of symptoms, while a score >9 indicated moderate to severe symptoms. Autism severity in children was measured by ADOS scores. All assessments were performed at the time of diagnosis. Spearman's correlation tests were used to examine associations between parental depressive and anxiety symptoms and children's characteristics.

Results:

The cohort included 2,091 eligible autistic children, aged 2–15 years (mean 4.7 years; 85.2% male). Among them, 960 parents (45.9%) reported depressive symptoms, with 298 (14.3%) experiencing moderate to severe symptoms. In a subsample of 518 children with data on both parents, 112 (21.6%) had both parents reporting depressive symptoms. A total of 1,047 (50.1%) parents reported anxiety symptoms, with moderate to severe anxiety present in 327 (15.6%) parents. In the subsample of 516 children with complete data on both parents, 130 (25.2%) had both parents reporting anxiety symptoms. More severe autistic symptoms and lower family income were significantly associated with higher levels of depressive symptoms (all $P < 0.001$), while children's sex and age at diagnosis showed no significant association with parental mental health.

Conclusions:

Parents of autistic children in this large Chinese cohort demonstrated a high prevalence of both depression and anxiety. Increased social support for these families could help improve their overall well-being.

401.072 Designing Targeted Trainings and Resources to Improve the Primary Care Experience for Autistic Individuals through Qualitative Stakeholder Feedback

A. K. Spitzer¹, R. Coleman², A. Taiwo³, K. Bonnet⁴, D. Schlundt⁵, T. E. Foster⁶ and J. F. Hine¹, (1)Vanderbilt University Medical Center, Nashville, TN, (2)Department of Pediatrics, Vanderbilt University of Medical Center, Nashville, TN, (3)Special Education and Clinical Sciences, University of Oregon, Eugene, OR, (4)Vanderbilt University, Nashville, TN, (5)Psychology, Vanderbilt University, Nashville, TN, (6)Division of Developmental Medicine, Vanderbilt University Medical Center / VKC TRIAD, Nashville, TN

Background: A high-quality medical home is an essential component of care for patients with autism spectrum disorder (ASD) however, pediatric primary care providers (PCPs) do not receive enough training to adequately support these patients and families (Badgett et al., 2023; Hine et al., 2019; Todorow et al., 2018). To address this gap in provider knowledge and training, our team is developing ASD-specific learning modules that integrate electronic health record (EHR) templates for use in primary care visits. As part of our stakeholder-informed process, we conducted focus groups with adults with lived experience related to ASD care within primary care settings.

Objectives: Our objective was to inform the development of PCP-focused trainings and tools to improve healthcare delivery for individuals with ASD across the lifespan and continuum of care — specifically: 1) post-diagnostic care coordination, 2) special-education planning and advocacy, and 3) transition-age planning and resources — and to examine stakeholder's perceived barriers, facilitators, and contingent factors to the implementation of the proposed trainings and tools. Further, we sought to identify key moderators of success for implementation of the training and proposed practice recommendations.

Methods: Psychologists on the study team conducted two one-hour focus groups for each of three stakeholder groups: providers ($n = 8$), caregivers ($n = 8$), and self-advocates ($n = 12$) using a semi-structured interview guide (Hennink et al., 2019). The virtual focus groups were recorded, transcribed, and coded. A unique, hierarchical coding system was developed and refined based on preliminary transcript review. Three members of the team double coded the first manuscript to establish reliability and reach consensus on coding procedures. The study team used an iterative inductive-deductive qualitative approach to analyze the data and identify a list of themes and subthemes (Fereday & Muir-Cochrane, 2019).

Results: Stakeholders identified a range of distinct, yet interconnected barriers, facilitators, and contingent factors to the successful implementation of the proposed visit types, trainings, and tools. Barriers identified throughout the groups were primarily logistics and knowledge based. Provider “expert syndrome” also emerged as a key disadvantage in receiving quality primary care. The facilitators that emerged from the six focus groups centered around resource availability to both providers and caregivers. Self-advocates also highlighted facilitators such as accommodations in medical settings and the importance of including autistic perspectives in training development and delivery. Many contingent factors also emerged from these conversations, factors that could contribute to visits going well or poorly. Overarching themes for the contingent factors revolve around the importance of trust and acceptance in a primary care relationship.

Conclusions: The themes highlighted in this study will be used to refine our existing training curriculum, develop an accompanying implementation guide, and create EHR templates for PCPs to use during visits with autistic individuals and caregivers. Our ultimate goal is to package, disseminate, and test this system on a larger scale. If successful, this program could provide PCPs with critical skills related to ASD care, leading to expedited family engagement with intervention and transition supports.

401.073 Development and Evaluation of a Training in Autism and Multilingualism for Providers: A Mixed Methods Randomized Controlled Study

M. R. Martin Loya¹ and H. Meadan², (1)Department of Psychiatry & Behavioral Sciences, UC Davis MIND Institute, Sacramento, CA, (2)University of North Carolina Charlotte, Charlotte, NC

Background:

Autistic children from heritage-language speaking homes (hereafter referred to as *multilingual autistic children*, in alignment with a strengths-based framework) are a historically marginalized population in the U.S. that would benefit from receiving tailored evidenced-based support from providers who implement culturally and linguistically affirming care. Previous research found that multilingual providers who support multilingual autistic children reported significant challenges, including the lack of translated resources and professional development (PD), which negatively impact their ability to provide high-quality multilingual care. This is a major area of inequity that needs to be further explored.

Objectives:

The purposes of the present mixed-methods study were to (a) gain a deeper understanding of the knowledge, experiences, and needs of behavior analyst leaders related to supporting multilingual staff, (b) measure the impacts of a one-hour asynchronous PD on providers' knowledge, self-efficacy, and attitudes related to supporting multilingual autistic children and the multilingual staff who support them, and (c) to understand how qualitative findings helped to develop an effective PD and how did the social validity data help to enhance our understanding of randomized waitlist control trial (RCT) results using meta-inferences.

Methods:

This study used an exploratory sequential mixed methods design to address the research questions. Phase one (P1) included qualitative data from focus groups and interviews to understand the needs and perspectives of behavior analyst leaders with experience supporting multilingual staff. P1 was analyzed using reflexive thematic analysis and a critical theoretical framework. Phase two (P2), a waitlist RCT, measured the effectiveness of a PD module tailored based on the needs and perspectives identified in P1. P2 analysis involved calculating composite scores across the three measures (i.e., knowledge, self-efficacy, and attitude scales) compared across groups (intervention and control) using MANOVA. Lastly, descriptive statistics from the social validity questionnaire were calculated, and open-ended responses were analyzed qualitatively.

Results:

In both P1 and P2, diverse behavior analysts from across the U.S. participated, including monolingual, multilingual, autistic, and non-autistic individuals. In P1, participants (N=14) reported experiences and needs that echoed those of multilingual behavior analysts from extant research (e.g., needing more bilingual support and training for staff). P1 findings were integrated to build the PD, resulting in careful attention to include needs reported by monolingual and multilingual behavior analysts. In P2, RCT results demonstrated a statistically significant increase in participants' (N=90) knowledge ($p = .007$) and self-efficacy ($p = .034$) after participating in the PD, but no significant changes in attitudes ($p = .095$). Finally, a joint display illuminates additional meta-inferences.

Conclusions:

Improving our understanding of the needs and experiences of professionals who greatly impact autistic children's learning environments is important for developing PD to promote equitable practices that honor diverse linguistic backgrounds. This study found that tailored PD could improve behavior analysts' knowledge and self-efficacy toward supporting multilingual autistic children, their families, and the professionals who support them. More research and PD are needed to improve autism providers' practices to increase autistic children's access to learning new or maintaining heritage languages.

401.074 Development of a Conceptual Model of Preference of Japanese Autistic Adults: Comparison between the Perception of Autistic Traits within the Medical Model of Disability and Neurodiversity Affirmative Approach

M. Kawashima¹, Y. Nitto², K. J. Tsuchiya³, S. Guan⁴, Y. Kawaguchi⁵, L. Hull⁶, H. Honda^{7,8,9} and F. Oshima⁵, (1)Research Center for Child Mental Development, Chiba University, Chiba, Chiba, Japan, (2)Sagami Women's University, Sagami-hara, Kanagawa, Japan, (3)Research Center for Child Mental Development, Hamamatsu University School of Medicine, Hamamatsu, Shizuoka, Japan, (4)Waseda University, Tokyo, Japan, (5)Research Center for Child Mental Development, Chiba University, Chiba, Japan, (6)Population Health Sciences, University of Bristol, Bristol, UNITED KINGDOM, (7)Shinshu University School of Medicine, Matsumoto, Nagano, Japan, (8)Shinshu University Hospital, Matsumoto, Nagano, Japan, (9)Nagano Information and Support Center for Persons with Developmental Disorders, Matsumoto, Nagano, Japan

Background:

Autism has been conceptualized within the medical model as a deficit or disorder, influencing the nature of support, interventions, and societal perceptions. This deficit-focused perspective has contributed to adverse outcomes of autistic individuals, such as stigma, diminished self-esteem, and mental health problems. Recently, the neurodiversity paradigm has shifted the perspective toward a social model, interpreting autism as one of many natural variations in neurodevelopment. While neurodiversity underscores the diversity of human neurodevelopment, it does not fully elucidate positive autism identity.

Objectives:

This study aims to develop a conceptual model based on the preferences of Japanese autistic adults to better interpret autistic identity within the framework of the social model. The ultimate goal of developing this conceptual model is to create a questionnaire that assesses autistic preferences. This questionnaire will enable clinicians, caregivers, parents, and others involved with autistic individuals to understand the autistic preferences a person has. And it facilitates the provision of appropriate and supportive interventions that are congruent with the preferences of the autistic community.

Methods:

The study collected data from twenty-nine Japanese adults with diagnosis of autism by a medical professionals. Participants completed an online free-writing questionnaire with eight questions, which are related to autistic traits as described in the DSM-5-TR. To interpret underlying meanings of the data, we employed the reflexive thematic analysis recommended by Braun and Clarke. An autistic individual was involved in the research discussion to verify the clarity and appropriateness of the questions, ensuring that the study was aligned with the perspectives of the autistic community.

To enhance the depth and appropriateness of the conceptual model, we plan to conduct follow-up interviews. We are recruiting twenty-two of the original twenty-nine participants from the online survey, and aim to develop an improved conceptual model, which will be presented at the poster session.

Results:

We generated three main themes ("homogeneity", "stability", and "concreteness") and twelve sub-themes. Under "homogeneity", participants expressed a preference for spending time with individuals who share similar characteristics or who understand their unique traits. The theme of "stability" included sub-themes such as avoiding multitasking, requiring specific stimuli for concentration, engaging in patterned behaviors, focusing intensely on one thing, and so on. The "concreteness" theme encompassed sub-themes like purposeful actions, a reliance on visible information, and the need for clear task instructions. These themes collectively contribute to a conceptual model that interprets autistic identity based on the preferences of Japanese autistic adults.

Conclusions:

In this study, we confirmed some characteristics of autism noted in the DSM-5-TR. However, we also revealed new aspects of autism that are not fully explained by conventional understandings. Specifically, while the DSM-5-TR highlights "persistent deficits in social communication and social interaction," many participants with autism expressed a preference for spending time with friends, partners, and colleagues at work. This suggests that autistic individuals may seek social engagement under conditions that align with their preferences. These insights contribute to a more nuanced interpretation of autistic identity.

401.075 Development of the Japanese Version of the Affiliate Stigma Scale for Autism

A. Taniguchi¹, N. Sakashita², Y. Hatakenaka³ and F. Oshima⁴, (1)Faculty of Education, Mie University, Tsu, Mie, Japan, (2)Shizuoka Prefecture East Child Consultation Center, Numazu, Shizuoka, Japan, (3)Faculty of Humanities and Sociologies, University of the Ryukyus, Nakagami, Okinawa, Japan, (4)Research Center for Child Mental Development, Chiba University, Chiba, Japan

Background: The stigma of autism is a significant social issue with an impact that extends from autistic individuals to their close relationships, hence requiring thorough attention. Affiliate stigma refers to when parents of autistic children internalize such stigma, often owing to blame or criticism regarding their children's condition (Mak & Kwok, 2008). Parents experiencing affiliate stigma are more prone to psychological difficulties and social isolation, and such stigma can lead to negative parenting behaviors toward children (e.g., Hutchison et al., 2016).

Objectives: This study aimed to develop a Japanese version of the Affiliate Stigma Scale, originally developed by Mak and Kwok (2008), for parents of autistic children.

Methods: A survey was conducted in August 2024 with parents of autistic children (ages 3–18 years) using an online questionnaire. The Japanese version of the scale was translated by the second and third authors with permission from the original creators, and back-translated by a native English speaker. All items were adjusted for relevance to individuals on the autism spectrum. The Japanese version of the scale comprises 22 items rated on a four-point Likert scale.

Results: Study 1 The scale's factor structure was examined using data from 578 participants (mean age = 43.55 years, *standard deviation* = 5.70) using an exploratory factor analysis with robust maximum likelihood and oblique rotation. Results revealed a 16-item, three-factor structure, as follows: Avoidance Behavior (*Cronbach's α* = .87), Negative Cognitions (*Cronbach's α* = .89), and Negative Emotions (*Cronbach's α* = .87; see Table 1). Although the original scale had a single-factor structure, the three-factor model was retained because of its improved interpretability.

Study 2 Using confirmatory factor analysis and a sample of 298 participants (mean age = 43.60, *standard deviation* = 6.01), this three-factor model was evaluated for goodness of fit. The model demonstrated acceptable fit to the data (CFI = .940, RMSEA = .075, SRMR = .046).

Conclusions: A three-factor structure was found to be optimal for the Japanese version of the Affiliate Stigma Scale, distinguishing it from both the original scale and the three-factor model (i.e., encompassing cognitive, emotional, and behavioral dimensions) proposed by Chang (2016). These divergent results may relate to the scale developed by Mak and Kwok (2008) being focused on intellectual disabilities and having been analyzed using the principal factor method, whereas this study targeted autistic individuals in a Japanese context. Future research should explore the construct validity, test-retest reliability, and predictive validity of the Japanese version of the scale.

401.076 Developmental Regression in Children with Autism: Insights from Parental Reports in Rural Eastern India

G. Kuanar^a and **C. Mahapatra^a**, (1)Life Science, Ravenshaw University, Cuttack, Odisha, India, (2)Neurology, Kalinga Hospital, Bhubaneswar, Odisha, India

Background: In rural India, Autism Spectrum Disorder (ASD) poses significant social challenges, often resulting in isolation and stigma for families. Limited access to community support hinders the development of vital social skills in affected individuals, worsening their difficulties. Understanding the prevalence and onset patterns of regression in ASD is essential in these areas, where healthcare and early intervention are scarce. Analyzing socio-demographic factors, birth history, and psychosocial events can help identify at-risk children and develop targeted interventions. This information can also inform public health initiatives and awareness campaigns, enhancing support for families impacted by ASD.

Objectives: This study aims to assess the prevalence and patterns of developmental regression in children with ASD while exploring potential correlations with socio-demographic factors and early life events. The findings will contribute to a better understanding of regression in ASD, informing clinical practices and future research directions.

Methods: We evaluated 188 children, aged 1-10, diagnosed with ASD based on DSM-5 criteria. The Modified Checklist for Autism in Toddlers (M-CHAT) was used for initial screening, followed by the Developmental Screening Test (DST) and Childhood Autism Rating Scale (CARS). Data were analyzed using SPSS version 22. In addition to the screening assessments, demographic data such as age, gender, birth history, and socioeconomic status were collected through parent interviews and questionnaires. Ethical approval for the study was obtained from the institutional review board, and informed consent was secured from the parents of all participating children before data collection.

Results: According to parental reports, 60.2% of the sample exhibited developmental regression, marked by the loss of both language and social skills. Among these children, 70% experienced regression before the age of 24 months, suggesting a critical window for intervention. No statistically significant differences were found in cognitive ability and autism severity between children with and without regression. Additionally, 25% of the children demonstrated a developmental plateau, where skills remained unchanged for an extended period. The study identified four distinct patterns of onset for ASD: pure delay, developmental plateau, delay with regression, and pure regression, with 15% of the sample classified under pure delay and 5% under pure regression, indicating the variability in symptom presentation among affected children.

Conclusions: The prevalence of regression observed in this study exceeds that of existing literature. The mean age of regression onset was found to be between 12-25 months, often preceded by medical or psychosocial events. Furthermore, these findings underscore the need for heightened awareness and early screening in pediatric populations to facilitate timely interventions. Addressing these regressions promptly could potentially mitigate their long-term impact on development and overall functioning.

401.077 Diagnostic Disclosure in Job Interviews: Experiences of Autistic Adults in Canada

T. Q. Boucher^a, **M. Waite^a**, **K. Armstrong^a**, **L. Ludwig^a** and **G. Iarocci^a**, (1)Psychology, Simon Fraser University, Burnaby, BC, Canada, (2)Spectrum Works Consulting Group, Vancouver, BC, Canada, (3)Community Partner, Burnaby, BC, Canada

Background:

Previous research has found that many autistic adults are uncomfortable disclosing their autism diagnosis to others due to autism stigma and potential discrimination (Thompson-Hodgetts et al., 2020). Stigma towards autistic youth may decrease following diagnostic disclosure in school settings (White et al., 2020); however, few autistic adults disclose their diagnosis to employers or educators (Huang et al., 2022). Autistic adults face greater unemployment than non-autistic adults, possibly due to insufficient support in the workplace (Hedley et al., 2018). Challenges specific to the job interview process may also contribute to lower rates of employment among autistic adults (Whelpley et al., 2023), and it is theorized that diagnostic disclosure may act as a facilitator (e.g., improve accommodations) or barrier (e.g., increasing discrimination) to job interviews with autistic adults.

Objectives:

The aim of this study was to understand the experiences and perceptions of Canadian autistic adults regarding disclosure of their autism diagnosis during job interviews.

Methods:

Interviews were conducted with 23 autistic adults (11 male, 6 female, 6 gender expansive) age 19 to 59 years, over Microsoft Teams ($n=11$) or through typed responses on Qualtrics ($n=12$). Participants were recruited on social media and through Canadian autism service providers. The interview protocol was created with a community-based research team comprised of an autistic adult with related lived experience, a non-autistic psychologist with experience supporting autistic adults with vocational development, and three non-autistic researchers. Questions specific to diagnostic disclosure were asked to all participants, who provided as much or as little as they felt comfortable sharing. An Interpretive Phenomenological Analysis approach was undertaken with Braun and Clarke's (2006) thematic analysis procedure to inductively generate codes and themes from the interview data. Participants also completed the Autism-Spectrum Quotient (AQ) and a demographics questionnaire (see Table 1).

Results:

Seven themes were generated from the data: (1) Autism Stigma and Discrimination, (2) Disclosure Improves the Experience, (3) Be Selective with Disclosure, (4) Disclosure is Challenging, (5) Disclosing Traits, Not Diagnosis, (6) Disclosing out of Necessity, and (7) Disclosure is Not Important. See Table 2 for themes, subthemes, and descriptions of themes.

Conclusions:

The findings highlight the complex reality of diagnostic disclosure in job interviews for autistic adults. Certain participants viewed disclosure as necessary to explain their autistic traits (e.g., interpersonal challenges) and to get access to accommodations for the interview. Others indicated that they fear, or have experienced, discrimination because of their disclosure. Many participants indicated that they preferred disclosing specific traits or "preferences" (e.g., "I need clear verbal communication") or disclosing only to specific employers, though it was reported by participants that there are few acceptable opportunities to disclose their diagnosis in a way that felt comfortable. Employment service providers for autistic adults should consider both the potential benefits and risks of disclosure, and workplace training to reduce stigma and discrimination. This may provide a safer environment for disclosure and accessibility for autistic job applicants. Furthermore, normalizing interview accommodations (e.g., 1-on-1 interviews, receiving questions in advance) could reduce the need to disclose in an interview altogether.

401.078 Does Participation Matter: The Implications of Educator Participation in Virtual-Based Remaking Recess Coaching on Self-Rated Fidelity

A. Du¹, O. Michael², W. I. Shih³, K. Wolf⁴, D. Cooney⁵, E. Kim⁶, C. Kasari⁷ and J. Locke¹, (1)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (2)University of Miami, Seattle, WA, (3)University of California - Los Angeles, Los Angeles, CA, (4)University of Washington, Seattle, WA, (5)University of Pennsylvania, Philadelphia, PA, (6)UCLA, Los Angeles, CA, (7)Education and Psychiatry, University of California Los Angeles, Los Angeles, CA

Background: Remaking Recess (RR) is an evidence-based practice (EBP) that supports autistic students' peer engagement at school (Kretzmann et al., 2015). Repeated trials of RR have found it improves social outcomes for autistic elementary aged youth (Locke et al., 2018; Shih et al., 2019). Although RR coaching typically occurs in person, the study team pivoted to virtual-based coaching and self-rated outcome measures during the COVID-19 pandemic to adhere to social distancing guidelines. Past studies suggest that online EBP coaching may be as effective as in-person coaching (Mallonee et al., 2017; Piffner et al., 2022), but may vary based on the online coaching design and complexity of the intervention (Olson et al., 2021).

Objectives: This study examined the relationship between educators' participation and engagement in virtual-based coaching and their self-rated RR fidelity. Previous RR studies have demonstrated that educators who received in-person RR coaching achieved an average of 83.5% self-rated fidelity (Locke et al., 2019), but it is unclear whether virtual-based coaching will achieve the same. We hypothesize that virtual-based coaching will support educators' learning of RR content and skills, and educators who are more participatory during coaching will have higher self-rated fidelity after coaching ends.

Methods: One hundred sixty-four educators (average age = 36.8 years, SD = 12.7 years; 76.2% female) from 44 elementary schools across the United States and Canada participated in RR. The ethnic breakdown was 40.2% Hispanic. The racial breakdown was 41.5% Other, 36.0% White, 13.4% Black, 6.1% Asian, 1.8% Multiracial, and 1.2% Native American. Educators received 60-to-90-min group coaching in RR over Zoom across 6 to 12 sessions. Educators were asked to self-rate RR fidelity at three time points in the study (baseline, midpoint, and exit). Educators received \$25 for each data collection time point. Six masked coders rated educators' participation in recorded coaching sessions at three time points - initial, middle, and final. The highest of the three participation ratings was used in the data analysis as it was the most accurate assessment of participation. Participation data coding is ongoing and will be completed by December 2024.

Results: We conducted a preliminary Spearman's Correlation on 52 of the 164 educators. The analysis revealed a moderate positive correlation ($r=.49$, $p=.001$) between educators' highest attained participation rating and their self-rated RR fidelity after coaching ended. Subscales of self-rated fidelity for the Transitions, In Vivo Social Skills, and Peer Conversations modules of the RR curriculum also were significantly correlated with educator participation scores.

Conclusions: Our preliminary analyses show a significant relationship between educators' coaching participation and their self-rated fidelity after coaching ends. While we recognize the limitations of virtual-based coaching and self-rated fidelity, these were necessary pivots due to COVID-19 restrictions that allowed us to disseminate and implement RR more widely. Additionally, the self-rated fidelity measure provided pivotal insight into educators' use and implementation of RR in the context in which autistic children are served (Locke et al., 2022). The results indicate future considerations around RR coaching structure to increase educators' confidence, fidelity, and application of the intervention.

401.079 Does Self-Compassion Moderate the Relationships between Loneliness and Depressive Symptoms in a Global Sample of Autistic and Non-Autistic Adults?

R. Y. Cai¹, A. M. Love², D. M. Dueber³, M. D. Toland³, C. Edwards⁴ and V. Gibbs¹, (1)Aspect Research Centre for Autism Practice, Autism Spectrum Australia, Sydney, NSW, Australia, (2)University of Toledo, Toledo, OH, (3)University of Kentucky, Lexington, KY

Background: Self-compassion involves treating oneself with kindness, understanding, and support, especially during difficult moments in life. Neff conceptualized self-compassion as comprising six subdomains: mindfulness, self-kindness, common humanity, over-identification, self-judgment, and isolation. Research consistently demonstrates that cultivating self-compassion can improve mental health, psychological well-being, and emotion regulation in non-autistic samples. Emerging evidence suggests that actively cultivating self-compassion can have a positive impact on the mental health of Autistic adults. The next important step is exploring how self-compassion influences mental health by interacting with other relevant factors, such as loneliness, to identify the mechanisms of change. In Autistic adults, loneliness is positively correlated with depressive symptoms. Self-compassion may mitigate the adverse effects of loneliness by fostering a more supportive internal dialogue. Recent evidence from non-autistic samples supports this notion. Given how Autistic adults self-report higher levels of loneliness, investigating whether self-compassion can reduce the impact of loneliness on depression is a pressing area of research.

Objectives: To examine the moderating effect of self-compassion on the relationship between loneliness and depressive symptoms in a global sample of Autistic and non-autistic adults. It was hypothesized that both positive (mindfulness, self-kindness, common humanity) and negative (over-identification, self-judgment, isolation) aspects of self-compassion would moderate the associations between loneliness and depressive symptoms in both groups.

Methods: 416 Autistic ($M_{age}=41.14$ years, $SD_{age}=13.30$) and 104 non-autistic adults ($M_{age}=41.39$ years, $SD_{age}=12.27$) completed questionnaires assessing loneliness (Adapted UCLA Loneliness Scale), self-compassion (Self-Compassion Scale), depression (Patient Health Questionnaire-9).

Results: When controlling for demographic factors, negative self-compassion had a statistically significant main effect on depression in both Autistic and non-autistic adults ($\beta=.31$, $p<.001$ and $\beta=.42$, $p<.001$, respectively). Furthermore, the effect of loneliness on depression was statistically significantly moderated by negative self-compassion in non-autistic adults ($p<.001$). For non-autistic participants with low negative self-compassion (<1 SD), loneliness had a small effect on depression ($\beta<.22$). For those with an average level of negative self-compassion, loneliness had a moderate impact on depression ($\beta=.39$). As for those with high negative self-compassion (>1 SD), loneliness had a large effect on depression ($\beta>.56$). In contrast, self-compassion did not significantly moderate the relationship between loneliness and depression in Autistic adults; for this group, loneliness had a statistically significant main effect on depression ($\beta=.31$, $p<.001$). Positive self-compassion had no significant main effect on depression and did not moderate the relationship between loneliness and depression in either participant group.

Conclusions: Our findings show that self-compassion moderates the relationship between loneliness and depressive symptoms in non-autistic adults but not in Autistic adults. With the growing interest in understanding the loneliness experiences of autistic individuals, these findings have critical implications for the development of loneliness interventions to support Autistic adults. Specifically, self-compassion may not play an essential role in mitigating the deleterious mental health effects of loneliness.

401.080 Does the University Sensory Built Environment Meet the Needs of Neurodivergent Students, Including Autistics? an Exploratory Approach Using Multiple Case Study

M. Couture¹, M. Chagnon² and E. Lagueux², (1)Rehabilitation, Universite de Sherbrooke, Sherbrooke, QC, Canada, (2)Université de Sherbrooke, Sherbrooke, QC, Canada

Background:

Education is key to individual and social advancement, economic growth, and human development. It affects our abilities, values, and perceptions. Acquiring academic knowledge is only one aspect of education. It develops diverse skills, including critical thinking, problem-solving, creativity, and communication (Paul & Suleman, 2005). In 2022, Canadian post-secondary institutions welcomed over 1.4 million students, including more individuals with disabilities from the neurodivergent and autistic community. Individuals with neurodivergence and autism process sensory information differently from the typical population. This difference in sensory processing leads to more stimulation when navigating non-accommodating environments (Kern et al., 2006; Lai et al., 2011). The built environment may evoke feelings of unpredictability, hostility, and fatigue (Ashburner et al, 2013). Neurodivergent students are less able to engage with academic activities because of the sensory environment at the university (Morgan, 2019).

Objectives:

To document the lived experiences of neurodivergent students, including autistic students, regarding the built environment's barriers to their academic participation.

Methods:

An autistic researcher conducted walking interviews and individual semi-interviews with eight neurodivergent students, including autistic students, enrolled in an undergraduate program. The interviewer inquired about the participants' experiences with the university's physical environment. The interviews were subjected to an inductive reflexive thematic analysis.

Results:

: Four primary themes were identified: lighting, vision, acoustics, and temperature. The participants indicated that the brightness, particularly due to the use of fluorescent lighting, flickering lights, or neon, constituted a barrier to their concentration and attention. Secondly, visual distractions, such as individuals moving around the table during small group work sessions or observing individuals outside the windows, and visual overload, such as the presence of numerous posters on the walls, were identified as negatively impacting attention in the classroom. Thirdly, noise, particularly in the classroom, cafeteria, and corridors, negatively impacted attention and comprehension of the task. These auditory disturbances include reverberations within the enclosed spaces, the sound of ventilation systems, and the voices of fellow students. Additionally, the temperature within the classroom, study hall, or cafeteria was frequently either excessively warm or cold, often causing discomfort. These sensory impediments, as reported by neurodivergent students, including autistic students, negatively impacted their on-campus experience, leading to feelings of anxiety, fatigue, a sense of inadequacy, or even burnout.

Conclusions:

Education must consider the needs of all students, including those from the autistic community, to facilitate their advancement. The study reveals the hurdles neurodivergent and autistic students encounter, especially regarding their educational environments. Barriers to neurodivergent and autistic students' learning include lighting, vision, noise, and temperature. They are more than mere inconveniences: they impede learning and wellbeing. To foster truly inclusive education, it is essential to adapt the built environment to create a learning-friendly campus for all. This requires increased awareness, specific accommodations, and collaboration between educational establishments and neurodivergent communities, including autistic community. By recognizing and responding to the unique sensory needs of neurodivergent and autistic students, we can enhance their academic experience and enrich the diversity and richness of contributions within the academic community.

401.081 Double Burnout: Exploring the Experiences of Autistic and Educator Burnout Among Autistic Educators in the United States

A. Newson¹, J. Callahan², L. Collier³, S. Goldman⁴, E. Hopkins⁵, L. Whitney⁶, H. M. Brown⁷, J. Duke⁸, M. Mueller⁹, V. VanUitert¹⁰ and K. ROSE¹¹, (1)University of Oregon, Eugene, OR, (2)WA, (3)UMass Amherst, MA, (4)MA, (5)Augustana College, IL, (6)CA, (7)Educational Psychology, University of Alberta, Edmonton, AB, Canada, (8)George Mason University, Fairfax, VA, (9)Columbia University, New York, NY, (10)Bowling Green State University, OH, (11)Psychology, KMR Training and Consultancy, Sunderland, United Kingdom

Background:

Autistic educators have the unique position of experiencing teacher burnout in addition to autistic burnout. Autistic burnout, “*a syndrome conceptualized as resulting from chronic life stress and a mismatch of expectations and abilities without adequate supports*”, when compounded with teacher burnout can lead to further loss of skills affecting mental health, physical well-being, and job performance. Current research has examined autistic-specific stressors, increased reported ACE’s for neurodivergent individuals, and general experiences of autistic educators, without specifically addressing the intersection between autistic burnout and burnout experienced by educators. This lack of understanding about the relationship between autistic burnout and educator burnout can have dangerous implications for the mental health and wellbeing of autistic educators. Research shows that individuals experiencing autistic burnout are at higher risk for experiencing trauma and suicide, the second leading cause of death among autistic adults. No studies yet explore how autistic educator burnout compounds or affects that risk or how it affects an autistic educator’s physical health and well-being.

Objectives:

1. Promote the inclusion and participation of Autistic Community Partners by co-creating and co-producing research through emancipatory participatory research design.
2. Explore experiences of Autistic educators who have left the field due to Autistic burnout and educator burnout to understand the interaction and interconnection of the two phenomena on mental health and wellbeing.
3. Determine a set of recommendations to support Autistic educators’ mental health and wellbeing through preventing and reducing the negative impacts of Autistic and educator burnout.

Methods:

Through emancipatory community-based participatory research design, in collaboration with five Autistic Community Partners, the research team interviewed five Autistic educators who had left the field of education and identified as being sexually and gender diverse (SGD) about their experiences with burnout, flourishing, mental health, and quality of life. Reflexive and template thematic analysis were used to understand the differences between Autistic and educator burnout, barriers and facilitators to Autistic mental health and flourishing, and recommendations to support Autistic mental health. Six themes were co-constructed by the research team and then sent back to the Autistic educators for review and member checks.

Results:

Results indicate that Autistic and educator burnout are separate but intertwined phenomena that deeply affect the mental health and wellbeing of Autistic educators even after leaving teaching. Six themes indicated by Autistic educators included sensory experiences, people and interactions, agency, climate and culture, environmental factors and embodied Autistic identity.

Conclusions:

Recommendations provided by Autistic educators included rejecting neuronormative and heteronormative standards in education, creating neuroinclusive spaces that allow all educators to feel psychologically safe, and fostering spaces for Autistic flourishing within school environments. Future research can use these recommendations to explore sustainable ways to promote Autistic flourishing and mitigate barriers to educator mental health.

401.082 Early Evaluation of a Community Engagement Toolkit’s Effectiveness in Supporting Caregivers of Neurodiverse Children to Access Screening and Care in India

S. Pal¹, D. Saini², **B. Malhotra³**, G. Kapoor⁴, A. Mutaher⁴, R. Deshpande⁵, S. Garg⁶, K. Leadbitter⁷, P. P. Gonsalves⁸, R. Roy⁹, J. Green⁹, G. Divan¹⁰ and N. Consortium¹¹, (1)Child Development Group, Sangath, Delhi, Delhi, India, (2)Sangath, Delhi, Delhi, India, (3)Child Development Group, Sangath India, Delhi, Delhi, India, (4)Quicksand, Delhi, Delhi, India, (5)Quicksand design studio, bangalore, Karnataka, India, (6)School of Health Sciences, University of Manchester, Manchester, United Kingdom, (7)University of Manchester, Manchester, UNITED KINGDOM, (8)COMPASS, Sangath India, New Delhi, Delhi, India, (9)University of Manchester, Manchester, United Kingdom, (10)Child Development Group, Sangath India, New Delhi, India, (11)NAMASTE consortium, Delhi, Delhi, India

Background:

Neurodevelopmental disorders (NDDs) are a significant global health concern, particularly in South Asia, which bears the highest prevalence of NDDs globally, contributing substantially to disability-adjusted life years. Early detection is crucial for bridging care gaps, supporting family adjustment, and maximising a child's developmental potential. The NAMASTE (Neurodevelopment and Autism research in South Asia Treatment and Evidence) program developed a community-engagement toolkit with nine multimedia materials to increase community knowledge of NDDs and enhance caregiver engagement with an NDD detection and care pathway in four districts of India, Sri Lanka, and Nepal. This paper presents insights from an early evaluation of the toolkit disseminated by non-specialist health and care workers (NHCWs) in North Goa and East Delhi, India.

Objectives:

This study aimed to:

1. Explore barriers and facilitators for NHCWs in distributing and using awareness posters, a child developmental milestone calendar, and an identification card during community screenings for NDDs.
2. Understand caregivers' experiences with the patient education materials provided at different stages of the NAMASTE program.

Methods:

A convergent parallel mixed-methods design was used, with data collected from 160 NHCWs who conducted NDD screenings and 120 caregivers who participated in screening questionnaires in East Delhi and North Goa. Purposive sampling was employed to gather qualitative and quantitative data through: (i) focus group discussions (n=12 NHCWs), (ii) semi-structured interviews (n=12 caregivers), and (iii) surveys (n=160 NHCWs, n=120 caregivers participating in NDD screening, and n=30 caregivers enrolled in the intervention). Data collection tools included self-designed surveys and interview guides.

Qualitative interviews and discussions were analysed using content analysis and quantitative data using cross tabulation analysis and descriptive statistics. The findings from the qualitative and quantitative analysis were compared and contrasted to corroborate the final set of interpretations for the study.

Results:

Preliminary results suggest that NHCWs encountered logistical barriers when distributing and using the toolkit materials during community screenings. However, they recognised their value in improving community knowledge about early childhood development milestones. Caregivers shared positive experiences of using the patient education materials. Many reported increased knowledge about early signs of NDDs and feeling reassured after an NDD detection. NHCWs expressed a need for continued training to use the toolkit effectively and caregivers requested additional materials in to further support their child's developmental progress.

Conclusions:

The early evaluation of the community-engagement toolkit within the NAMASTE program demonstrates its potential to enhance awareness and early detection of neurodevelopmental disorders among caregivers and non-specialist health and care workers in India. The toolkit materials improved caregivers' understanding of developmental milestones and increased their engagement with the detection-care pathway. However, barriers related to accessibility and the need for additional information were identified. Addressing these challenges will be essential for scaling the intervention and ensuring its effectiveness in diverse settings.

401.083 Echo Autism Hawai'i: Outcomes of a Pilot Program for Supporting Autism Providers in Family-Centered Care

K. Oliver¹, M. Matheis² and M. Čolić³, (1)Department of Special Education, University of Hawai'i at Mānoa, Honolulu, HI, (2)Center on Disability Studies, University of Hawaii, Honolulu, HI, (3)Department of Special Education, University of Hawaii at Mānoa, Honolulu, HI

Background: As the prevalence of autism grows, the need for comprehensive support and services increases, especially in rural, remote, and underserved areas. In Hawai'i, disparities in access to services for racial and ethnic minorities, combined with the state's geographic isolation as an island chain, exacerbate these challenges. There is a pressing need for effective sharing of knowledge and resources for autism service providers across the islands.

Objectives: Project Extension Community Healthcare Outcomes (ECHO) has proven to be an effective model for disseminating best practices for various medical and mental health conditions. This pilot study assessed the feasibility and acceptability of applying the ECHO framework to deliver family-centered care didactics and resources to autism service providers across Hawai'i.

Methods: The ECHO Autism Hawai'i program was implemented with fidelity to the original ECHO model, incorporating minor adaptations for local needs. Four 90-minute Zoom sessions were conducted biweekly, each featuring a didactic presentation from an expert in the field, a de-identified case presentation by an ECHO member, and a group discussion. Sessions focused on key aspects of family-centered care, including Introduction to Family-Centered Care and Engagement, Early Childhood/Diagnostics, School-Aged Support, and Transition Age Services, addressing the diverse needs of families at various stages of care. Participants completed satisfaction surveys following each session, including feasibility and applicability, and a post-program survey evaluated the overall acceptability and perceived impact of the program.

Results: Twenty-two service providers participated in the pilot, including clinical psychologists, speech-language pathologists, early interventionists, and special education teachers, with an average of 13 participants per session. Surveys administered after each session indicated that participants consistently agreed that the strategies discussed were feasible and acceptable to implement and that their knowledge of the session topics increased. Participants reported that each didactic presentation was informative, engaging, and easy to understand. Post-program surveys revealed unanimous satisfaction with the program, with participants expressing that the ECHO Team created a supportive learning environment where participants felt comfortable sharing ideas. Additionally, most respondents strongly agreed that their knowledge of family-centered practices for autism had increased as a result of the program.

Conclusions: The ECHO Autism Hawai'i pilot program was well received, with participants highlighting its potential to bridge service gaps for autism providers in geographically isolated and underserved areas. Given its success, additional cohorts are planned for Fall 2024 and Spring 2025, with expanded participation as well as follow-up with the first cohort. Additional data will provide further insight into the program's impact, with updated findings to be presented at the time of the conference. This program represents a promising solution for overcoming service barriers in rural and remote communities.

401.084 Measuring the Specific Behaviors of Proficient Autism Advocates

K. Sohl¹, A. Brewer Curran², K. Boles³ and K. Koehn⁴, (1)ECHO Autism Communities, University of Missouri School of Medicine, Columbia, MO, (2)Department of Pediatrics, University of Missouri, Columbia, MO, (3)Child Health, University of Missouri, Columbia, MO, (4)Pediatrics, ECHO Autism Communities, University of Missouri, Columbia, MO

Background:

Newly diagnosed autistic individuals and their family caregivers face a long list of tasks and recommendations provided by the diagnostic clinician. If diagnosed in an autism center, the center may also have a support person to help families and individuals navigate these recommendations. However, with the expansion of clinicians with diagnostic capabilities due to best practice training by ECHO Autism comes additional need for navigational support systems. In 2022, ECHO Autism Communities (EAC) began a program to fill in this gap with trained autism advocates taking on the role of Connector in the ECHO Autism Community Connections (EACC) project. Connectors were selected from the ECHO Autism: Advocates (EAA) program due to their ability to support newly diagnosed individuals and their families. To allow for continued expansion and the maintenance of a symbiotic relationship across diagnostic, advocate, and connector programs, we realized a metric for evaluating the readiness of advocates was necessary. In 2024, we began the process of creating a rubric to assess the level of proficiency an advocate has reached. This rubric would provide guidance for growth to the advocate and a measure for placement in a connector role.

Objectives:

- Identify and describe the knowledge, skills, and specific behaviors of proficient advocates
- Develop a rubric for measuring advocate proficiencies

Methods:

A consultant outside the three programs, but familiar with EAC and the creation of evaluation metrics, performed a meta-analysis of existing advocate proficiency research and developed a focus group protocol. The consultant and lead author held three focus groups with constituencies who had direct access to autism advocates. The three groups were: expert hub team members of the EAA program, EACC Connectors, and EAC leadership. Following the focus groups, the lead author and second author independently coded transcripts using an inductive qualitative analysis approach to categorize proficiencies and extrapolate examples of manifest proficiencies. We then created a rubric prototype for initial review by focus group members; we also asked EACC referring clinicians to review and provide input from their perspective. Following results of these reviews, we will modify the rubric and test it. Quality improvement methodology will be utilized to guide any further adaptations necessary before implementation within the ECHO Autism: Advocates program.

Results:

The first rubric iteration included 12 specific proficiencies within 4 categories: Knowledge, Communication Skills, Professionalism, and Personal Development and Mentorship. Each proficiency in the rubric would be rated on a multi-point scale from not proficient to proficient, with not applicable for situations where examples to demonstrate proficiencies were not possible. We are still collecting data from reviewers but anticipate having more results to share during this presentation at INSAR.

Conclusions:

Through February 2025, the rubric will be tested in real-time. Quality improvement methodology will guide the process of modifying the instrument to ensure consistency and objectivity in measuring proficiency in EAA participants.

401.086 Empowering Women of Color through Family Echo: Autism – Addressing Disparities in Care and Broadening DEIA Initiatives

A. Hess¹ and A. Phillips², (1)Nationwide Children's Hospital, Columbus, OH, (2)Autism Speaks, Mullica Hill, NJ

Background: Families of children with autism are key members of care teams and often the primary coordinators for their child's treatment. Despite calls for interdisciplinary training and collaboration across medical, education, and community systems, families typically receive very little education and training in autism, care coordination, or team-based care. Family ECHO: Autism adapted the Project Extension for Community Healthcare Outcomes (Project ECHO) model to build the knowledge and confidence of families raising children and adolescents with autism. The series provides access to interdisciplinary subject matter experts from a learning health network, autism resources, resource coordinators, and community connectedness to build care and treatment knowledge of families. A notable addition to this initiative is the Empowering Women of Color sessions, specifically designed to address the barriers and disparities faced by families of color when accessing autism care.

Objectives: The Empowering Women of Color series within the Family ECHO: Autism program focused on the lived experiences of women of color, addressing the unique barriers they encounter in accessing autism services for their children, and providing skills to enhance family empowerment and advocate for equity in healthcare. The series aligns with Diversity, Equity, Inclusion, and Accessibility (DEIA) efforts by ensuring that marginalized communities receive the support they need to improve outcomes for their children on the autism spectrum. Series strives to

- Increase self-efficacy in knowledge and confidence to care for children with autism.
- Build confidence in women of color to overcome barriers in managing care and treatment for children with autism.
- Connect to resources.

Methods: Sessions were developed in collaboration with a robust panel of women of color including mothers and professionals in autism. The existing Family ECHO Autism subject matter experts supported this effort. The sessions, conducted in two parts, provided participants with skills to navigate disparities in care and connected them with subject matter experts, peers with lived experience and resources. Interactive case discussions, and live Q&A segments promote a collaborative learning environment.

Results: From April 2020 to March 2024, the Family ECHO: Autism series engaged over 18,000 participants from 73 countries and all 50 U.S. states. Over 7,500 participants attended live sessions. Sessions are delivered in multiple languages with 93% of participants identifying themselves as mothers. Participant satisfaction is high, with an 86% approval rate, underscoring the program's success in addressing autism-related disparities for families of color. The Empowering Women of Color sessions led to a significant increase in participation among Black or African American families, rising from a standard attendance of 14.7% to 46.5% in the inaugural session.

Conclusions: The Empowering Women of Color series demonstrates how a targeted, culturally responsive approach can bridge the gaps in autism care and support DEIA initiatives within under-resourced communities. By broadening the reach of the Family ECHO: Autism platform, this program fosters empowerment, providing families of color with the tools to advocate for their children's care. Further expansions are planned to enhance outreach and support for more diverse populations, contributing to a more equitable healthcare landscape for all families impacted by autism.

401.087 Engaging Individuals with Lived Experience of Autism and Intellectual Disability to Create Community Awareness for Promoting Early Identification and Uptake of Intervention Services: A Scoping Review

B. Malhotra¹, S. Pal¹, M. Mishra¹, R. Mitra¹, S. Shukla¹, N. Consortium², K. Leadbitter³, J. Green⁴, G. Divan⁵ and R. Roy⁶, (1)Child Development Group, Sangath, Delhi, Delhi, India, (2)NAMASTE consortium, Delhi, Delhi, India, (3)University of Manchester, Manchester, UNITED KINGDOM, (4)University of Manchester, Manchester, United Kingdom, (5)Child Development Group, Sangath India, New Delhi, India, (6)COMPASS, Sangath India, New Delhi, Delhi, India

Background: Community-based health surveillance for early detection and intervention of neurodevelopmental disorders (NDDs) like autism and intellectual disability has increasingly received prominence in public health research. Community-based programs allow for more diagnostic opportunities, however, lack of awareness of child development, social support, and standardized practices in care pathways delay autism diagnoses and access to early intervention services. In response, research involving and engaging the community is important to facilitate trust, improve quality and access to care. There are programmes and synthesised literature on community engagement and involvement in intervention development for NDDs. However, there is no synthesized knowledge of practices to involve the lived experiences of autistic individuals and their caregivers in conceptualizing community awareness through the unique lens of autism specifically for promoting early detection and improving the uptake of services.

Objectives: This scoping review will aim to report on the community-engaged and/or involved research methodologies employed within community-based programs to create awareness by leveraging lived experiences to promote early identification and uptake of intervention.

Methods: PubMed, Scopus, Ovid and Web of Science were searched. Studies after 1980s were included to follow the advocacy movement following deinstitutionalization. These needed to involve autistic individuals and their caregivers, in conceptualizing awareness resources, and reporting on the use of resources toward early detection or intervention services. Studies were excluded if beneficiaries were above 18 and not in English considering costs of translation and time, and if they were purely biomedical studies. Four reviewers double-reviewed all abstracts in COVidence software, two reviewers were involved in extraction, and one to check data accuracy.

Results: 13254 abstracts were screened, of which 31 were identified for full-text review, 10 met eligibility, and 6 were included in this review. All 6 studies involved community members, specifically caregivers of autistic children and care providers, and one engaged autistic adults to identify knowledge gaps, needed information, and preferences for presenting information, i.e., content and format. The most used methods reported in 4 studies were collaborative partnerships through stakeholder consultations, advisory boards, and stakeholder committees. Majority studies (n=4) used semi-structured and unstructured interviews. One study used boot camp translations based on a community-based participatory research framework. Other studies (n=2) included focus group discussions and knowledge translations sessions. One study each used participatory design workshops, rapid prototyping workshops, kick-off meetings, conferences, and market analysis. 5 out of 6 studies were based in high-income countries (HICs), with 1 study in a low-and-middle-income country (LMIC).

Conclusions: Involving relevant stakeholders to create awareness resources promoting early detection and intervention are happening across disciplines like design research and public health. Researchers' use of key terms and definitions varies; hence, the process varies. This difference is also attributed to knowledge and resource gaps between HICs and LMICs. Future research may benefit from standardising community-engaged practices across community-based programmes, specifically, collaborating with LMICs to determine best practices keeping in mind cultural contexts.

401.088 Enhancing Inclusion and Support in the Hospital for Children on the Autism Spectrum: Experiences and Needs of Healthcare Staff

L. W. Xue¹, Q. W. Sng¹, S. S. Pok¹ and C. M. Wong², (1)KK Women's and Children's Hospital, Singapore, Singapore, Singapore, (2)Department of Child Development, KK Women's and Children's Hospital, Singapore, Singapore, Singapore

Background: In a hospital setting, some patients on the autism spectrum may display challenging behaviors due to core difficulties involving communication, and sensory sensitivities during an anxiety-inducing period. Consequently, healthcare staff may encounter difficulty in caring for autistic patients, impeding effective care provision.

Objectives: The aim of this study was to explore the experiences and needs of healthcare staff when caring for autistic children, in order to identify ways to enhance inclusion and support in a pediatric hospital setting.

Methods: Focus group discussions (FGD) were conducted in a tertiary pediatric hospital, using a semi-structured interview guide. Participants were recruited from hospital staff using purposive sampling. The FGDs were recorded, transcribed and coded. Thematic analysis was subsequently conducted using NVivo 12.

Results: Twenty-one healthcare staff participated in the FGD (13 nurses, 5 doctors, 2 allied health professionals and 1 administrator). Five had worked in the hospital for <5 years, 6 for 5-10 years, and 10 for >10 years. Three had an immediate family member who was autistic. Findings highlighted the need to equip all healthcare staff with good communication skills for collaborative relationships to be effective, both in order to work in partnership with autistic children and their caregivers, as well as inter-professionally. Strategies and resources should also be taught to manage any externalizing behaviors exhibited by autistic children coming into a hospital setting. The impact of the hospital environment on patient experience, such as the design of the hospital or the need for an individualized 'hospital passport' for autism, and specialized management of medical/nursing procedures and devices, were also identified as key areas of need. Finally, there were significant conflicts of interest faced by healthcare staff when caring for children on the autism spectrum, such as between wanting to see to their individual needs, and yet having other patients to tend to and waiting times to adhere to.

Conclusions: The key themes identified from the study included: fostering collaborative relationships, improving multistakeholder communication, managing externalizing behaviors in a hospital setting, improving the healthcare environment, and managing conflicts of interest. Using these themes to effect change would hopefully enhance inclusion and support for children on the autism spectrum in the hospital setting.

401.089 Evaluating a Neurodiversity-Affirming Framework for STEM Workshops: Impact of Participatory Approaches on Staff Practices and Autistic Engagement

E. G. Kilgallon¹, S. O'Brien², E. Grossman³, D. Grevalle⁴, A. R. Arista⁵, J. Suárez⁶, C. Edano⁷, A. Arif⁸, G. Cordova-Castellanos⁹, R. Obeid¹⁰, M. Henry¹¹, P. Dwyer¹², J. Delos Santos¹³, B. Kofner¹⁴, A. Yan¹⁵, A. Hurst¹⁵ and K. Gillespie-Lynch¹⁶, (1)Department of Psychology, University of Massachusetts Boston, Boston, MA, (2)2800 Victory Blvd 4s-103, College of Staten Island; CUNY, Staten Island, NY, (3)Psychology, CUNY Graduate Center, New York, NY, (4)The Graduate Center, City University of New York, New York, NY, (5)Center for Children and Technology, Education Development Center, New York, NY, (6)Tandon School of Engineering, New York University, Brooklyn, NY, (7)Wilf Family Department of Politics, New York University, New York, NY, (8)City University of New York, Staten Island, New York City, NY, (9)Hunter College, New York City, NY, (10)Case Western Reserve University, Cleveland, OH, (11)Education Development Center, New York, NY, (12)Olga Tennison Autism Research Centre, La Trobe University - OTARC, Melbourne, VIC, Australia, (13)Hunter College, City University of New York, New York, NY, (14)College of Staten Island, Staten Island, NY, (15)New York University, New York, NY, (16)Department of Psychology, CUNY Graduate Center, Staten Island, NY

Background: Autism intervention research traditionally focuses on reducing Autistic traits¹, often neglecting social validity—how acceptable and meaningful interventions are to those affected². The disconnect between controlled efficacy and real-world relevance has stimulated advocacy for neurodiversity-affirming and participatory frameworks that prioritize Autistic individuals' self-determination^{3–6}. We present a framework for evaluating a neurodiversity-affirmative approach to delivering STEM workshops, in which we co-create processes with Autistic individuals, focus on strengths over deficits, foster community diversity, respect all forms of communication, and ensure accessibility.

Objectives:

Within a STEM workshop for Autistic adolescents, evaluate impacts of:

1. Centering neurodiversity-affirming practices on staff practices and beliefs
2. Utilizing ongoing student feedback on engagement

Methods:

The research occurred in Years 2 and 3 of a three-year NSF-funded study to create and assess online game-design and employment workshops for Autistic youth⁷. The Year 2 workshop included 22 participants ($M_{age}=16.82$, $SD_{age}=2.24$), and Year 3 workshops included 36 randomized participants: Workshop 3a ($n=17$, $M_{age}=16.9$, $SD=2.6$) and Workshop 3b ($n=19$, $M_{age}=17.2$, $SD=2.3$). After some staff applied deficit-based approaches in Year 2, leadership and the participatory team redesigned staff hiring, training, and curriculum to center neurodiversity-affirming approaches in Year 3. Workshop alignment with neurodiversity-affirming principles was assessed through staff self-report and coding of recorded workshop sessions. Coders, masked to timepoints and research questions, achieved interrater reliability ($\kappa=0.88$, $p < .001$).

Across both years, students self-reported engagement to provide real-time, iterative feedback on workshop activities. During “advocacy check-ins,” students collectively considered feedback patterns to suggest workshop improvements. In Year 2, engagement surveys and check-ins were framed as research activities, while in Year 3, staff framed these as opportunities to practice self-advocacy.

Results:

Video coding revealed that Year 3 staff used neurodiversity-affirming practices more frequently than Year 2 staff ($F(2, 15) = 9.182$, $p = 0.002$; $\eta^2 = 0.550$), suggesting improvements following revised training and hiring practices. Open-ended staff responses revealed that Year 2 staff focused more on behavior management, while Year 3 staff reported using student-centered, strengths-based approaches, including student-made “diversity profiles.” Year 3 staff reported higher satisfaction with training, particularly in fostering student self-advocacy. Student self-reported engagement were analyzed using hierarchical ordinal regressions. No across-year engagement differences were observed. Year 3 students reported more interest at the second ($\beta = 0.99$, $p < .001$) and third advocacy check-ins ($\beta = 1.05$, $p < .001$) relative to the first across both workshops, while check-ins in Year 2 did not improve engagement.

Conclusions:

Results suggest systemic changes between Years 2 and 3 improved neurodiversity-affirming practices and student engagement. Developing comprehensive training improved educators' adherence to neurodiversity-affirmative principles and their satisfaction with training. Findings highlight how authentic participatory work can foster more inclusive educational approaches. When engagement ratings were not framed as advocacy tools (Year 2), check-ins did not improve engagement. However, training staff to explicitly empower students to advocate for their learning preferences enhanced student engagement (Year 3), highlighting how empowering Autistic students to shape their educational contexts can promote self-determination.

401.090 Evaluating the Feasibility and Efficacy of a School-Home Communication Intervention Among Families of Children with Autism

R. Li, *Special Education, Vanderbilt University, Nashville, TN*

Background: School-home communication is a critical factor in supporting the education and development of children, particularly those with autism. Effective communication strategies can lead to enhanced family involvement, better educational outcomes, and stronger family-professional partnerships (Flessa, 2008). However, research indicates that only half of all families with school-aged children receive any communication from their child's school (McQuiggan & Megra, 2017), and this communication is often not aligned with the needs and preferences of families, particularly those of children with autism (Azad et al., 2018). Therefore, there is a critical need for interventions that can improve communication between families and schools, specifically tailored to the unique needs of children with autism (Tucker & Schwartz, 2013). The proposed School-Home Alliance for Relationship Enhancement (SHARE) intervention seeks to address these gaps by offering a low-intensity, flexible, and evidence-based approach.

Objectives: The primary objectives for families and educators of children with autism are: (1) assess the efficacy of the SHARE intervention in improving satisfaction and quality of school-home communication; (2) evaluate the intervention's impact on family-professional partnerships; and (3) determine the feasibility and acceptability of the intervention.

Methods: The study will involve a convenience sample of family-educator dyads from various geographical regions in the United States. Eligibility criteria include families with a child with autism between the age of 3-21 years and educators who work with their children. The SHARE intervention, grounded in Bronfenbrenner's Ecological Systems Theory, consists of three virtual, one-hour weekly sessions, with engagement in interactive discussions, role-play activities, and the development of communication action plans using SMART goals.

The presurvey includes demographic items, a researcher developed measure on school-home communication, two established measures to evaluate communication and family-professional partnership, and an established measure to assess the child's autism severity and maladaptive behavior. The formative evaluations include four close-ended and three open-ended items to determine feasibility and usability of the intervention sessions. The post-survey will be comprised of the same measures as the pre-survey but without demographic items or child measures and additionally include an established measure to evaluate intervention acceptability.

Descriptive statistics will be calculated for pre- and post-intervention measure scores. Mixed-effects models will be used to assess the intervention's efficacy, controlling for baseline and child characteristics. Correlation analyses will be used to examine the alignment between family and educator ratings, and paired-samples t-tests will be conducted to evaluate changes in family-professional partnerships. Additionally, open-ended responses from the formative evaluations will be analyzed using the constant comparative method to identify themes related to feasibility and acceptability.

Results: The SHARE intervention is hypothesized and expected to enhance family-professional partnerships, improve school-home communication, and establish more consistent support for the child's development.

Conclusions: This study addresses a gap in existing literature by focusing on the nuanced aspects of school-home communication. The goal is to determine the SHARE intervention's impact on communication satisfaction, quality, and alignment, as well as on the quality of family-professional partnerships, hypothesizing positive outcomes and the intervention's feasibility for educators and families of children with autism.

401.091 Evaluating the Need for Autistic-Led Autism Instruction for Education Professionals

D. Batkin¹, A. Ashraf², M. Cutler³, M. Elliot⁴, B. Kofner⁵, S. M. Shore⁶, Z. Zaks⁷ and K. Gillespie-Lynch¹, (1)Graduate Center, CUNY, New York, NY, (2)College of Staten Island, New York, NY, (3)Graduate Center, CUNY, New York, NY, (4)College of Staten Island, Staten Island, NY, (5)Special Education, Adelphi University, Garden City, NY, (6)Towson University, Towson, MD, (7)Department of Psychology, CUNY Graduate Center, Staten Island, NY

Background:

Stereotypes about autism include functioning labels (i.e., high- or low-functioning) and are highly prevalent among lay people (Draaisma, 2009), as is stigma surrounding autism (Gillespie-Lynch et al., 2022). Educators have the power to dismantle stereotypes and reduce stigma (Gillespie-Lynch et al., 2022), by educating themselves about autism via structured trainings (Gillespie-Lynch et al., 2017, 2022; Waisman et al., 2023). Structured trainings can have a greater impact if delivered by autistic people, due to their firsthand experiences of autism (Gillespie-Lynch, 2017). It is important to include diverse autistic perspectives (e.g., non-speaking autistic people) in these trainings as well (Lebenhagen, 2020).

Objectives:

1. Explore education professionals' views on autism and experiences that shaped their views.
2. Evaluate impacts of a primarily autistic-led autism sabbatical program for educators.

Methods:

Thirty-seven education professionals signed up for a year-long autism sabbatical program that includes two 2.5 hour courses each term and a fieldwork component; twenty-eight professionals completed the survey. One student withdrew from the program. One track is on Monday, one on Wednesday. The Monday classes are taught by one autistic and one non-autistic instructor; the Wednesday classes by two autistic instructors. Students were assigned to each day without consultation. Instruction includes contemporary issues surrounding autism in education, diagnosis, and interventions. Responses were coded qualitatively by two independent coders. Students also completed weekly logs wherein they recounted key experiences in each class, including synthesis of similarities and differences in what they learned in each class, and a mid semester survey about their experiences so far. Coding of logs is ongoing but illustrative quotes are provided in Table 2.

Results:

All results are exploratory. See Table 1.

Participants who described autism as involving executive functioning ($p=.012$) and/or structural language difficulties ($p=.003$) were more likely to describe having a negative experience in the education system surrounding autism. Further analysis revealed that participants who defined autism as involving structural language difficulties ($p=.008$) reported not having enough training to effectively support autistic needs.

Participants who described special education settings having an impact on their perspectives on autism were more likely to describe autism as involving structural language difficulties ($p=.027$).

Participants who described their professional experiences impacting their understanding of autism were more likely to describe autism in terms of functioning levels or severity ($p=.022$) but were also more likely to describe autism as a positive difference ($p=.016$).

Conclusions:

Exploratory results indicate that education professionals require training on alternative communication methods used by autistic people to effectively support them in education settings.

Additionally, education professionals may be absorbing stereotypes about autism (e.g., Draaisma, 2009) as a result of their professional experiences.

Autistic people leading this program may be especially needed not only to train participants to effectively support autistic people's needs in education settings, but to help them dispel stereotypes about autism (Gillespie-Lynch, 2017; Lebenhagen, 2020).

Further research will involve coding participants' weekly journal logs and assignments completed throughout the semester. Weekly logs will show if instruction by autistic people impacts educators' views and understanding of autism.

401.092 Examining Racial and Socioeconomic Disparities in Autism Classifications in the Deep South

J. Albright¹ and M. A. Patterson², (1)Department of Psychology, Virginia Polytechnic Institute and State University, Blacksburg, VA, (2)Psychology, University of South Alabama, Mobile, AL

Background:

Recent studies have shown that the rate at which autism is identified among children varies widely from state to state (Safer-Lichtenstein et al., 2020; Aylward et al., 2021). Factors that contribute to the variation in identification include socioeconomic status and state education policies. Historically, minority groups have exhibited lower diagnostic rates (Tromans et al., 2020). In recent years racial disparities in nationwide diagnostic rates have leveled out (Maenner et al., 2023). Given that Alabama's public education system currently ranks among the lowest in the country, we were interested in examining whether racial and socioeconomic disparities remain at the state level (McCann, 2024).

Objectives:

Determine whether race and socioeconomic status remain important predictors of autism educational classifications in the state of Alabama. Hypothesis: Percent of Black/African-Americans (%Black), percent with a Bachelor's degree (%Bachelors), and percent living below the poverty level (%Poverty) at the county level would predict percent of children with a special education classification of autism not yet in kindergarten (%Pre-K), as well as total number of autism cases (TotalASD) in each county.

Methods:

For each of the 67 county school districts, the total number of children ages 3-21 with an educational classification of autism were pulled from the 2023 Child Count report. The percent of children with an educational classification of autism between ages 3-5 (not yet in kindergarten) was then calculated. The %Black, %Bachelors, and %Poverty in each county were pulled from the U.S. Census data. IBM SPSS Statistics software (Version 28) was used to run descriptive statistics and multiple regressions.

Results:

In Alabama, 103,931 students are served within the special education system with 12,406 having an educational classification of autism ($M=114.81, SD=159.71$), and the mean %Pre-K is 5.40%. The mean %Bachelors is 19.13%, mean %Poverty is 18.42%, and mean %Black is 29.01% across all counties.

A multiple regression was run to predict %Pre-K from %Bachelors, %Poverty, and %Black. This model was significant ($R^2 = 0.117, F(3,63) = 2.771, p = 0.049$). The only significant predictor was %Poverty, which was a negative predictor ($p = 0.038$).

A multiple regression was run to predict TotalASD cases from %Bachelors, %Poverty, and %Black. This model was also significant ($R^2 = 0.507, F(3, 63) = 21.592, p < 0.001$). The only significant predictor was %Bachelors, which was a positive predictor ($p < 0.001$).

Conclusions:

In Alabama counties where there is a higher percentage of the population living below the poverty level, there is a statistically lower percentage of children ages 3-5 not yet in kindergarten who have been identified with autism. Additionally, in Alabama counties with higher educational attainment, there is a statistically higher percentage of children identified with autism. These findings illustrate that socioeconomic factors remain critical indicators of access to autism identification within schools. Targeted outreach efforts surrounding early autism identification are needed, particularly within low-income communities with low-educational attainment in Alabama. Future directions and limitations will also be discussed.

401.094 Executive Functioning Predicting Health Outcomes: A Dyadic Analysis of Parents with Autistic Children

L. Dominguez Ortega¹, M. Krushena², A. Sturm³ and A. Gulsrud⁴, (1)UCLA Semel Institute for Neuroscience & Human Behavior, University of California, Los Angeles, Los Angeles, CA, (2)Central Michigan University, Mount Pleasant, MI, (3)Loyola Marymount University, Los Angeles, CA, (4)UCLA Semel Institute for Neuroscience & Human Behavior, Los Angeles, CA

Background: Adverse outcomes, like increased stress, are common in parents given the demanding nature of their role (Nomaguchi, 2020). That said, parents of autistic children report particularly high rates of adverse health outcomes compared to their counterparts with neurotypical children or children with other developmental disorders (Dimachkie Nunnally et al., 2023). Parental executive functioning is one factor known to buffer such outcomes (Korucu et al., 2020), but research to date has only considered its role in individual parents, neglecting the bidirectional and interconnected nature of the parenting dyad (Zeng et al., 2021). Appropriate statistical methodology is needed to assess the viability of protective factors within the parenting dyad and promote positive health outcomes in parents of autistic children.

Objectives: The present study engaged in an exploratory dyadic analysis examining the influence of parents' executive functioning abilities (emotion regulation and inhibitory control) on parental health outcomes (anxiety, depression, parental stress, and well-being). Actor effects, the impact of parents' executive functioning on their *own* outcome variables, and partner effects, the impact of parents' executive functioning on their *partner's* outcome variables, were considered for anxiety, depression, parental stress, and well-being.

Methods: Sixty-three different-sex parenting dyads with a biological, autistic child from Simons Powering Autism Research for Knowledge (SPARK), a nationwide autism genetics study, completed online surveys. Data were analyzed using path analysis, guided by the Actor-Partner Interdependence Model (Cook & Kenny, 2005) to account for their non-independence. Four saturated models were run, one for each outcome variable (anxiety, depression, parental stress, and well-being) with emotion regulation and inhibitory control as predictor variables.

Results: Analyses indicated strong emotion regulation actor effects. Deficits in mother and fathers' emotion regulation predicted worsening personal anxiety, depression, parental stress, and well-being. Additionally, one partner effect was found, such that moms' worsening emotion regulation predicted dads' decreased well-being. Inhibitory control did not share the same predictive ability as emotion regulation aside from one finding -- worsening inhibitory control predicted lower well-being in fathers.

Conclusions: Parents' emotional regulation is a viable predictor of their own anxiety, depression, parental stress, and well-being, highlighting its potential as a protective factor against adverse health outcomes related to parenting an autistic child. This study gives insight into parental dynamics through the partner effect finding of moms' emotion regulation predicting dads' well-being. We posit this relates to moms' increased caretaking role within the family. As moms tend to be more involved in parenting and other family-related tasks, their ability to manage their emotions may have a greater impact on broader family functioning. Further, dads' well-being, overall, may be more sensitive to executive functioning challenges, which could explain our sole actor effect for inhibitory control. These results can be used to inform prevention and intervention efforts by emphasizing the importance of emotion regulation for parents of autistic children. They also highlight the importance of providing additional support to mothers around emotion regulation to minimize potential negative effects on personal and partner well-being.

401.095 Expectations of Puerto Rican Caregivers of Autistic Individuals Regarding Romantic Relationships

N. Rivera Caquilas¹ and M. Vega Carrero², (1)Ponce Health Sciences University, Ponce, PR, (2)Albizu University, Mayagüez, Puerto Rico

Background: Many parents of autistic youth express a need for guidance in providing education on sexuality and romantic relationships, yet they may hesitate to do so if they do not anticipate that their child may develop sexual relationships (Holmes et al., 2015). Current data on parental expectations for their autistic children's ability to engage in romantic relationships is significantly limited within collectivistic and family-oriented societies such as Latino populations (Espinosa et al., 2020).

Objectives: The objectives were: (1) to describe the expectations of Puerto Rican caregivers of autistic individuals regarding romantic relationships and (2) to determine if a relationship existed between caregivers' expectations and the levels of support established for their child's autism spectrum disorder (ASD) diagnosis, as defined by the DSM-5-TR.

Methods: In this descriptive and correlational study, a convenience sample of 50 self-identified adult caregivers of autistic individuals, whose ages ranged from 5 to 34 years, was voluntarily recruited through social media flyers. Participants completed two instruments via REDcap: a sociodemographic questionnaire and a caregiver expectations survey, adapted and translated using a back-translation method, from Holmes et al. (2015) and Holmes & Himle (2014). The survey measured caregivers' expectations using a 5-point Likert scale where higher scores indicated higher expectations. Frequency analyses by premise were conducted on the survey data. For the second objective, a Shapiro-Wilk test confirmed a normal distribution, and a bivariate Pearson correlation analysis was performed.

Results: The majority of participants ($n=29$, 58%) believed it was likely or very likely that their child would experience sexual attraction. For romantic relationships, 23 participants (46%) saw some likelihood of their child going on dates, while 14 (28%) viewed this as unlikely or very unlikely. Regarding falling in love, 22 participants (44%) anticipated this possibility, compared to 12 (24%) who did not. When asked about healthy sexual relationships, 22 participants (44%) expressed likelihood, while 23 (46%) expected likelihood for marriage or finding a life partner. Finally, 23 participants (46%) expected their child to likely have children. Finally, a moderate negative relationship was observed between caregiver expectations and identified support levels for the ASD diagnosis, showing that higher levels of support in the areas of social communication ($r = -0.568$) and restricted interests and repetitive behaviors ($r = -0.459$) were associated with lower expectations regarding romantic relationships.

Conclusions: This study significantly contributes to the field of ASD in Puerto Rico by collecting quantitative data on caregiver expectations regarding the sexuality and romantic relationships of their autistic children. Despite the small sample size, the data revealed variability in caregiver responses which was related, in part, to the level of support required by their child's ASD diagnosis. Nonetheless, many caregivers reported high expectations, with consistency found across several premises in the Caregiver Expectations Survey, offering novel findings in comparison to previous studies (Holmes et al., 2015; Holmes & Himle, 2014). These insights have important implications for developing educational programs, support groups tailored to families' needs, public policies on sexual education and relationship guidance, and training for health professionals in this area.

401.096 Experiences and Well-Being of Rural Mothers That Have a School-Aged Autistic Child

Z. E. Arnold¹, **A. Mercier¹**, **B. Stein¹**, **C. R. Newsom²** and **S. O'Kelley¹**, (1)Department of Psychology, The University of Alabama at Birmingham, Birmingham, AL, (2)Department of Neurobiology, The University of Alabama at Birmingham, Birmingham, AL

Background: Families with a child with autism spectrum disorder (ASD) who live in rural communities face many barriers to receiving care, including a lack of access to knowledgeable intervention (Murphy & Ruble, 2012) and primary care providers (PCP; Rhoades et al., 2007). Due to these barriers, these families must find ways to care for their children, often at a detriment to their own well-being (Ault et al., 2021). Caregivers from rural communities report overwhelming levels of stress (Hoogsteen & Woodgate, 2013), rate themselves poorly on measures of family quality of life (Higgins et al., 2005), and have poor social supports (Parsons et al., 2020). However, previous literature has only analyzed rural communities in comparison to urban communities or as a unitary group, but rurality is not a uniform geographic region and should be precisely defined (Danek et al., 2022).

Objectives: To explore how increasing rurality impacts healthcare delivery and subsequent caregiver well-being by interviewing caregivers of autistic children. It was hypothesized that caregivers from increasingly rural communities would report unique themes about their service providers (school-based interventions, outpatient interventions, and primary care) and endorse unique well-being themes in the areas of stress, quality of life, and social support.

Methods: Caregiver neighborhoods were categorized using census tracts defined by Rural-Urban Commuting Areas (RUCAs; Morrill, Cromartie, & Hart, 1999) that define rurality by population density, urbanization, and daily commuting. Caregivers from Large Rural, Small Rural, and Isolated Rural communities completed semi-structured interviews focused on their well-being (e.g., stress, quality of life, and social support) and child's healthcare to appreciate the unique needs and differences between rural communities. Interviews were preliminarily coded via a qualitative content analysis in NVivo 14. Child healthcare themes for intervention and PCPs included the following: caregiver's feelings about their providers, how they contacted their providers, their interactions with their providers, and the support obtained from providers.

Results: Eleven primary caregivers (4 Large Rural, 4 Small Rural, and 3 Isolated Rural; $Mage = 33$; $SD = 6.2$; 100% female) completed interviews. Mothers were 64% White, most attended some college (36%), and reported a median household income of \$50,000 to \$75,000. Autistic children were 64% male ($Mage = 7.3$; $SD = 4.8$). In comparison to mothers from Large Rural communities, mothers from Small Rural and Isolated Rural communities uniquely noted the following concerns: their child's therapy providers were not meeting their child's needs, caregiver-provider interactions could be contentious, a lack of knowledgeable providers, felt stigmatized in their communities, isolated themselves and their families, and had uncontrolled levels of stress.

Conclusions: Findings suggest that RUCA categorizations of rurality help to reveal that families with an autistic child from increasingly rural communities experience unique challenges with their service providers and their subsequent well-being. Although efforts to increase provider capacity (Tomeny et al., 2023; P. Nowell et al., 2020) and implementation of parent interventions to promote caregiver well-being (Lee et al., 2024; Tsujita et al., 2023) could benefit all communities, these services may be particularly crucial in smaller rural communities.

401.097 Experiences of Affiliate Stigma and Depressive Symptoms in Caregivers of Autistic Children: The Moderating Effect of Social Support

M. Susko, **K. Gordon**, **L. de la Roche** and **E. Kelley**, Department of Psychology, Queen's University, Kingston, ON, Canada

Background: Caregivers of autistic children are often subjected to stigma which can have negative consequences on their mental health. Affiliate stigma refers to the internalization of stigma among individuals closely associated with a person from a stigmatized group. Previous research has found a mediating effect of social support on the relationship between affiliate stigma and depression among caregivers of children with neurodevelopmental conditions. Extending this work to explore the *moderating* effect of social support can help determine if there is an interaction between affiliate stigma and social support that influences the strength and direction of this effect on depressive symptoms. As such, we conducted an online study to examine social support as a moderator of affiliate stigma on depressive symptoms among caregivers of autistic children.

Objectives: (1) To examine the relationship between affiliate stigma and depressive symptoms. (2) To examine the relationship between social support and depressive symptoms. (3) To examine the moderating effect of social support on the association between affiliate stigma and depressive symptoms.

Methods: Participants included 110 caregivers (95 mothers) of autistic children under 18 ($M = 11.28$, $SD = 3.80$). In addition to demographic information, caregivers completed online questionnaires including the Family Stigma Questionnaire, the Multidimensional Scale of Perceived Social Support, and the Center for Epidemiological Studies Depression Scale. A hierarchical regression was run to determine if social support moderated the association between affiliate stigma and depressive symptoms. Child age and household income were included as control variables. **Results:** Higher levels of affiliate stigma were associated with greater depressive symptoms ($\beta = .34$, $t(109) = 3.77$, $p < .001$). Higher levels of social support were associated with fewer depressive symptoms ($\beta = -.25$, $t(109) = -2.79$, $p = 0.006$). When social support was added as a moderator, the interaction accounted for only an additional 0.80% of the variance in depressive symptoms and the moderating effect of social support was not significant ($R^2 = 0.23$, $F(103) = 1.10$, $p = 0.297$).

Conclusions: Caregivers of autistic children with high levels of affiliate stigma reported high levels of depressive symptoms. Additionally, those who reported greater social support reported fewer depressive symptoms. However, social support did not moderate the relationship between affiliate stigma and depressive symptoms. Findings suggest that social support may not be an ideal intervention target for reducing depression that is associated with affiliate stigma in caregivers of autistic children. Future research should explore the moderating effects of other variables, such as mindfulness. While social support did not directly impact the association between affiliate stigma and depression, it did appear to influence depressive symptoms more generally. These findings support the need for increased social support access for caregivers of autistic children as it may mitigate negative impacts on caregiver well-being.

401.098 Experiences of Autistic Students in a Canadian Neuro-Affirming Blended-Learning Centre

C. L. Ferguson, *The Penticton Centre for Exceptional Learning, Penticton, BC, Canada; Humanities and Social Sciences, Athabasca University, Athabasca, AB, Canada*

Background: Traditional brick-and-mortar schools can act as a systemic barrier to autistic students, as many students experience overwhelm due to social expectations and sensory-overload (Rizzo et al, 2012). Research is emerging that the real-world effects of inclusive education may not be as positive as idealized (Chan et al., 2018; Lindsay, 2007). Due to its broad-reaching effects, autism research is conducted by a diverse range of professionals (including architects, speech-and-language pathologists, occupational therapists, psychologists, educators, and self-advocates): each offers guidance and best practices to support autistic individuals. There are literature gaps in both 1) the synthesis of multi-disciplinary best-practice approaches, and 2) between research and the practical implementation of said best-practices (Hallinan, 1996), or rather, a lack of organized and implemented common-sense (Punch, 2014). A set of guidelines is needed for educators and policy makers such that autistic students' mental well-being are positively affected by feeling understood, supported, and safe in their learning environments, so that they may embrace their autistic identities and positively connect with peers, while building a foundation of skills needed to live a joyful and engaged life.

Objectives: The purpose of this study is to benefit the autistic community by gathering empirical data from the lived experience of autistic students who attended a neuro-affirming blended-learning centre: I created the program under study based on synthesized knowledge and best-practices from current autism research, learning science, psychology, and brain science. These data will inform social-policy makers and service providers, having the goal of affecting neuro-affirming change that will increase the mental well-being of autistic students (Mertens, 2009): I will investigate how autistic students perceived their experiences while they attended said neuro-affirming blended-learning centre, and how those experiences affected their mental well-being.

Methods: I will undertake an interpretive-hermeneutical phenomenological study (Creswell & Creswell, 2018), with 10 individual semi-structured qualitative interviews (Creswell & Poth, 2018). Participants will be recruited through purposive sampling (Cresswell & Poth, 2018). Participants will be asked a pre-set list of questions, with researcher flexibility to modify questions and follow an iterative path as the research unfolds. Due to the challenges of researching my own organization, I will have a researcher conduct the interviews. Each interview will be video recorded and transcribed, with the aim to tease out the participant's rich lived experiences and perceptions of those experiences. The transcripts will be organized, stored and sorted using NVivo software, as well as printed for manual paper-based reading and coding.

Results: IN PROGRESS. To increase credibility, reduce unconscious bias, and reduce my position of power, I will involve a second researcher in coding, analyzing, and interpreting the data. Personal observations and research suggests that data should show an improvement in participants' mental health.

Conclusions: IN PROGRESS. I will conclude the presentation of my findings with a highlight of significant quotes from the transcribed interviews, which will be analyzed through a disability-theory lens (Mertens, 2009), formulated into themes, and used to describe and portray the essence of the participant's experiences.

401.099 Experiences of Pregnancy and Early Parenthood Among Autistic People in Australia

A. M. Love¹, **R. Y. Cai²**, **B. Rideout³**, **L. Hollenberg³**, **G. McKeown⁴**, **C. Edwards⁵**, **C. Benzie⁶**, **A. Robinson⁶** and **V. Gibbs¹**, *(1)Aspect Research Centre for Autism Practice, Autism Spectrum Australia, Sydney, NSW, Australia, (2)School of Nursing, Midwifery, and Health Practice, Victoria University at Wellington, Wellington, New Zealand, (3)Reframing Autism, Melbourne, VIC, Australia, (4)University of Tasmania, HOBART, TAS, Australia, (5)School of Nursing and Midwifery, La Trobe University, Bundoora, VIC, Australia, (6)Building 1, Level 2, 14 Aquatic Drive, Autism Spectrum Australia (Aspect), Sydney, NSW, Australia*

Background: Autistic adults face significant barriers accessing quality healthcare and frequently report negative experiences with practitioners. These challenges are evident across all areas of healthcare, including maternity care. Despite the importance of accessible prenatal and antenatal care, research on the experiences of Autistic people during pregnancy remains scarce, leaving healthcare practitioners without an evidence base to guide care.

Objectives: The purpose of this qualitative study was to explore the pregnancy and early parenthood experiences of Australian Autistic individuals. By addressing this critical gap, the study seeks to provide insights that can guide healthcare providers in offering more tailored and effective healthcare for Autistic people.

Methods: Nineteen Autistic individuals (60% White, $M_{age} = 34.11$, $SD_{age} = 4.4$) participated in this study. Seventeen were professionally diagnosed, while two self-identified as Autistic. All participants resided in Australia and were currently pregnant or had been pregnant within the past five years. They represented both rural and urban settings and identified as either female ($n = 15$) or non-binary ($n = 4$). Participants came from diverse backgrounds and shared a range of pregnancy experiences, including loss and premature birth. To enhance accessibility, participants were able to choose their preferred mode of interview (written, Zoom, or phone). The data were analyzed using reflexive thematic analysis.

Results: We generated four themes with associated subthemes from the stories that were shared. The first theme generated, "Pregnancy was good for me," reflected feelings of body positivity and empowerment during pregnancy. Theme 2, "Hyperfocus as an understatement," illustrates participants' desire to seek information on every aspect of their pregnancy and parenthood journey. We describe how this intense research and the pursuit of answers resulted in both facilitators and barriers to wellbeing. Theme 3, "I'm lost in the system," describes the social drain caused by unpredictable interactions with healthcare workers. Finally, Theme 4, "Making things work for me," addresses the coping mechanisms employed by participants to offset the high demands of pregnancy, including positive support and the intentional strategies they used to cope and persevere through each stage of pregnancy and early parenthood.

Conclusions: This paper and our findings amplify the stories of competence and empowerment among Autistic people during pregnancy and early parenthood, highlighting their resilience and agency in navigating these life transitions. This study enhances understanding of the pre- and postnatal experiences of Autistic people, filling a critical gap in healthcare knowledge. Importantly, these findings have broader implications for improving healthcare in other areas where Autistic people face similar challenges, emphasizing the need for more inclusive and effective care to enhance quality of life.

As an outcome of this research, our team developed an Australia-first digital platform offering resources for both Autistic women and the practitioners who support them. The platform was co-developed along with a team of Autistic parents who have guided the lifecycle of this project. The platform aims to increase the knowledge and confidence of Australian maternal healthcare professionals, while also offering Autistic people validation and shared experiences of pregnancy and early parenthood.

401.100 Exploration of Chinese Autism Terminology Among Autism Community Stakeholders in Hong Kong

G. Y. H. Lam¹, W. Chan¹, Y. C. Wong² and C. C. M. Cheng², (1)Department of Educational Psychology, The Chinese University of Hong Kong, Shatin, NT, Hong Kong, (2)Department of Psychology, The Chinese University of Hong Kong, Shatin, NT, Hong Kong

Background:

Autism terminology has been increasingly concerned by the autistic community. Not only different terms referring to autism represent various meanings and narratives, terms in different languages can also be understood and preferred by local stakeholders differently. While most of the discussions were from Western contexts, autism terminology in Chinese contexts is unknown.

Objectives:

To explore the perceptions of autism terminology in Hong Kong autism community.

Methods:

This presentation reported the results from a larger interview study about the needs of autism community in Hong Kong. One of the sections was focused on the use of autism terminology. Questions included: What considerations do you have about autism terminology? What term(s) do you or others in the community use or prefer? What do you think about the different terms? 49 stakeholders from the Hong Kong autism community (20 autistic adults, 19 parents of autistic individuals, and 10 professionals who had experience working with autistic individuals) completed semi-structured individual interviews using Cantonese Chinese. Interviews were audio-recorded and transcribed verbatim. Thematic analysis was conducted to reveal the patterns of their responses and any commonalities or differences between stakeholder groups.

Results:

All stakeholder groups described the theme of "stigma" and negative images associated with autism circulating in Hong Kong, such as confusing autism with intellectual disability or "being crazy". The Chinese term for autism literally means "self-isolated", which many expressed concerns of misleading information that autistic people only are aloof and reject social relationships. To avoid being ridiculed or maltreated, some autistic adults and parents avoided associating themselves with autism, so instead they used fuzzy ways to talk about autism.

A sense of "indifference" was expressed by autistic adults and parents as they expressed that "[whatever autism terminology] does not matter". Parents were more concerned about their children receiving the right interventions. Some autistic adults appeared to "let it go" due to autistic burnout.

Other two themes were related to sociocultural influences. Some stakeholders described the generational differences in the usage of autism terminology. Some parents indicated their senior family members (e.g., grandparents) do not believe about autism. Professionals also recalled terms (e.g., "bai-yi") that might not be accepted by contemporary Hong Kong society, but was commonly used by older generations because and did not bother them.

Some autistic adults and professionals preferred terms adopted from Western narratives, such as neurodiversity and "Aspie", because these conveyed concepts that are more supportive of identity development and inclusion. However, they recognized that these terms are influenced by Western values and are not familiar by local people.

Conclusions:

Autism terminology and (mis)understanding of autism are interrelated, which are influenced by various sociocultural factors. The notable absence of debate between person-first and identity-first language is sensible as Chinese language does not have grammar markers to distinguish these two terms. The tendency to sustain group harmony also makes autism-identity assertion more culturally costly in Chinese society. To promote authentic understanding and sensible framing of autism, choice of autism terminology needs to be sensitive to local cultures and narratives.

401.101 Gender Differences in the Prevalence of Autistic Experiences of Interpersonal Violence: A Mixed Methods Systematic Review and Meta-Analysis

K. Cooke¹, K. L. Ridgway², L. A. Pecora³, E. Westrupp⁴, D. Hedley⁵, M. Hooley⁶ and M. A. Stokes⁶, (1)Healthy Autistic Life Lab; School of Psychology, Deakin University Australia, Melbourne, VIC, Australia, (2)Healthy Autistic Life Lab; School of Psychology, Deakin University - Healthy Autistic Life Lab, Melbourne, VIC, Australia, (3)School of Psychology, Deakin University, Melbourne, VIC, Australia, (4)School of Psychology, Deakin University, VIC, Australia, Melbourne, VIC, Australia, (5)Olga Tennison Autism Research Centre, La Trobe University, Melbourne, VIC, Australia, (6)Healthy Autistic Life Lab; School of Psychology, Deakin University, Burwood, VIC, Australia

Background: Interpersonal violence is a leading cause of mortality among youths and incurs significant costs to public health and safety, globally. Increasing empirical evidence suggests rates of interpersonal violence are particularly high among autistic people, particularly among females and gender minorities (e.g., non-binary/gender-fluid, transgender); however, findings are mixed and vary by form of violence.

Objectives: We undertook a mixed methods systematic review and meta-analysis to explore violence prevalence among autistic people of various gender identities. We utilised a random effects meta-analysis to examine gender differences in interpersonal violence prevalence among comparative groups of males, females, and gender minorities.

Methods: A systematic database search of EMBASE, CINAHL, SocINDEX, MEDLINE Complete, PsychINFO, and Web of Science identified 64 studies examining combined and varying forms of physical, sexual, and psychological interpersonal violence among autistic people diverse in gender, age, and level of support needs. We undertook a random effects meta-analysis with pooled data from 24 eligible studies comprising 12,375 autistic participants aged between 2 to 83 years examining gender differences in violence prevalence among comparative groups of males (73.7%), females (17.7%), and gender minorities (1.6%). Data not included in the meta-analysis were assessed via narrative review of 62 studies comprising 19,539 autistic participants (73.7% males, 23.1% females, 1.6% gender minorities, 1.7% other/non-specified [n/s]), and 301,864 non-autistic participants (34.1% males, 62.9% females, 0.01% gender minorities, 2.66% other/n/s).

Results: Analyses found increased overall violence prevalence among autistic females compared to males ($d = 0.32$, $p < .001$), during adulthood, and childhood and adolescence combined, but not during childhood or adolescence when examined separately, regardless of intellectual disability co-occurrence. The largest effect size was for sexual violence ($d = 0.67$, $p < .001$). Autistic gender minorities (e.g., transgender, gender-fluid) were more likely to experience overall violence than autistic males ($d = 0.73$, $p < .05$), yet not autistic females. Narrative synthesis of 62 studies indicated autistic people were more likely to experience lifetime violence compared to non-autistic controls. Gender-marginalized groups (e.g., females, transgender, non-binary) had higher rates of violence than cis-males; however, this difference varied by age and violence type.

Conclusions: Findings suggest that autistic populations face disproportionate experiences of overall and various types of interpersonal violence relative to general populations, implicating a concerning high prevalence of violence and repeated violence across the lifetime, particularly among females and gender minorities.

**401.102 Exploring Character Strengths Using Values in Action-Youth Survey in Autistic Young People – a Cognitive Interview and Reflective Practice Qualitative Study**

J. Lei¹, E. Jewitt¹, E. Leigh² and C. Creswell¹, (1)Department of Psychiatry, University of Oxford, Oxford, Oxford, United Kingdom, (2)Department of Experimental Psychology, University of Oxford, Oxford, United Kingdom

Background:

The shift towards celebrating neurodivergence including strengths and differences have led to more Strength-Based Approaches (SBA) in autism research. Most SBA focus on skills, talents and focused interests that improve functional outcomes (e.g., academic attainment). Few explore how personal characteristics can support identity development and wellbeing in autistic young people (YP). Using the Values in Action (VIA)-Youth survey, we explored how Character Strengths (CS) can enable autistic YP to be at their best and live authentically in daily life, to foster identity development and wellbeing.

Objectives:

- Explore the acceptability and feasibility of using VIA-Youth survey to identify CS in autistic YP (12-15 years-old) using cognitive interviewing technique.
- Explore autistic YP's reflections on building awareness of, exploring, and applying CS in daily life.

Methods:

13 autistic YP (M (SD) years: 13.54 (1.27); Table 1) recruited online participated in two one-to-one interviews. Interview one: YP each completed the VIA-Youth (98 items to evaluate 24-CS) survey with an interviewer (~90 minutes). The interviewer elicited examples and clarified confusing items by explaining the CS being examined. YP reviewed personal CS profile for 1-2 weeks before returning for interview two. Interview two: YP reflected on face validity of the CS report, what they learnt about themselves during the process, and strengths they wished to share with others and why (~60 minutes). All interview data were analysed using reflexive thematic analysis (Braun & Clark 2013).

Results:

[Aim 1] Autistic YP found the VIA-Youth survey acceptable and feasible to use. However, poor context specificity made it harder to identify an accurate rating. For example, YP reported high levels of Curiosity and Love of Learning if the statements specifically related to areas of focused interests, but less so for general daily activities. YP found the abstract language used for Spirituality questions harder to interpret beyond religious contexts.

[Aim 2] YP found the CS profile to have good face validity (Figure 1). YP endorsed certain strengths (e.g., Humour and Creativity) as part of neurodivergent thinking, and related Social Intelligence to masking (i.e., "acting normal" without understanding social context). Many highly endorsed Honesty and Fairness, leading to higher Bravery (standing up for others being treated unfairly), and lower Forgiveness (when trust has been broken in relation to negative social experiences). Co-occurring mental health conditions influenced Prudence (rumination over decision-making for fear of making a mistake), and Hope (lack future-oriented thinking when stuck in a difficult situation). YP found the CS profile helped consolidate and improve self-awareness and identified strengths to rely on to navigate stressful situations. Some YP wished to share the profile with their school to improve strengths-based learning and reduce misunderstanding.

Conclusions:

This is the first study to show that a structured CS profile can scaffold conversations to help YP notice personal qualities as strengths that guide their actions beyond skills and talents. Improving self-awareness of CS to navigate difficult situations may enhance resilience. Collaborative use of VIA-Youth survey for CS identification can support autistic YP to build self-awareness, positive identity, and better wellbeing.

401.103 Exploring Character Strengths in Autistic Young People Based on Parental Responses on the Values in Action-Youth Survey – a Cognitive Interview and Reflective Practice Qualitative Study

E. Jewitt, E. Leigh, C. Creswell and J. Lei, (1)Department of Psychiatry, University of Oxford, Oxford, Oxford, United Kingdom, (2)Department of Experimental Psychology, University of Oxford, Oxford, United Kingdom

Background:

The increase in neuroaffirmative practises and strength-based approaches in autism research have often focused on skill-based strengths that improve life outcomes, with few exploring how personal characteristics and values most important to autistic young people (YP) can support their identity development and wellbeing. Using the Values in Action (VIA)-Youth survey with parents/carers (here on: parents), we explored how parents can identify and apply Character Strengths (CS) to support their autistic YP.

Objectives:

- Explore the acceptability and feasibility of parents using the VIA-Youth survey to identify autistic YP's (8-15 years) CS using cognitive interviewing.
- Explore parents' reflections on building awareness of, exploring, and supporting their autistic YP to use their CS in daily life.

Methods:

15 parents (M (SD) years: 43.6 (1.46); Table 1) of autistic YP (aged 8-15) recruited online, participated in two one-to-one interviews. Interview one: interviewer and parents completed the VIA-Youth (98 items to evaluate 24-CS) survey together. Interviewer focused on eliciting examples from YP's life and clarified confusing items by explaining the CS being identified (~90 minutes). After reviewing the CS profile (1-2 weeks), parents returned for interview two. Interview two: parents reflected on the face validity of the CS report, what they learnt about their YP, and which CS they wished to share with others in their YP's life and why (~60 minutes). Interview data was analysed using reflexive thematic analysis (Braun & Clark 2013).

Results:

[Aim 1] Parents found using the VIA-Youth survey acceptable and feasible. However, many parents reported higher levels of Zest and Love of Learning only about areas of focused interest, but less so for typical day-to-day activities. Parents found some concepts (e.g., Spirituality and Forgiveness) too abstract to apply to their YP due to their maturity and cognitive functioning. Parents noted some CS (e.g., Humour and Curiosity) are expressed differently in autistic YP and their definitions can be improved through a neuroaffirmative lens.

[Aim 2] Parents found the CS profile to have good face validity in general (Figure 1). Parents identified some CS (e.g., Curiosity, Honesty, and Bravery) that enable their YP to live authentically, can also increase social misunderstanding. Parents noted Social Intelligence may relate to masking in unfamiliar or challenging environments. Difficult peer relationships give rise to few opportunities for Leadership and Teamwork beyond the family environment. Opportunities for YP to express and parents to identify YP's CS are limited by the impact of having many co-occurring mental and physical health conditions. Parents found focusing on strengths in autistic YP a refreshing experience that allowed them to navigate challenging situations by drawing on their YP's strengths. Going forwards, parents hoped to celebrate and share their YP's CS with others, enabling understanding and foster supportive environments to promote CS development.

Conclusions:

This is the first study to demonstrate that guided conversations around CS enable parents to identify qualities and values within their autistic YP, beyond skill-based talents. Supporting parents to build awareness of, explore, and apply CS within their YP may strengthen their YP's resilience and wellbeing.

401.104 Exploring Familial Support Needs and Impact of Amount of Service Use on Parental Mental Health in Families with Autism and Related Conditions: A Mixed-Method Approach

A. Tangarife¹, Z. Ghanem¹, S. Khawar², C. Tilson³ and E. Kang⁴, (1)Montclair State University, Montclair, NJ, (2)Department of Pediatrics/Masonic Institute for the Developing Brain, University of Minnesota - Twin Cities, Minneapolis, MN, (3)Helping Hands ABA, P.C., NEW YORK, NY, (4)Department of Psychology, Montclair State University, Montclair, NJ

Background: Evidence-based interventions and auxiliary (e.g., speech, occupational therapy) services are important in meeting the unique needs of developmentally/intellectually disabled (D/ID) children (Khawar, 2024). Notably, families of children with D/ID may experience structural, cultural, and familial barriers while accessing services, which can lead to a negative impact on parental mental health (Frazee et al., 2012; Moodi et al., 2014; Pickard & Ingersoll, 2015). Relatedly, parents of D/ID youth report greater symptoms of stress and depression (Dukmak & Alkhatib, 2021) than parents of neurotypical children

Objectives: This study uniquely compared parental mental health based on their child's service utilization, presence of diagnosis of or support around their mental health conditions via mixed methods approach to understand family support needs.

Methods: Forty parents (87.5% female; 60% non-white; 80% ages 35-54) of children with D/ID (72.5% ASD; 10% Down Syndrome; $Mage=11.60$, $SDage=5.62$; 77.7% male) completed a measure of parental depression (BDI-II; Beck, 1996), parenting stress (PSI-4-SF; Abidin, 1995), parental psychological flexibility (AAQ-II; Bond et al., 2011), and parental emotion regulation (DERS; Gratz & Roemer, 2004), and provided information on child's and their service utilization. The parents were also asked two open-ended questions: a) what is your greatest struggle with your D/ID child? and b) what type of supports would be helpful for you?

ANOVAs (child receiving ABA vs. auxiliary services vs. no services vs. both; parent receiving counseling or not; and parent with diagnosed mental health condition) and content analysis of survey responses (Levitt et al., 2017) were conducted to assess study aims.

Results: There were significant differences in parental psychological flexibility and parental depression (all $ps<0.05$) between parents with and without a diagnosed mental health condition as well as those seeking counseling or not, the latter also manifesting differences in parenting stress. No significant differences (all $ps>0.05$) in parental depression, parental psychological flexibility and parental emotion regulation were noted based on child's receiving varying services. Further, qualitative analyses revealed that parents struggled to find suitable, accessible and effective services for their child, while balancing multiple vocational and personal responsibilities (e.g., other children in the household). Moreover, corroborating with the quantitative results, qualitative analyses indicated parents reporting 1) the need for mental health interventions for themselves and their child (e.g., mindfulness, stress management), 2) the need for parental education to improve parent-child interaction (e.g., behavior management training) to increase parental sense of competency and 3) support for transition-age youth.

Conclusions: Overall, our findings suggest the importance of specific supports for parents and caregivers of D/ID children. Ultimately, navigating services is a stressful experience, and case management/social worker support may be beneficial in order to alleviate the negative impact on parental mental health. Further, timely diagnosis of parental psychopathology and ongoing therapeutic supports may be integral to foster parental mental health. Crucially, access to educational information that cater to diverse demographic groups need to be implemented in policy-making initiatives to enhance parental empowerment and advocacy. Additionally, there is a dire need for transition-age therapeutic and vocational programs (e.g., social skills, life skills) for families.

401.105 Exploring the Barriers and Facilitators Faced By Caregivers and Healthcare Workers Supporting Children with Autism in Sri Lanka: Perspectives from a Lower- Middle-Income Country

R. Haggapola Arachchi¹, C. Hansamalee¹, S. Rajapaksha², H. Weeratunga¹, B. Fernando¹, S. Pal³, D. V. Vipulaguna⁴ and A. Hewamalage⁵, (1)Sri Lanka College of Paediatricians, Colombo, Western, Sri Lanka, (2)NAMASTE, Colombo, Western, Sri Lanka, (3)Child Development Group, Sangath, Delhi, Delhi, India, (4)Ministry of Health, Sri Lanka, Colombo, Western, Sri Lanka, (5)Namaste Sri Lanka, Colombo, Western, Sri Lanka

Background:

Autism is a neurodevelopmental condition with a multifactorial etiology, making it essential for stakeholders in the autism care pathway to stay informed about its evolving nature and available support. Caregivers and healthcare workers serve as pivotal first points of contact, significantly impacting the support provided to children with autism. While Sri Lanka is recognized for its established healthcare infrastructure, this alone is inadequate; raising awareness about availability and accessibility of healthcare services is crucial to ensure effective use of healthcare resources for children with autism. To enhance the effectiveness of comprehensive care and support services to children with autism, it is important to understand the dynamic barriers and facilitators within the existing healthcare system as well as the caregivers' needs.

Objectives:

To gain an in-depth understanding of 1) the barriers and facilitators experienced by caregivers of children with autism and healthcare workers providing services for children with autism in the Western Province, Sri Lanka, 2) what these findings might mean for future research and service delivery.

Methods:

This qualitative study was conducted in the Western Province of Sri Lanka comprising 8 caregivers of children with autism and 8 healthcare workers, from Public Health Midwives, Medical Officer of Health to officials from the Ministry of Health, providing services for children with autism. Semi-structured onsite individual key-informant interviews were conducted to gather data. Thematic analysis was carried out following the Braun and Clarke, 2006 method.

Results:

Caregivers face challenges such as limited parent-child interaction time, stigma, inadequate awareness about autism and lack of support systems. Despite a well-established healthcare system, the majority of caregivers are unaware of available services; healthcare workers report a decline in caregivers of children with autism seeking healthcare services. Healthcare workers encounter similar issues: societal misconceptions leading to denial of diagnosis among parents, disparities in service availability and uneven distribution of services, with most services centered in urban areas, shortages in trained professionals due to brain drain, and lack of specified tailor-made training sessions on autism.

Facilitators for caregivers include awareness of typical child development, access to information through technology, proactive parenting, and support from family and social networks. For healthcare workers, established information-sharing systems, trust in frontline healthcare workers, and general capacity-building initiatives enhance their effectiveness.

Conclusions:

The findings indicate a notable gap between the experiences of healthcare workers and parents about accessing healthcare. Additionally, variations in knowledge and training requirements among healthcare workers highlight the need to address these gaps to enhance the quality of care provided. Many healthcare workers lack specialized knowledge about autism following talent migration, and this creates the need for more tailored training and capacity-building sessions for healthcare workers on autism. This would help address the gap in expertise and improve specialized care for children with autism.

401.106 Exploring the Camouflaging Experiences of Canadian Autistic Women and Nonbinary People through the Lens of Impression Management

I. Weigel-Mohamed¹, E. Derworiz², A. Gagnon¹, E. Coombs³, C. Bendevis⁴, C. Devlin⁵, N. Pogue⁶, C. Hack⁷, H. Ma¹, A. Wang¹, M. Janse van Rensburg⁸, S. Thompson-Hodgetts⁹ and H. M. Brown¹⁰, (1)University of Alberta, Edmonton, AB, Canada, (2)Rehabilitation Medicine, University of Alberta, Edmonton, AB, Canada, (3)Counselling Psychology, University of Alberta, Calgary, AB, Canada, (4)First Nations Technical Institute, Elphin, ON, Canada, (5)Ryerson University, London, ON, Canada, (6)Vancouver Island University, Nanaimo, BC, Canada, (7)University of Calgary, Calgary, AB, Canada, (8)Carleton University, Ottawa, ON, Canada, (9)Occupational Therapy, University of Alberta, Edmonton, AB, Canada, (10)Educational Psychology, University of Alberta, Edmonton, AB, Canada

Background: Autistic and non-autistic individuals use Impression Management (IM) to positively shape others' perceptions.¹ For Autistic individuals, IM also involves suppressing Autistic traits, mimicking non-autistic behaviours, and self-monitoring (called camouflaging/masking).^{2,3,4} Despite much research, there is no clear consensus on defining, measuring, or understanding the processes of Autistic camouflaging.⁵ Ai and colleagues¹ aimed to bridge IM literature with research on Autistic camouflaging, proposing four components for understanding its mechanisms: individual skills, motivators, behaviours, and consequences. This qualitative analysis of interview data,⁶ collected to understand the camouflaging experiences of Autistic women and non-binary Canadians, evaluated the extent to which the IM Framework captured the experiences of camouflaging amongst our participants.

Objectives: This study explored 3 questions: (1) Is the IM framework effective at capturing all aspects of our participants' experiences of camouflaging? (2) To what extent do our participants describe similar individual skills, motivators, behaviours and consequences of IM? (3) Did the framework not capture any aspects of the participants' descriptions? If so, how might the framework need to be adapted?

Methods: Data was initially gathered through semi-structured interviews with 10 Canadian Autistic women and nonbinary individuals (aged 18 to 35) related to camouflaging. Interviews were transcribed and segmented into thought units (t-units; i.e., meaningful chunks of text).⁷ The analysis was pre-registered on OSF.⁸ Using Framework Analysis, a codebook was developed based on the IM framework.^{9,10} Two research assistants independently coded each transcript, adding new codes to capture participants' experiences. Newly identified codes from uncategorized t-units were analyzed, leading to proposed modifications to the IM framework. Analytic memoing and bracketing were used to mitigate biases and ensure rigour and transparency.^{11,12} The trustworthiness of findings was supported through memoing and peer debriefing.^{13,14}

Results: Participants' experiences validated three aspects of IM: self-concealment, self-presentation, and self-monitoring of their situation. The motivators and consequences of *not* engaging in IM were missing in the original framework. Three key motivations emerged for not using IM included pride in Autistic identity, the presence of safe and accepting environments (often among other neurodivergent individuals), and a desire to increase visibility and challenge stereotypes about autism. Participants often used IM to fit in and avoid stigma, aiming to counter unjust judgments and marginalization from non-Autistic individuals. Notably, both using and reducing IM had similar negative consequences, such as feelings of disconnection or shame. Autistic individuals often faced a double bind: they felt ashamed for being "too Autistic" while also for not being "Autistic enough."

Conclusions: The experiences shared by our participants underscore the need for societal transformation that embraces autism as a distinct neurotype rather than a collection of deficits. One participant reflected on how using IM influenced her life, "I definitely would not be living the life I'm living today ... because of the way people see autism almost as a burden. [So no], I would not be where I am today. [But] I think if everybody were accepting, it would be completely different."

401.107 Factors Predicting Stress in Ethnoracial Minority Families of Autistic Children

M. I. Cargill¹, S. Khawar², W. Bsharat¹, E. Lynch¹, D. Casolaro³ and E. Kang¹, (1)Department of Psychology, Montclair State University, Montclair, NJ, (2)Department of Pediatrics/Masonic Institute for the Developing Brain, University of Minnesota - Twin Cities, Minneapolis, MN, (3)Psychology, Montclair State University, Montclair, NJ

Background: Parents of autistic children endorse high stress levels, seemingly driven by several factors, including their child's higher level of autistic traits, increased stigma, and lack of access to supports (Bonis, 2016). However, much of the extant research has focused on the experiences of White families, so less is known about factors driving familial stress in ethnoracial minority families, though these families may need additional supports due to intersecting, marginalized identities (Hatzenbuehler et al., 2013). Furthermore, autistic children from ethnoracial minority groups are less likely to access autism-specific services, leaving these families with varied, unaddressed needs (Benevides et al., 2016; Smith et al., 2020; Vohra et al., 2014).

Objectives: We aim to consider the effects of autism stigma, autism knowledge, unmet needs, and access to services on the relationship between a child's autistic traits and familial stress. This endeavor may provide insight into how to better support ethnoracial minority families of autistic children in order to reduce stress.

Methods: Fifty-two parents (90.4% mothers) of autistic youth ($M_{age}=10.98$, $SD_{age}=4.61$; 78.8% male; 71.2% South Asian, 13.5% Middle Eastern/North African, 7.7% East African, 7.7% multiracial) completed measures about their child's autistic traits (Constantino & Gruber, 2012), their experiences navigating systems of care (Jafarabadi et al., 2021), their autism stigma and knowledge (Harrison et al., 2017), and familial stress (Gottlieb et al., 2014).

Results: Correlational analyses demonstrated that autistic traits negatively related to access to services ($r=-.31$; $p=.03$) but positively related to unmet needs ($r=.30$; $p=.04$) and total stress ($r=.48$; $p<.001$). Familial stress was also negatively correlated with autism knowledge ($r=-.37$; $p=.01$) and autism stigma ($r=-.39$; $p=.007$) such that higher stress was associated with less autism knowledge and greater stigma.; However, familial stress was positively correlated with unmet needs ($r=.37$; $p=.01$). Path analysis revealed a significant direct effect of autistic traits ($\beta=.37$, $p<.001$) on familial stress, while adjusting for other variables in the model. There were also direct effects of level of autistic traits on unmet needs ($\beta=-.30$, $p=.03$) and access to services ($\beta=-.30$, $p=.03$). However, no direct effects were observed between level of autistic traits and autism stigma or knowledge, and the indirect effects in the model were not significant (all $ps>.05$). Overall, approximately 35% of the variance in familial stress is collectively explained by autism knowledge, autism stigma, total unmet needs, access to services, and autistic traits.

Conclusions: In an understudied, racially-diverse sample, a child's level of autistic traits seems to directly impact familial stress, unmet needs, and access to services. Overall, autistic traits predict familial stress above and beyond other factors for these groups. These results suggest that families of children with more autistic traits may struggle to access services to the necessary extent and therefore have unaddressed needs. It is imperative that families most in need of support and services be able to access them to reduce stress and improve overall well-being. Future research should seek to understand additional mechanisms that may impact the relationship between level of autistic traits and familial stress in ethnoracial minority families.

401.108 Family Environment and Child Adaptive Skills, Not Autism Symptoms, Predict Parenting Stress in FMR1 Conditions

R. M. Hantman¹, K. B. Cortez¹, J. Roberts¹, S. Hartley², A. Fairchild¹ and H. Arnold¹, (1)Department of Psychology, University of South Carolina, Columbia, SC, (2)University of Wisconsin-Madison, Madison, WI

Background: The *FMRI* premutation (FXp) is caused by an expansion of 55-200 CGG repeats on the *FMRI* gene, affecting 1:148-291 females^{1,2}. The primary risk initially associated with FXp women was expansion into the full mutation (FXS; >200 CGG repeats) for offspring. Research now shows FXp women may have a child with FXp and are at-risk for mental health and parenting difficulties³⁻⁵, with 20-85% of these mothers reporting high-to-clinical parenting stress⁶⁻¹² and greater stress in FXp mothers than mothers of neurotypical (NT) children¹³. The FXp child phenotype is associated with elevated autism symptoms and mild developmental impairment in some, while the FXS phenotype is more severe, with elevated autistic features and intellectual impairment in most¹⁴. Parenting stress theory posits parenting stress is a function of child, parent, and environmental factors^{15,16}, with autism implicated with higher stress^{17,18} but child adaptive level and positive family environments associated with lower stress¹⁹. Identifying factors that impact parenting stress during infancy to buffer chronic elevated stress' impacts²⁰ in vulnerable groups, like FXp mothers with genetic liability, makes this research critical for intervention targets.

Objectives: Determining predictors of parenting stress in FXp mothers with infants.

Methods: Participants included 128 mothers and their 12-month FXp, FXS, or NT infants ($n_{FXS} = 36$ (64% male), $n_{FXp} = 30$ (53% male), $n_{NT} = 62$ (71% male); $\bar{x} = 12.38$, $s = 0.77$). Measures included the *Parenting Stress Index*²¹ and *Family Environment Scale*²² for mothers; for infants, measures included the *Vineland Adaptive Behavior Scales*²³⁻²⁵ and *Autism Observation Scale for Infants*²⁶. An ANOVA tested group differences. Hierarchical linear regression models tested which family or child factors predicted parenting stress, correcting for multiple comparisons.

Results: Mothers of FXS infants reported significantly more stress than mothers of NT ($p < 0.001$) and FXp ($p = 0.012$; Figure 1) infants. For NT and FXp, no factors predicted parenting stress. For FXS, family expressiveness ($\beta = -6.04$, $p = 0.005$) and child adaptive ability ($\beta = -0.19$, $p = 0.008$) significantly predicted parenting stress (Figure 2), with family expressiveness and child adaptive ability ($F(2, 29) = 6.24$, $p = 0.006$) explaining more variability ($R_{family+child}^2 = 0.25$) in parenting stress than each factor alone ($R_{family}^2 = 0.21$, $R_{child}^2 = 0.17$).

Conclusions: Despite FXp mothers' genetic vulnerability for mental health difficulties, mothers of FXS infants uniquely reported more stress than mothers of FXp and NT infants, independent of autism symptom severity. Factors contributing to parenting stress differed per infant genetic group. For mothers of FXS infants, higher family openness and child independence was associated with lower mother stress, supporting findings that positive family environments and child adaptive skills in FXS buffer maternal stress^{9,10,27-29}, distress³⁰, and internalizing symptoms³¹. The combined effect of child adaptive ability and family expressiveness accounting for the most variance in maternal stress suggests interventions targeting *both* characteristics could harness a strengths-based approach, bolstering family openness and child independence to minimize parenting stress in vulnerable mothers. This work is critical as it advances understanding of gene-environment interactions in *FMRI* conditions highly associated with autism.

401.109 Family Resilience in Parenting Young Children with ASD

L. Dijkstra-de Neijls¹, H. Swaab², I. A. van Berckelaer-Onnes³ and W. A. Ester^{4,5}, (1)SARR Expert Center for Autism, Lucertis Child- and Adolescent Psychiatry, Parnassia Group, Rotterdam, Netherlands, (2)Leiden Institute for Brain and Cognition, Leiden University, Leiden, Netherlands, (3)Sarr Expert Centre for Autism, Lucertis Child and Adolescence Psychiatry, Rotterdam, Netherlands, (4)Sarr Expert Centre for Autism, Youz Child- and Adolescent Psychiatry, Parnassia Group, Rotterdam, Netherlands, (5)LUMC Curium - Child and Adolescent Psychiatry, Leiden University Medical Center, Oegstgeest, Netherlands

Background:

Resilience within families may temper the risk of high parenting stress faced by parents of young children with ASD. Within families, individual differences between parents may contribute differently to resilience.

Objectives:

To explore the contribution of intrapersonal and contextual factors associated with resilience within families of young children with ASD.

Methods:

A cross-sectional study ($n=249$ individuals) wherein resilience within families is addressed by investigating (1) family parenting stress, (2) associated factors contributing to maternal ($n=87$) and paternal ($n=74$) resilience, and (3) factors relating to resilience within families ($n=74$) of 3-to-6-year-old children with ASD ($n=88$).

Results:

(1) The percentage of families with regular parenting stress in both parents (33%) is almost equal to the proportion of families with (sub)clinical parenting stress in both parents (36%), families with mothers experiencing (sub)clinical and fathers experience regular parenting stress are twice as common (22%) than the other way around (9%). Contributors to (2) mothers' resilience to parenting stress are good planning/organizing skills and satisfaction with their social relations. Contributors to fathers' resilience are low levels of 'worrying' and good social relations. The shared contributing factor to resilience within families (3) is the satisfaction of both parents with their social relations.

Conclusions:

Most of the parents of the same young child with ASD experience a comparable degree of parental stress, with different dynamics in individual parents contributing to resilience within families to parenting stress. This suggests the need for a personalized parental approach within families with young children with ASD.

401.110 Characterizing Correlates of Caregiver-Reported Quality of Life Amongst Individuals with Neurogenetic Conditions

R. K. Schuck¹, E. K. Baker², K. M. Baiden³, A. Y. Hardan⁴, T. W. Frazier⁵ and M. Uljarevic¹, (1)Department of Psychiatry and Behavioral Sciences, Department of Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA, (2)Genetics, Murdoch Children's Research Institute, Parkville, VIC, (3)Gevirtz Graduate School of Education, University of California, Santa Barbara, Santa Barbara, CA, (4)Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA, (5)Psychology, John Carroll University, Cleveland, OH

Background: Prior research has found that quality of life (QoL) is lower amongst autistic individuals and their families when compared to other disability groups. Individuals with neurogenetic conditions have a high probability of having a co-occurring autism diagnosis. Although several studies have explored the associations between autism diagnosis/traits and QoL amongst individuals with neurogenetic conditions, the role of other factors, including mental health conditions and sleep difficulties, remains unexplored, despite these issues being common amongst individuals with autism and other neurogenetic conditions.

Objectives: To characterize correlates of different aspects of caregiver-reported QoL amongst individuals with neurogenetic conditions.

Methods: Caregivers of individuals with neurogenetic conditions (e.g., PTEN Hamartoma syndrome, SYNGAP1, Malan Syndrome, etc.; N=255, 125 Female, 130 Male; Mage=14.2 [range: 3-45]) completed a battery of online surveys. Two five-step hierarchical linear regression models were used to understand the unique contributions of each subset of variables (demographics, autistic traits, internalizing symptoms, externalizing symptoms, and sleep) on two subcategories of caregiver-reported QoL: family and physical/mental health.

Results: With regards to family QoL (FQoL), in the first step, demographic variables significantly predicted FQoL ($F = 22.18, p = .001$), with 30.1% of the variance explained. In the second and third step, autism traits and internalizing symptoms provided an additional 18% ($F = 31.49, p < .001$) and 6% ($F = 26.32, p < .001$) of variance, respectively; in the fourth and fifth steps externalizing symptoms and sleep did provide significant increase in the variance explained. In the final model, significant correlates of FQoL (a total of 55.1% of variance explained) included speech level, challenging behavior, and executive functioning (see Table 1). With regards to physical/mental health QoL (HQoL), the first step including demographic factors accounted for 7.1% of the variance ($F = 3.95, p = .004$). Each step in the hierarchical regression model resulted in a significant change in the amount of variance explained, with the final model explaining 48.2% ($F = 12.08, p < .001$). Significant correlates in the final model included participant sex, RRB, executive functioning, mood, restless sleep, and difficulty waking (see Table 2).

Conclusions: This study highlights the need to examine correlates of QoL beyond autistic traits in individuals with neurogenetic conditions. More specifically, speech level and challenging behavior predicting FQoL suggests that interventions need to do a better job of supporting individuals who have less reliable speech (e.g., by encouraging alternative modes of communication) and who exhibit challenging behaviors. HQoL findings also point to the need for supports that target sleep and mood dysregulation. Support programs that enhance executive functioning are also needed, as this was a significant correlate of both QoL subtypes. It is thus crucial that support services address these factors as opposed to solely focusing on “core” autism traits. Longitudinal research is needed in this area in order to understand causal influences of these factors. Additionally, future research should include other potentially contributing factors, such as perceived stigma and satisfaction with services received. Similar investigations of correlates of self-reported QoL in this population is also needed.

401.111 Autism Community Perspectives on Identity-First and Person-First Language: A Systematic Review of the Literature

R. K. Schuck¹, L. Chetcuti², K. Milosavljevic³, S. M. Bury⁴ and M. Uljarevic²; (1)Department of Psychiatry and Behavioral Sciences, Department of Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA, (2)Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA, (3)Touro University, New York, NY, (4)Olga Tennison Autism Research Centre, La Trobe University, Melbourne, VIC, Australia

Background: Terms to describe individuals with a (formal or self) diagnosis of autism can be broadly characterized into two categories: person-first language (PFL) and identity-first language (IFL). PFL refers to terms where the “person” is emphasized before the disability (e.g., “person with autism”). IFL refers to terms where the identity label comes before the “person” noun (e.g., “autistic person”). Because of implied meanings (i.e., separating people from their disability; celebrating disability identity), there are sometimes heated debates around these terms, though both are rooted in disability justice. Until recently, PFL was the predominant terminology used in academic discourse about autism, though there is now a shift toward recommending IFL. While recent studies have addressed community preferences regarding language, a review is needed to better inform recommendations and research moving forward.

Objectives: To synthesize findings from quantitative studies regarding autism language preferences amongst autistic individuals and parents/caregivers.

Methods: PubMed and PsycInfo were searched in July 2024 for studies related to autism language preferences. Included studies needed to quantitatively assess preferences from autistic people and/or their families and be written in English. Qualitative studies were excluded. Independent coders extracted the following information from studies: study country and methodology (e.g., type of questionnaire, terms included), sample size, participant demographics, recruitment methods, and participants’ most preferred term. Terms were categorized into “IFL,” “PFL,” or “on the spectrum (OTS)” (while OTS technically is PFL, we coded it separately because it is sometimes seen as a “neutral” alternative). A third coder reviewed the coding and highlighted areas of disagreement; they then met with one of the initial coders to resolve discrepancies by consensus.

Results: Of 1,650 abstracts screened, 30 underwent full-text review; 14 met inclusion criteria. All studies were conducted online. Most were conducted in English; three were in Dutch and two were in French. Sample size ranged from 32-1,026; countries represented included US, UK, Netherlands, France, Canada, Australia, and Belgium. Females were the majority gender in 11/14 studies. Only one reported on participants’ cognitive abilities. There was little consistency across studies regarding which terms were included in surveys. Autistic participants preferred a variety of terms, though 9/12 studies found a preference for IFL. Two of the three studies that found a PFL preference were conducted in Dutch (one was in English); none included an OTS answer choice. A “no preference” option was included in 4 studies; 14.6—35.63% of participants endorsed this. Family preferences were assessed in 4 studies; a PFL preference was endorsed in 3 studies, though there was variation.

Conclusions: While there was a slight preference for IFL amongst autistic individuals, results indicate there is no clear consensus regarding language preferences, with many indicating no preference. Similar variability existed amongst family members. These findings caution against assuming what kind of language an individual/community prefers. Given that study methodologies varied greatly, and online studies are subject to selection and accessibility bias, more standardized research is needed before concrete suggestions can be made.

401.112 Autistic-Led Assessments of Australian Airports Using an Autism-Friendly Framework

C. Edwards¹, A. M. Love¹, R. Y. Cai¹, T. Tutton² and V. Gibbs¹; (1)Aspect Research Centre for Autism Practice, Autism Spectrum Australia, Sydney, NSW, Australia, (2)Autism Spectrum Australia, Chatswood, NSW, Australia

Background: Airports are uniquely complex environments, often overwhelming for autistic travellers due to a combination of unpredictable sensory stimuli, crowded spaces, and the demands of security procedures. While autism-friendly initiatives have gained momentum in other sectors, the application of these principles in airport settings remains limited. This is particularly concerning given the importance of air travel for maintaining connections in countries like Australia, where long distances necessitate flying. Despite some progress in making airports more accessible, comprehensive research grounded in autistic perspectives is lacking.

Objectives: This study aimed to:

1. Identify key accessibility challenges in Australian airports through autistic-led assessments.
2. Evaluate how existing airport environments align with established principles of autism-friendly design.
3. Generate specific recommendations for enhancing airport accessibility based on autistic perspectives.

Methods: We conducted a reflexive thematic analysis of environmental assessment reports from six Australian airports (Sydney, Gold Coast, Canberra, Townsville, Mount Isa, and Melbourne). These assessments, carried out between 2017 and 2024, were led by autistic consultants using an evidence-informed autism-friendly framework. The framework emphasizes eight key elements: inclusive culture, preparation and predictability, structure and visual organization, sensory adaptations, communication supports, proactive problem solving, staff training, and continuous improvement. Our analysis focused on identifying patterns in the autistic consultants' observations and recommendations across these diverse airport environments.

Results: Our analysis generated three overarching themes. The first theme ("Variety of sensory experiences") highlighted how visual, auditory, and olfactory stimuli within airports can significantly impact autistic travellers' comfort and ability to navigate. Positive features included natural lighting and calming visual elements, while challenges included harsh lighting, reflective surfaces, and strong odours. Theme two ("Help passengers to understand what to expect, and what they're expected to do") emphasized the critical role of clear communication and intuitive wayfinding. Autistic consultants identified a need for more comprehensive pre-travel resources, consistent and accessible signage, and visual supports throughout the airport journey. The final theme ("Consider implementing strategies to assist with crowding") underscored the importance of effective crowd management and queue systems. Recommendations included dedicated assistance lanes, clear queuing structures, and collaboration with airlines to implement best practices for supporting autistic travellers.

Conclusions: Our findings highlight both strengths and ongoing gaps in the accessibility of Australian airports for autistic travellers. By centring autistic perspectives, this study provides crucial insights into making complex, high-stress environments more inclusive. The recommendations that emerged provide a roadmap for airports to enhance accessibility, potentially enabling more autistic individuals to engage confidently with air travel. Moreover, this study underscores the value of autistic-led assessments in identifying nuanced environmental factors that may be overlooked in traditional accessibility evaluations. Future research should explore the impact of the proposed changes on diverse autistic travellers' experiences and investigate how these principles can be applied throughout the entire air travel journey.

401.113 Exploring Autism-Friendly Initiatives in Australian Airports: Insights from Autistic Travellers and Families

C. Edwards¹, A. M. Love¹, R. Y. Cai², T. Tutton² and V. Gibbs¹, (1)Aspect Research Centre for Autism Practice, Autism Spectrum Australia, Sydney, NSW, Australia, (2)Autism Spectrum Australia, Chatswood, NSW, Australia

Background: Airports can be overwhelming environments for autistic people, characterized by sensory overload, unpredictable procedures, and complex social interactions. These challenges make air travel particularly stressful and often inaccessible for many autistic travellers. Although some airports have implemented autism-friendly initiatives, such as sensory maps, quiet spaces, and the Hidden Disability Sunflower program, however, the effectiveness of these initiatives remains underexplored. Many autistic individuals and their families continue to report barriers that prevent them from having a comfortable and supportive travel experience, highlighting the need for more inclusive and effective approaches to improving accessibility in airports.

Objectives: This study aimed to explore the experiences of autistic adults and parents of autistic children traveling through two Australian airports with autism-friendly initiatives, and identify gaps and opportunities for improving airport accessibility and comfort for autistic travellers.

Methods: We conducted semi-structured interviews with autistic adults ($n = 8$) and parents of autistic children ($n = 5$) who had recently travelled through either Sydney or Gold Coast Airport. Participants were predominantly female ($n = 11$), with ages ranging from 25 to 57 years. Both airports had been implementing autism-friendly initiatives for over five years, including the Hidden Disability Sunflower program, sensory maps, and ongoing autism-specific staff training. Interviews were conducted via email/text, phone, or video, based on participant preference, and ranged from 14 to 30 minutes in duration. Data were analyzed using reflexive thematic analysis, led by an autistic insider-researcher to ensure authentic representation of autistic perspectives.

Results: Three main themes were created. Theme 1 (Airports need to be more accessible) highlighted persistent challenges with sensory overload, emphasizing the need for quiet spaces and comprehensive pre-travel planning. Many participants were unaware of existing accessibility resources until prompted by participating in the study, indicating a need for better communication of available support. Theme 2 ("Those Sunflower lanyards are magic..." when they are recognized) described how the Hidden Disability Sunflower program facilitated more compassionate interactions when recognized by staff, though participants called for greater visibility of the program and more proactive support. Theme 3 ("A greater awareness within the whole industry of hidden disabilities") addressed the inconsistent experiences across different airports and airlines, underscoring the need for industry-wide improvements in understanding and supporting autistic travellers.

Conclusions: Our findings highlight both the progress made and ongoing challenges in creating truly accessible air travel experiences for autistic individuals. The positive impact of initiatives like the Hidden Disability Sunflower program demonstrates the potential for meaningful change. However, persistent issues with sensory overload and inconsistent implementation of supports across the industry underscore the need for continued efforts. To achieve genuinely inclusive air travel, airports and airlines should prioritize autistic perspectives in the design and implementation of accessibility initiatives, provide comprehensive staff training, and work towards standardized, industry-wide approaches to supporting autistic travellers. Future research should explore these issues with larger, more diverse samples and across a wider range of airports to further inform policy and practice in this critical area of accessibility.

401.118 "Not One Size Fits All": Redefining Emotion Regulation Support for Autistic People through Lived Experience

D. Blackwell¹, A. E. Lane¹, A. Bhojti² and S. J. Lane³; (1)Olga Tennison Autism Research Centre, La Trobe University, Melbourne, VIC, Australia, (2)Department of Occupational Therapy, Monash University, Melbourne, VIC, Australia, (3)Occupational Therapy, Colorado State University, Fort Collins, CO, Australia

Background: Traditional approaches to emotion regulation support often fail to address the unique needs and experiences of autistic people, potentially contributing to poor outcomes and reduced well-being.

Objectives: To understand how autistic people experience and manage their emotions, and to identify critical components of effective, neurodiversity-affirming emotion regulation supports

Methods: Qualitative analysis of survey responses from 26 autistic adults and 19 caregivers, examining lived experiences of emotion regulation challenges and perspectives on current supports.

Results: Autistic participants reported diverse strategies for managing emotions, with 77% using music, 65% using weighted objects, and 58% seeking silence. However, 85% reported feeling misunderstood by professionals, and 77% reported feeling helpless. Three key themes emerged: (1) the importance of sensory-based regulation strategies, (2) the impact of environmental factors on emotional well-being, and (3) the need for supports that validate rather than suppress autistic ways of being

Conclusions: Findings emphasise the need to reconceptualise emotion regulation support for autistic people, moving away from standardised approaches toward more personalised, sensory-informed strategies that respect autistic experiences and preferences.

401.119 Emotion Regulation in Autism: A Multi-Stakeholder Investigation of Lived Experiences and Support Preferences

D. Blackwell¹, A. Bhojti², S. J. Lane³ and A. E. Lane¹; (1)Olga Tennison Autism Research Centre, La Trobe University, Melbourne, VIC, Australia, (2)Department of Occupational Therapy, Monash University, Melbourne, VIC, Australia, (3)Occupational Therapy, Colorado State University, Fort Collins, CO, Australia

Background: Understanding emotion regulation in autism requires examining diverse perspectives, yet few studies have simultaneously investigated the views of autistic people, caregivers, and professionals regarding emotion regulation supports.

Objectives: To examine and compare perspectives on emotion regulation supports across three key stakeholder groups: autistic people, caregivers, and health professionals.

Methods: mixed-methods study incorporating surveys (n=45; 26 autistic adults, 19 caregivers) and a Delphi study with health professionals (n=13). Quantitative data analyzed descriptively; qualitative data analyzed using reflexive thematic analysis.

Results: While 92% of autistic participants identified personalized emotion regulation tools as essential, only 20% reported satisfaction with professional support. Caregivers reported significant impacts on family life, with 95% hiding their own emotions during their child's dysregulation. Health professionals demonstrated evolving views toward neurodiversity-affirming practices, with 100% emphasizing the importance of understanding neurodiversity in support provision. Key themes included the need for individualized approaches, the impact of environmental factors, and the importance of moving beyond traditional cognitive-behavioral strategies.

Conclusions: Findings reveal significant gaps between stakeholder perspectives and current support practices, highlighting the need for more neurodiversity-affirming approaches that consider both individual and environmental factors in emotion regulation support.

401.120 Introduction to Healthy Engagement in Autism Research Dialogue (HEARD)

J. Phan¹, S. A. Harker², C. van der Merwe³ and A. Halladay⁴; (1)George Mason University, Fairfax, VA, (2)School of Life Sciences and College of Health Solutions, Arizona State University, Tempe, AZ, (3)Stanley Center for Psychiatric Research, Broad Institute of MIT and Harvard, Cambridge, MA, (4)Autism Science Foundation, New York, NY

Background:

In recent years, evolving diagnostic criteria for autism has expanded the diversity of diagnosed individuals. This has led to a wide range of opinions within the autism community about the meaning and implications of a diagnosis. Perspectives vary from those who see autism as an integral part of their identity to those who view it as a condition requiring treatment or support. These differing views sometimes have different priorities, for example, research focused on the prevention of autism vs. lifespan quality of life and wellbeing. Such disagreements have varied in intensity, ranging from respectful discourse to more confrontational exchanges, often heightened by social media interactions.

Objectives:

To address these challenges, the Autism Science Foundation and the Broad Institute established HEARD: Healthy Engagement in Autism Research Dialogue. HEARD brings together a diverse leadership committee of 16 members, including clinicians, researchers, bioethicists, policymakers, self-advocates, and family members of autistic individuals, as well as additional discussants nominated by the leadership committee. The group aims to foster open and respectful conversations on controversial topics in autism research, ensuring that all voices are represented. Approximately half of the leadership committee consists of individuals with direct personal or family experience with autism, guaranteeing that the group's work is grounded in a variety of lived experiences.

The primary goals of HEARD are to: 1) facilitate structured discussions on sensitive research topics within the autism community, 2) develop and disseminate communication strategies for productive dialogue, and 3) expand engagement to include additional community partners, including autistic individuals and emerging researchers.

Methods:

After consultation with researchers engaged in similar endeavors, we developed a set of guiding principles and invited a limited number of autistic and non-autistic researchers who had previously expressed an interest in participating in a dialogue. This included individuals from a global diverse demographic background. Due to geographic diversity, we met virtually and discussed challenges and future directions of these conversations and how they could best be productive. Each discussion was followed by discussant feedback and nomination for topics for future discussions.

Results:

HEARD's initial discussion series for 2023-2024 focused on the role of genetics research in autism, featuring eight sessions that addressed subtopics such as ethics, risk communication, genetic testing, and community partner perspectives. These discussions, moderated by a leadership committee member and an autistic individual, helped refine HEARD's approach to facilitating meaningful engagement. Notes and video recordings were taken and those who were not able to attend in person were able to participate and listen.

Conclusions:

From the discussions that have been conducted, the overarching themes are that this was a very productive method of engaging different communities to discuss scientific topics that have garnered debate. Keeping the group small allowed for individual perspectives to be voiced and heard, however, we realize that this group may not fully represent the spectrum of experiences of autism. Future discussions will include more community members who are not autism researchers and could possibly be inclusive of a wider audience.

401.121 Supporting Caregivers Following Their Child's Neurodevelopmental Diagnosis: A Scoping Review

M. Thorbecke¹, T. Chau², N. Mizzi³, C. Bernie⁴, M. Spencer-Smith⁵, B. Johnson⁶, M. Alshawsh⁶ and A. Ure⁷. (1)School of Psychological Sciences, Monash University, Clayton, VIC, Australia, (2)Department of Paediatrics, Monash University, Clayton, VIC, Australia, (3)Monash University, Melbourne, VIC, Australia, (4)Southern Cross University, Gold Coast, QLD, Australia, (5)Monash University, Notting Hill, VIC, Australia, (6)Paediatrics, Monash University, Clayton, VIC, Australia, (7)Paediatrics, Monash University Department of Paediatrics, Clayton, VIC, Australia

Background:

The experience of receiving their child's neurodevelopmental diagnosis and navigating the subsequent steps can be overwhelming for caregivers. A diagnosis can have wide-ranging emotional impacts for caregivers, leaving many feeling uncertain about what to do next. Navigating services to access the recommended therapies, support, and resources can be difficult. This time is particularly challenging for families with limited resources, living in remote or underserved areas, and those from culturally and linguistically diverse backgrounds, exacerbating inequities between families seeking post-diagnostic support. Caregivers globally report that the support offered to them during the post-diagnosis period is inconsistent and inadequate, highlighting the need to better understand current practices and gaps in caregiver support during this critical period.

Objectives:

This scoping review aims to identify and describe existing intervention programs designed to support caregivers in the 12 months following their child's neurodevelopmental diagnosis, with a focus on promoting caregiver or family-related outcomes (e.g., caregiver mental health, well-being, family quality of life). This review also explores the characteristics of these interventions, their outcomes measured, and how these interventions are tailored to meet the needs of diverse populations, including those from culturally and linguistically diverse backgrounds.

Methods:

This review is registered on OSF (DOI: 10.17605/OSF.IO/C8TW3). The scoping review is being conducted in accordance with JBI methodology and adheres to PRISMA-ScR guidelines. A comprehensive search across MEDLINE, Embase, and PsycINFO identified 6,274 articles. Titles and abstracts were screened, followed by full-text review of 241 articles by two independent reviewers based on predefined inclusion and exclusion criteria. Studies examining post-diagnostic caregiver support interventions delivered within 12 months of diagnosis, focusing on improving caregiver or family-related outcomes were included. Studies that focused solely on child-related outcomes or were descriptive or observational in design, and/or lacking a comparator group, were excluded. Data extraction includes key study characteristics (e.g., study design, objectives, inclusion/exclusion criteria), participants (e.g., target population, sample size and characteristics), child information (e.g., age, diagnoses), intervention details (e.g., description, delivery mode, setting), and outcomes. Extracted data is charted and presented in both tabular and narrative formats. Data synthesis employs a descriptive approach to map intervention characteristics, identify patterns, and highlight gaps for future research.

Results:

Data extraction is ongoing, and full results with synthesized findings are expected by February 2025. We anticipate including approximately 10 studies in the final synthesis.

Conclusions:

This scoping review will provide a detailed mapping of existing post-diagnostic support interventions for caregivers of children with neurodevelopmental conditions. The synthesized findings will contribute to identifying gaps in current interventions, highlighting effective strategies, and informing the development of more comprehensive models of post-diagnostic support. These insights will guide future research and practice, aiming to enhance caregiver well-being and family functioning following diagnosis.

401.122 Participation in Practice: Using Workshops for Analysing Research Findings to Improve Accessibility of Cultural Heritage for Neurodivergent Adults

A. L. Fletcher¹, **M. Economou¹**, **D. R. Simmons²** and **C. Horlin²**, (1)Information Studies, University of Glasgow, Glasgow, Scotland, United Kingdom, (2)School of Psychology and Neuroscience, University of Glasgow, Glasgow, Scotland, United Kingdom

Background:

Despite a recent movement towards participatory practices in cultural heritage and neurodiversity research, there remains a gap in participatory approaches for enhancing accessibility to these organisations for autistic and neurodivergent adults (AuND). Following high response to the surveys associated with an earlier stage of this participatory PhD project, creative approaches were taken to ensure that experts by lived experience (AuND adults and museum workers) were consulted in finalising the findings. This presentation shall discuss the methodological decisions that informed the development of participatory workshops, how these sessions shaped the direction of research and the lessons learned when utilising qualitative and participatory practices in research to inform changes to benefit AuND people.

Objectives:

To demonstrate the benefits and challenges of working with AuND people using participatory methods to enhance accessibility for traditionally under-served audiences.

Methods:

In-person workshops with: 1) Neurodivergent adults and 2) museum workers.

Participants: 1) two workshops, one formally recorded and one workshop for information held at Autscope for AuND individuals (30 across both workshops). 2) two workshops held at different Scottish Museum Federation (SMF) events for museum workers (many openly AuND) (30 across both workshops). Participants were required to be 18+, and attendance at Autscope (ND-majority conference) and SMF (an organisation for museum workers) ensured they met the criteria for participating.

Presentation slides and participation information was sent in advance. A brief research summary was given using Mentimeter offering opportunities for anonymous responses, as well as printed questionnaires distributed, in room with grouped tables for discussions.

Analysis:

Thematic analysis was applied to qualitative responses (Mentimeter and questionnaires); visualisations of quantitative data were utilised for content analysis. Autoethnographic analysis of discussions in the room, and cross-referencing with data collected in 700 survey responses to assess the generalisability of findings.

Results:

The workshops provided additional information in response to the findings from the survey responses gathered earlier in the research. By presenting the findings to groups of neurodivergent adults and museum workers, and asking for direct feedback while facilitating discussions, I could re-visit code terms and groups to ensure they reflected the experiences and preferences of the community groups that the research was designed to serve. By conducting the workshops in different contexts, and providing different ways to contribute, these led to unexpected discussions about the barriers within museums that prevent museum visiting and addressing systematic barriers from the organisation's perspective.

Conclusions:

The findings from the workshop marked the final phase of this PhD project and will be used for planning the creation of a guidance toolkit for the cultural heritage sector that is informed and co-developed by AuND people, with an openly autistic researcher coordinating the process.

Throughout each stage of this project, AuND adults and museum workers expressed their gratitude for being consulted and their experiences considered. By developing projects that directly involve the AuND community in meaningful ways, both research and real-life practice developments can improve the quality of life for AuND and address the historic under-representation of AuND people in decision-making that impacts their lives.

Poster Session**402 - Brain Function (fMRI, fcMRI, MRS, EEG, ERP, MEG) I**

May 1st, 2025, 12:30 PM - 1:30 PM - Hall 4A

402.123 The Relationship between Brain Activity, Tryptophan-Related Gut Metabolites, and Autism Symptomatology in Autistic Youth

S. M. Ringold^{1,2}, **J. Labus^{3,4,5}**, **A. Jayashankar^{2,6}**, **E. Kilroy^{1,2}**, **C. Butera^{1,2,7}**, **J. P. Jacobs^{3,4,5}**, **S. Tanartkit^{3,4,5}**, **S. Joshi^{3,4,5}**, **M. Dapretto^{8,9}**, **E. A. Mayer^{3,4,5}** and **L. Aziz-Zadeh^{1,10}**, (1)Brain and Creativity Institute, Dornsife College of Letters, Arts and Sciences, University of Southern California, Los Angeles, CA, (2)Mrs. T.H. Chan Division of Occupational Science and Occupational Therapy, University of Southern California, Los Angeles, CA, (3)Oppenheimer Center for the Neurobiology of Stress and Resilience, David Geffen School of Medicine, University of California Los Angeles, Los Angeles, CA, (4)Vatche and Tamar Manoukian Division of Digestive Diseases, Department of Medicine, David Geffen School of Medicine, University of California Los Angeles, Los Angeles, CA, (5)Goodman-Luskin Microbiome Center, David Geffen School of Medicine, University of California Los Angeles, Los Angeles, CA, (6)Brain and Creativity Institute, Dornsife College of Letters, Arts and Sciences, Tufts University - Department of Psychology, Los Angeles, CA, (7)Division of Biokinesiology and Physical Therapy, University of Southern California, Los Angeles, CA, (8)Department of Psychiatry and Biobehavioral Sciences, University of California Los Angeles, Los Angeles, CA, (9)Ahmanson-Lovelace Brain Mapping Center, University of California Los Angeles, Los Angeles, CA, (10)Mrs. T.H. Chan Division of Occupational Science and Occupational Therapy, USC, Los Angeles, CA

Background: The gut microbial ecosystem generates an estimated 40% of all metabolites in the body's circulation, including neuroactive and inflammatory molecules. Gut metabolites have been theorized to play a causative role in the pathophysiology of autism spectrum disorder (ASD) via the brain-gut-microbiome (BGM) axis. This hypothesis is based on results from prior research showing differences in gut microbial composition between autistic and neurotypical (NT) populations that correlate with ASD symptoms (Needham et al., 2021). Tryptophan metabolites, such as the neurotransmitter serotonin, have been linked to ASD. Roughly 30% of autistic individuals show elevated blood serotonin levels, which have been linked to the regulation of symptoms such as mood, appetite, and social interactions via vagal afferent signaling (Gabriele et al., 2014; Muller et al., 2015; Schain et al., 1961). Some tryptophan metabolites can cross the blood-brain-barrier and have neuroprotective or neurotoxic effects especially during critical periods of development, potentially influencing brain microstructure, activity and development (Bohar et al., 2015; Pappolla et al., 2021; Chen et al., 2021; Cherkova et al., 2021). Although prior research has found correlations between tryptophan metabolites and behavior in ASD, alterations in how the human brain interacts with gut metabolites in ASD have not been examined. As the brain controls behavior, to fully understand the implications of dysregulation of the brain-gut-microbiome (BGM) axis in ASD, the brain must be considered.

Objectives: The objective of this study was to assess group differences in tryptophan metabolites and study the association between metabolite levels, neural activity during socio-emotional and sensory tasks, and behavior in ASD and NT children. We additionally explored whether neural activity was a mediator between metabolite levels and behavior.

Methods: 43 ASD (32 Males, AgeM=12.06) and 41 NT children (21 Males, AgeM=11.86) underwent task-based functional magnetic resonance imaging (fMRI), provided fecal samples, and completed behavioral assessments. General linear models were applied to examine group differences in tryptophan metabolites and to assess the associations between tryptophan metabolites and evoked brain activity and behavior. Age, sex and body mass index were included as covariates. The Benjamini-Hochberg method to correct for multiple comparisons was used with the threshold set at 10%. Mediation modeling was performed to assess whether the neural activity was a mediator of metabolites and behavior.

Results: The NT group had significantly higher levels of the tryptophan metabolite kynurenate compared to the ASD group ($q < 0.10$). Specifically in the ASD group, metabolites were significantly negatively associated with: brain activity in the insula and cingulate, autism severity, sleep quality, and sensory sensitivities and positively associated with disgust sensitivity (Figure 1; $q < 0.10$). Mediation analyses in the ASD group found that activity in the mid-insula and mid-cingulate significantly mediated relationships between the metabolites, indolelactate and tryptophan betaine, and ASD severity (Figure 1).

Conclusions: This study supports prior research implicating dysregulation of the BGM axis, specifically related to the tryptophan pathway, in ASD. To our knowledge, this is the first study to elucidate how interactions between gut metabolites and brain activity may impact autism symptomatology.

402.124 Visual Evoked Potentials in Autism and ADHD As a Neurophysiological Metric of Sensory Sensitivities in Young Children
D. Akinsooto¹, A. Claveria¹, S. Major², H. L. Morgan³, R. E. Aiello⁴, H. Akkineni⁵, N. Chaudhry⁶, J. Courtland⁶, N. O. Davis¹, M. Sabatos-DeVito⁷, L. Franz⁸, J. N. Grapel⁹, E. Peters¹⁰, J. Schechter³, M. Spanos¹, K. L. Carpenter¹⁰ and G. Dawson⁷, (1)Department of Psychiatry and Behavioral Sciences, Duke University Medical Center, Durham, NC, (2)Psychiatry and Behavioral Sciences, Duke Center for Autism and Brain Development, Durham, NC, (3)Department of Psychiatry and Behavioral Sciences, Duke University School of Medicine, Durham, NC, (4)Duke Center for Autism and Brain Development, Duke University, Durham, NC, (5)Duke University, Durham, NC, (6)Psychiatry, Duke University Medical Center, Durham, NC, (7)Department of Psychiatry and Behavioral Sciences, Duke University, Durham, NC, (8)Duke Global Health Institute, Duke University, Durham, NC, (9)Psychology, Duke Center for Autism and Brain Development, Durham, NC, (10)Department of Psychiatry and Behavioral Sciences, Duke Center for Autism and Brain Development, Durham, NC

Background:

Early sensory response differences exist in both autistic individuals and those with ADHD. The visual evoked potential (VEP) paradigm uses a rotating checkerboard to measure early visual processing and the balance of cortical excitation and inhibition. In sensory processing disorders like synesthesia, early component amplitudes are reduced. VEP results vary with age, showing decreasing amplitudes and latencies up to age 30. Studies in autistic cohorts indicate reduced P1 amplitude, suggesting sensory sensitivities impact these associations. Delayed N1 latency has also been observed in autistic individuals, while P1 reduction occurs in those with ADHD compared to typical peers. Despite neurophysiological differences seen during the VEP paradigm in both autistic and ADHD populations independently, responses to VEP in autistic individuals with co-occurring ADHD are limited. Current evidence indicates reduced P1 amplitude in comparison to autistic children without ADHD and neurotypical children.

Objectives:

This study aims to (1) investigate group differences in the P1 and N1(amplitude & latency) between autistic children, children with ADHD, and autistic children with co-occurring ADHD in reference to neurotypical peers and (2) understanding how group differences in the P1 and N1 are related to caregiver reported sensory processing differences.

Methods:

Participants were ages 3-7 years old from 4 groups: neurotypical, ADHD, autism, and co-occurring autism and ADHD. Participants (N = 96) were included in the VEP analysis if the following criteria were met: (1) <16 channels interpolated, (2) <33% bad channels in midline occipital, (3) >33% good trials and (4) valid morphology. VEP stimuli consisted of two black and white checkerboards that reversed phase. Mean amplitude and latency of the N1 and P1 peaks were derived using MATLAB 2024a with epochs of -100-300 ms and artifact rejection of $\pm 200 \mu V$.

Autism and ADHD features were assessed via caregiver report on the Social Responsiveness Questionnaire-2 (SRS-2) and the Attention Deficit/Hyperactivity Disorder-RS (ADHD-RS), respectively. Finally, sensory Hyper/Hypo-responsivity were assessed using the caregiver completed Sensory Experience Questionnaire. Data was analyzed in RStudio using linear models (Eq.1). Model covariates are summarized in Table 1.

Results:

As age increased autistic children exhibited a decrease in P1 amplitude, while children with ADHD demonstrated an increase in N1 amplitude, in comparison to neurotypical children ($p < 0.001$ & $p < 0.02$). This pattern was observed irrespective of any co-occurring diagnoses. When exploring autism and ADHD features (via caregiver report), the ADHD group showed decreased P1 amplitudes as SRS-2 scores increased ($p < 0.02$).

Increased ADHD symptoms associated with earlier N1 latency ($p = 0.025$).

In children with ADHD, hyper-responsivity scores didn't change P1 latency, but did in neurotypical children, with higher hyper-responsivity scores leading to earlier latencies ($p < 0.03$ & $p < 0.01$). Individuals with co-occurring autism and ADHD showed no significant differences from neurotypical peers.

Conclusions:

Children with ADHD exhibited increased excitation and reduced inhibition in response to visual stimuli. Similarly, autistic children showed signs of reduced inhibition to VEP stimuli, along with relatively stable excitation levels (unless co-occurring ADHD was present). These findings further reinforce the notion that reduced P1 amplitude could serve as a reliable biomarker associated with autism.

402.125 A New Paradigm for Autism Spectrum Disorder Discrimination in Children Utilizing EEG Data Collected during Cartoon Viewing with a Focus on Atypical Semantic Processing

L. Deng¹, F. Li², C. Miao³ and M. Lu⁴, (1)*Xinhua Hospital, Shanghai Jiao Tong University School of Medicine, Shanghai, China, Shanghai, Shanghai, China,* (2)*Department of Developmental and Behavioral Pediatric and Child Primary Care & Ministry of Education-Shanghai Key Laboratory for Children's Environmental Health, Xinhua Hospital, Shanghai Jiao Tong University School of Medicine, Shanghai, 200092, China., Shanghai, Shanghai, China,* (3)*Institute of Science and Technology for Brain-Inspired Intelligence, Fudan University, Shanghai, Shanghai,* (4)*Shanghai Municipal Public Security Bureau, Shanghai, 200042, China., Shanghai, Shanghai, China*

Background: ASD is a prevalent neurodevelopmental disorder with early onset, affecting individuals across their lifespan. Early diagnosis is crucial for improving outcomes, but existing diagnostic methods are time-consuming and labor-intensive. This highlights a significant gap—the need for more efficient and cost-effective auxiliary diagnostic tools that can be readily implemented in clinical settings.

Objectives: To address this gap, we developed a novel, child-friendly discrimination paradigm utilizing EEG data collected during cartoon viewing to assess atypical semantic processing in children with ASD.

Methods: We employed a machine learning algorithm that combines pre-trained language models with regression techniques. Furthermore, we investigated the preferences and neural mechanisms underlying atypical semantic processing across various word dimensions using the Six-Dimensional Semantic Database (SSDD) system and EEG topographic mapping.

Results: Our method demonstrated high sensitivity (91.3%) and moderate specificity (61.0%) in screening for ASD. Notably, the visual dimension significantly contributed to ASD detection ($p = 0.001$). EEG signals originating from the right temporal lobe were pivotal in distinguishing children with ASD from typically developing peers.

Conclusions: This innovative approach offers a promising pathway toward developing more accurate and efficient auxiliary discrimination tools for ASD. By integrating neuroimaging data with semantic processing analysis, our method provides a multifaceted understanding of ASD characteristics. This paradigm not only enhances the potential for early diagnosis at the grassroots level but also opens new avenues for targeted interventions and future research in ASD.

402.126 Abnormal Functional Hierarchy Development during Childhood in Autism

Y. Zhang¹, Y. Liu², J. Feng³, F. Li⁴ and C. Miao¹, (1)*Institute of Science and Technology for Brain-Inspired Intelligence, Fudan University, Shanghai, Shanghai, (2)Xinhua Hospital, Shanghai Jiao Tong University School of Medicine, Shanghai, China, Shanghai, Shanghai, China, (3)Institute of Science and Technology for Brain-Inspired Intelligence, Fudan University, Shanghai, Shanghai, China, (4)Developmental and Behavioral Pediatric Department & Child Primary Care Department, Brain and Behavioral Research Unit of Shanghai Institute for Pediatric Research and MOE Shanghai Key Laboratory for Children's Environmental Health, Shanghai, Shanghai, China*

Background:

Autism is a disorder affecting information processing across multiple functional domains, exhibiting distinct differences in perception, emotion, and higher cognitive development compared to typically developing children. These differences suggest potential developmental anomalies in the functional hierarchy. Early research points to abnormal connections between low-level sensory processing and higher cognitive functions in autistic children, potentially causing imbalances in information processing, which affect behavior and learning. However, the exact developmental patterns of the functional hierarchy in autistic children are still unclear.

Objectives:

To investigate the developmental patterns of functional hierarchy in children with ASD and typically developing children, and to identify potential developmental abnormalities in children with autism.

Methods:

We employed a large functional MRI dataset comprising 476 children aged under 13 years old from the Shanghai Autism Early Development (SAED) Cohort, including 200 NC children (aged 1.04-12.93 years, 42.0% males), 276 ASD children (aged 1.67-12.87 years, 79.3% males). We performed gradient decomposition analysis on the voxel-level functional connectivity matrices of different age groups and plotted scatter plots of the core gradients. To explore the longitudinal changes in the global topography and regional gradient scores of the functional connectivity gradient, we also performed an cross-participant age sliding window analysis. Subsequently, we calculated the convex hull areas of different networks and the distances between networks in the scatter plots of core gradient scores, and fitted their relationship with age to explore whether developmental abnormalities exist in the functional hierarchical structures of autism children. Finally, for each voxel, we calculated the age at which the core gradient reached its peak to generate a maturation map. We then compared the average gradient maturation age across different networks between ASD and typically developing (NC) children.

Results:

In early and mid-childhood, the visual-sensorimotor gradient dominated in both the NC and ASD groups (Fig. 1A-B). In late childhood (11.0-13.0 years), the NC group exhibited a transition to the primary-to-transmodal gradient, which was less evident in the ASD group (Fig. 1A-D). Age sliding window analysis (Fig. 1E) revealed that in the NC group, the explanation ratio of the visual-sensorimotor gradient gradually decreased ($t = -2.44$, $p < 0.05$), while the explanation ratio of the primary-to-transmodal gradient gradually increased ($t = 4.94$, $p < 0.01$), becoming dominant around age 12. In contrast, the ASD group showed no significant age-related change in the primary-to-transmodal gradient ($t = -0.585$, $p = 0.561$). Furthermore, the range of the primary-to-transmodal gradient in the ASD group showed a reduction related to age ($t = -2.92$, $p < 0.01$). We then found that the somatosensory network, dorsal attention network, and ventral network in the ASD group were abnormally developed in the core gradient structure (Figure 2A-B). Finally, we found that there were significant differences between the ASD and NC groups in the functional maturation patterns of the first two core gradients (Figure 2C-D).

Conclusions:

These results suggest that children with ASD exhibit atypical developmental patterns in the functional hierarchy, particularly in the primary-to-transmodal gradient and key brain networks, compared to typically developing children.

**402.127** Neural Symmetry in Parent-Child Dyads with Autistic and Non-Autistic Children

K. M. Stockwell¹, A. M. Marzoratti², G. R. Sjoberg³, K. A. Pelphrey⁴, S. M. Boker¹ and T. M. Evans², (1)*Psychology, University of Virginia, Charlottesville, VA, (2)School of Education and Human Development, University of Virginia, Charlottesville, VA, (3)University of Pittsburgh, Pittsburgh, PA, (4)Department of Neurology, University of Virginia School of Medicine, Charlottesville, VA*

Background: Hyperscanning, the simultaneous recording of brain activity from interacting participants (Duane & Behrendt, 1965), provides insight into neural dynamics underlying parent-child interactions. Our understanding of how these dynamics differ when a child is autistic is conflicting, as few studies have used hyperscanning with neurodiverse parent-child dyads (see Zhou & Wong, 2024). Studies on inter-brain dynamics typically focus on coordinated patterns of neural activity, often termed synchrony. However, “symmetry” may be a more term appropriate given the range of associations that occur (Sjoberck et al., 2024).

Objectives: (1) Examine length and variability of symmetry segments and time lag of associations between dyads’ neural activity during turn-based and continuous interactions. (2) Examine how symmetry segments and lags may differ based on child’s autism status and similarity of parent-child autistic traits (AT).

Methods: Participants were 39 parent-child dyads (14 autistic, 25 non-autistic children), with children averaging 8.43 years (6–11 years; 33% female). Parents completed the Autism Quotient (AQ) for themselves and the AQ Child for their child.

EEG data were recorded using Cognionics dry wireless Quick-20m headsets at 500Hz while dyads engaged in musical freeplay (MF) and a musical patterns (MP) task.

During MF (5 minutes), dyads played instruments together as if they were at home. During MP (5 minutes), parents played a short xylophone pattern, their child copied, then both participants played the pattern together. Participants alternated roles throughout MP.

EEG artifacts were removed via a preprocessing pipeline including band pass filtering, bad channel detection/interpolation, and independent components analysis (Bigdely-Shamlo et al., 2015).

We used Windowed Cross Correlations (WCC; Boker et al., 2002) and the Pairwise Approximate Spatiotemporal Symmetry (PASS) algorithm (Sjoberck et al., 2024) to analyze associations between dyad members’ EEG signals. WCC measures the strength and lag of these associations over time. The PASS algorithm identifies segments of symmetry in paired time series. Multi-level models examined dyadic symmetry using task, child autism status, and parent-child AT similarity as predictors.

Results: Dyads with autistic children showed greater mean lag variability ($b=3.54$, $p=.024$). Greater differences in ATs predicted lower lag variability for dyads with autistic children ($b=-0.10$, $p=.045$).

Dyads with an autistic child exhibited longer symmetry segments than those with non-autistic children ($b=3.39$, $p<.001$) and shorter segments during MP compared to MF ($b=-0.95$, $p=.001$). Greater differences in parent-child ATs predicted longer symmetry segments during MP ($b=0.05$, $p<.001$).

Dyads with an autistic child had more variable symmetry segment lengths ($b=204.83$, $p<.001$). Segment length was more variable during MF ($b=-43.80$, $p=.009$), particularly for dyads with autistic children ($b=-57.43$, $p=.03$). Greater similarity in parent-child ATs predicted increased segment length variability in dyads with autistic children ($b=-3.41$, $p=.028$; Fig 1). Greater dissimilarity in ATs predicted increased segment length variability during MP ($b=2.31$, $p=.001$; Fig 2).

Conclusions: This study highlights how child autism status and interaction demands influence parent-child neural dynamics. Effects are moderated by similarity of AT between parents and children, a potentially fruitful area for further research.

402.128 Altered Functional Connectivity Hub Patterning across the Sensory-Association Axis in an Autism Subtype with Low Levels of Language, Intellectual, and Adaptive Functioning

I. Severino^{1,2}, **V. Mandelli**³, **N. Bertelsen**⁴ and **M. V. Lombardo**⁵, (1)Center for Neuroscience and Cognitive Systems, Università degli Studi di Trento, Rovereto, Italy, (2)Center for Mind/Brain Sciences, University of Trento, Rovereto, Trentino, Italy, (3)Center for Neuroscience and Cognitive Systems, Istituto Italiano di Tecnologia, Rovereto, Italy, (4)Center for Neuroscience and Cognitive Systems, Laboratory for Autism and Neurodevelopmental Disorders, Istituto Italiano di Tecnologia, Rovereto, Italy, (5)Laboratory for Autism and Neurodevelopmental Disorders, Italian Institute of Technology, Rovereto, Trento, Italy

Background:

Prior work has shown that early developing non-core language, intellectual, motor, and adaptive functioning (LIMA) features may be important for identifying phenotypically distinctive autism subtypes that are also different in their underlying neurobiology (Mandelli, Severino et al., 2024). Here, we extend this subtyping work on older individuals and investigate whether it can identify subtypes with different functional connectomic organization.

Objectives:

Here we utilize phenotypic measures of non-core language, intellectual, and adaptive functioning features to develop a stratification model applied to individuals older than 5 years of age and then test whether these subtypes show difference at the level of resting state fMRI global functional connectivity.

Methods:

Phenotypic measures of verbal and non-verbal intelligence (e.g., Wechsler, DAS) and adaptive functioning (e.g., Vineland) were obtained from $n=419$ autistic individuals from the National Institute of Mental Health Data Archive (NDA) for the purposes of building and validating a phenotypic stratification model of autism. Stratification models were tested using stability-based relative clustering validation (*reval*; Landi, Mandelli, & Lombardo, 2021). To examine resting state fMRI global functional connectivity, we utilized available data with similar intelligence and adaptive functioning phenotypic measures from the Autism Brain Imaging Data Exchange (*ABIDE*) and Gender Exploration of Neurogenetics and Development to Advance Autism Research (GENDAAR) datasets ($n=186$ typically developing; $n=174$ autism, age: 5-39 years). Global functional connectivity was estimated for each region from the HCP-MMP parcellation using weighted degree centrality as the metric for global functional connectivity. Standard preprocessing was implemented along with wavelet-based denoising to help mitigate motion-related artifact. ComBat was utilized to remove site-related effects on connectivity. Linear modeling was used to statistically test for differences related to subtype, sex and age, while covarying for mean framewise displacement and eyes open versus closed conditions. Multiple comparison correction was achieved using an FDR $q<0.05$.

Results:

Two autism subtypes were identified as the optimal clustering solution, and this 2-subtype model achieved 92% generalization accuracy in an unseen validation dataset. The two subtypes can be described as relatively high versus low on all phenotypic non-core features. A main effect of subtype was observed in global functional connectivity, which was driven by the low subtype showing hyperconnectivity in social brain default mode related areas (e.g., PCC, MPFC) alongside hypoconnectivity in sensory areas (e.g., visual, auditory).

Conclusions:

This work demonstrates that autism subtypes defined by non-core language, intellectual, and adaptive functioning features can be robustly identified in individuals beyond the age of 5 years. This subtype distinction was helpful in isolating a specific pattern in the low subtype of hyperconnectivity in social brain circuitry and hypoconnectivity in sensory-related areas. Such differential patterning of hub-related connectivity measures across sensory-association axes may be important in pointing towards differential biological mechanisms related to cortical patterning in autistic individuals with relatively low levels on non-core features.

402.129 Anomalous Pattern of Left Hemisphere Visual Connectivity in Children with Autism: Association with Impaired Praxis
J. McLaughlin¹, D. Crocetti¹, S. H. Mostofsky¹ and D. E. Lidstone², (1)Center for Neurodevelopmental and Imaging Research, Kennedy Krieger Institute, Baltimore, MD, (2)Kinesiology, Penn State Harrisburg, Middletown, PA

Background: Prominent theories of autism suggest autism-associated differences in visual-motor integration (VMI) may disrupt learning of motor and social skills typically acquired by observation and imitation. Supporting these theories, children with autism spectrum disorder (ASD) show robust differences in motor tasks reliant on dynamic VMI (e.g., ball-catching and motor imitation) and anomalous visual-motor connectivity between higher-order visual (HOV) and sensory-motor cortices. Use of functional MRI (fMRI) to examine HOV functional connectivity (FC) has been particularly revealing with other conditions. For instance, research with congenitally blind adults reveals a particular pattern of altered HOV connectivity, showing reduced HOV connectivity with primary sensory-motor (SM1) and primary auditory (A1) cortices yet "compensatory" increased connectivity between HOV and prefrontal cortex (PFC).

Objectives: Informed by these findings, we used fMRI to examine HOV FC in children with ASD, hypothesizing they would show a distinct pattern of HOV connectivity relative to typically developing (TD) children, with decreased HOV-SMC connectivity (but no alterations in HOV-A1 connectivity) and increased "compensatory" HOV-PFC connectivity. We further hypothesized that this altered pattern of HOV connectivity would correlate with autism-associated difficulties with performing skilled actions ("praxis"); often learned through visual imitation.

Methods: 427 children, 127 ASD (27 girls) and 300 TD (98 girls) aged 8-12 years completed resting fMRI on a 3T Philips scanner and were included if there was 5 minutes of continuous usable data (3mm of translation and 3 of rotation). Praxis was measured using the Florida Apraxia Battery modified for children. Seed-based analyses were performed using an in-house pipeline, which included nuisance regression (aCompCor). Inter-regional FC was assessed between HOV, SM1, A1 and PFC ROIs as defined in a previous study (Tian et al., 2024). Multiple linear regression models examined diagnosis-by-ROI interactions. Separate multiple linear regression models were applied to each ROI to examine diagnosis and diagnosis-by-age interaction effects. Model covariates included handedness, IQ (GAI), sex, and head coil.

Results: A significant diagnosis-by-ROI interaction was observed between HOV-PFC and HOV-SM1 connectivity ($p=0.04$). Compared to TD children, those with ASD showed reduced HOV-SM1 connectivity and greater HOV-PFC connectivity. Examining left and right hemispheres independently, revealed significant in left hemisphere ($p=0.0006$) and not right hemisphere ($p=0.32$). No diagnosis-by-ROI interaction was observed between HOV-PFC and HOV-A1 connectivity ($p=0.92$). Associations with praxis revealed a significant diagnosis-by-HOV-SM1 connectivity interaction for praxis average total errors in left hemisphere ($p<0.0001$), where increased HOV-SM1 connectivity was associated with better praxis for ASD, but worse praxis for TD; overall model $R^2=0.496$, $p<0.0001$.

Conclusions: Our finding suggests ASD children show an altered pattern of higher-order visual (HOV) connectivity that is characterized by reduced HOV connectivity with primary sensory-motor cortex (SM1) yet increased connectivity with prefrontal cortex (PFC). Further, this HOV connectivity correlated with impaired praxis in children with ASD, suggesting that altered patterns of HOV connectivity may contribute to difficulty acquiring a range of skilled behaviors observed in autism.

402.130 Aperiodic Activity in Resting State EEG Differentiates Autistic and Schizophrenic from Non-Autistic Groups.

B. E. Cairney¹, A. Naples², J. H. Foss-Feig³, V. Srihari⁴ and J. McPartland⁵, (1)Psychiatry, Yale Child Study Center, New Haven, CT, (2)Yale Child Study Center, Yale University School of Medicine, New Haven, CT, (3)Simons Foundation, New York, NY, (4)Program for Specialized Treatment Early in Psychosis (STEP), Department of Psychiatry, Yale University School of Medicine, New Haven, CT, (5)Yale Child Study Center, Yale Child Study Center, New Haven, CT

Background:

Traditional EEG analyses measure spectral power within distinct frequency bands associated with specific cognitive states (i.e., periodic power). Measuring oscillations requires an assumption about activity observed within a predefined frequency band, which disregards individual variance. However, non-oscillatory signals (i.e., aperiodic power), often treated as noise, can affect power spectrum calculations and provide informative data. Aperiodic activity is accounted for by calculating the slope of the power spectrum—the rate of decay in spectral power as a function of frequency—which follows the natural decrease in power observed at higher frequencies in humans (i.e., a negative slope). Recent studies have identified aperiodic brain activity as a reliable predictor of neurodevelopmental conditions, including schizophrenia and autism. Among autistic and non-autistic participants, individual aperiodic power spectra identified patterns of activity that complemented results of a non-parametric model and discriminated between the two groups.

Objectives:

The current study aimed to evaluate aperiodic activity derived from resting EEG as a meaningful predictor of clinical diagnosis across adults with autism, schizophrenia, or no neuropsychiatric condition.

Methods: Resting state EEG was recorded from 59 adults with autism (ASD; 47 men, 12 women; 17.9–43 years, $M = 25.0$, $SD = 6.1$), 42 with schizophrenia or psychosis (SZ; 37 men, 5 women; 19.2–43.6 years, $M = 25.5$, $SD = 5.5$), and 61 with no known neuropsychiatric disorder (NT; 35 men, 26 women; 18.3–46.6 years, $M = 26.4$, $SD = 6.3$). EEG was recorded for 80 seconds while participants' eyes were closed. Power spectrum densities were calculated across all electrodes. Linear regression was applied to frequency and median power to derive the slope for each participant. Participants' slopes were submitted to linear regression with group as a predictor

Results:

Power spectrum density slopes (i.e., oscillatory + aperiodic activity) were affected by group diagnostic status, $F(2, 151) = 3.69$, $p = 0.03$, $R^2 = 0.05$. Compared to TD participants, slopes were significantly more negative among ASD ($= -0.0014$, $p = 0.01$) and SZ ($= -0.0013$, $p = 0.04$) groups. There was no difference between ASD and SZ groups, ($= 0.0001$, $p = 0.84$).

Conclusions:

In this transdiagnostic sample, aperiodic EEG effectively differentiated between clinical and non-clinical groups. Specifically, autistic and schizophrenic participants had a steeper decay in slope compared to those without a neuropsychiatric condition, consistent with prior studies. This pattern may be indicative of less efficient neural processing, differences in connectivity, or an imbalance between excitatory and inhibitory neural firing (i.e., stronger low-frequency oscillations relative to high-frequency activity). Greater variability in EEG signals has been reported in both autism and schizophrenia which may explain the absence of a difference in slope values between the two clinical groups. Indeed, both conditions share similar patterns of atypical functional connectivity as well as comparable behavioral traits, cognitive impairments, and genetic variants. Additional study of oscillatory and non-oscillatory neural patterns may help elucidate the biological underpinnings of autism and schizophrenia.

402.131 Assessing Whether Affinities Elicit Different Neural Activation Patterns in Autistic and Neurotypical Young Children

J. S. Wilson¹, M. Pecukonis², A. Daniels³, P. Shankar³, H. Gustafson-Alm³ and H. Tager-Flusberg⁴, (1)Department of Psychological and Brain Sciences, Boston University, Boston, MA, (2)Department of Psychological and Brain Sciences, Smith College, Boston, MA, (3)Boston University, Boston, MA, (4)Psychological and Brain Sciences, Boston University, Boston, MA

Background: Research has shown that the brains of autistic individuals process spoken language differently than that of neurotypical individuals. Previous neuroimaging work suggests reduced activation in left-lateralized frontal and temporal regions of the brain, including the bilateral frontal and temporal gyri and the temporoparietal junction (TPJ), may contribute to the development of language differences in ASD. It remains unknown if the affinities of autistic and neurotypical (NT) children change their neural responses to language.

Objectives: We investigated whether autistic and NT children demonstrated differences in neural activation, beyond what is explained by receptive language ability, when listening to stories that contained reference to either their affinity or a neutral topic.

Methods: Participants included 14 autistic children ($M_{age}=5.35$ years, $range = 3.8-6.9$, $M_{receptive\ language\ SS}=90.4$) and 13 NT children ($M_{age}=5.12$ years, $range = 3.7-6.1$, $M_{receptive\ language\ SS}=121.0$). Receptive language skills were measured using the Preschool Language Scales (PLS-5). Functional near-infrared spectroscopy (fNIRS) was used to measure children's brain function while they listened to two different stories read by a live experimenter. One story included the child's affinity (e.g., Bluey), while the other story did not (neutral). Each story included 15 trials which were 10 seconds each. Oxygenated hemoglobin concentration values (HbO) were averaged over 0-to-10 seconds (trial length). We performed correlation analyses between HbO and PLS scores, and paired samples t-tests comparing conditions (Affinity/Neutral) within groups (ASD/NT). Finally, we ran linear regression models for hypothesized ROIs to see whether group predicted HbO when controlling for receptive language skills and age.

Results: Paired samples t-tests yielded a significant differences in the right TPJ (rTPJ) in the NT group, wherein HbO for the affinity condition was significantly greater than the neutral condition (Figure A; $t(10)=2.67$, $p=0.031$), and the superior and middle temporal gyrus (SMTG) in the NT group, wherein HbO for the affinity condition was significantly greater than the neutral condition (Figure B; $t(9)=2.47$, $p=0.046$). One linear regression was significant; NT kids show significantly less deactivation than ASD kids in the left IMFG during the affinity condition when controlling for receptive language abilities and age (Figure C; $p=.027$). Correlation analyses demonstrated one significant, strong correlation between receptive language and HbO in the rTPJ for the affinity condition within the autistic group ($r=.69$, $p=.023$).

Conclusions: NT participants showed significantly greater activation in the left SMTG and rTPJ during the affinity condition, suggesting that brain regions involved in language processing, attentional control, and mentalizing were more active during affinity stories. Significantly greater deactivation of the left IMFG in the ASD group suggests that autistic kids show greater social attention during the affinity condition, as deactivation of the frontal gyri has previously been associated with attention to socially relevant information. The strong positive association between receptive language and rTPJ activation in the autistic group suggests the role of attention in both PLS and book reading tasks and/or that autistic kids with higher receptive language are mentalizing more with the live reader or characters in affinity condition. Findings may inform whether affinities can be leveraged in language interventions for different neurotypes.

402.132 Assessment of Bilateral Hearing Loss in a Minimally Verbal Autistic Female Using Auditory Event-Related Potentials: A Case Study

R. Yosick¹, K. Gerencser¹ and A. Key², (1)Marcus Autism Center, Atlanta, GA, (2)Dept. of Pediatrics, Emory University School of Medicine, Atlanta, GA

Background:

Minimally verbal autistic children (MVA; e.g., use less than 20 spoken words; Koegel et al., 2020) make up ~30% of the autistic population. A small part of the autistic population (i.e., up to 3.5%) is also considered deaf or hard of hearing (DHH). Both autism and hearing loss are known contributors to altered communicative functioning, but little is known about DHH autistic children beyond clinical features and challenges with obtaining accurate diagnosis (Shield, 2014). Auditory event-related potentials (ERPs) are a promising approach to assessing language processing in MVA (Tager-Flusberg & Kasari, 2013) and have been previously used to document the effects of amplification in pediatric hearing loss (Key et al., 2010).

Objectives:

A primary objective of this pediatric case study was to determine the impact of hearing amplification and intensive behavioral intervention on receptive communication in MVA with hearing loss.

Methods:

A 5-year-old MVA female with completed behavioral and ERP measures to assess the impact of hearing amplification on speech processing during intensive intervention targeting social communication. She passed her newborn hearing screening and a sedated ABR was conducted due to limited growth in receptive language despite intensive intervention. She subsequently received her hearing loss diagnosis in early 2024, but the cause and timing of hearing loss is unknown. A passive listening ERP protocol (presented in sound field, at 75 dB SPL) evaluating sound onset detection, speech sound discrimination (consonant-vowel syllables with varied place of articulation), and known word recognition was completed along with behavioral measures at 2 (Time 1) and 4 (Time 2) months after hearing aid acquisition. All data were collected in the aided condition with both hearing aids at their regular settings. Between study visits, receptive (e.g., one-step instructions) and expressive tasks (i.e., via speech generating device and introduction of sign language).

Results:

At Time 1, behavioral measures indicated expressive and receptive skills fell between 18-30 months. ERP data indicated age-appropriate P1-N1-P2 response to sound onset, confirming that the hearing aids' amplification was sufficient for the auditory input to reach the auditory cortex. However, evidence of speech sound and word-nonword discrimination (frontal P3a and left temporal negativity at 200-500 ms) was limited, consistent with limited experience with sound. At Time 2, the ERPs replicated the sound detection and speech discrimination findings while word-nonword amplitude differences emerged at the right temporal sites. While immature relative to chronological age, that finding was consistent with prior observations in younger language learners (Mills et al., 2014), including those at risk for autism (Kuhl et al., 2013).

Conclusions:

Findings demonstrate that increased auditory experience with speech following access to hearing technology in MVA children with hearing loss may facilitate development of receptive communication abilities, as has been previously reported in children with hearing loss without autism. Results highlight the importance of identifying and treating hearing loss in MVA children who are not making progress on receptive tasks and demonstrate the utility of ERP in assessment of language processing for these children.

402.133 Atypical Cerebellar Functional Connectivity Gradient in Autism Spectrum Disorder

X. Wang¹, X. Li¹, N. Pan¹, S. Shen², J. Jing³, L. Lin⁴ and B. Wan^{5,6}, (1)Key Laboratory of Brain, Cognition and Education Sciences, Ministry of Education; Institute for Brain Research and Rehabilitation, and Guangdong Key Laboratory of Mental Health and Cognitive Science, South China Normal University, Guangzhou, Guangdong, China, (2)Maternal and Child Health Department, School of Public Health, Sun Yat-sen University, Guangzhou, Guangdong, China, (3)Sun Yat-sen University, Guangzhou, China, (4)Department of Occupational and Environmental Health, School of Public Health, Sun Yat-sen University, Guangzhou, Guangdong, China, (5)Max Planck Institute for Human Cognitive and Brain Sciences, Leipzig, Leipzig, Germany, (6)Research Center Jülich, Institute of Neuroscience and Medicine (INM-7: Brain and Behavior), Jülich, Jülich, Germany

Background: An increasing body of research indicates that the cerebellum, functioning as a central hub within the nervous system, is associated with the onset and progression of autism spectrum disorder (ASD). Similar to the cerebrum, the cerebellum exhibits a gradient organization, which underscores its spatial characteristics and developmental transformations. Although prior studies have documented changes in functional connectivity gradients within the cortical structures of individuals diagnosed with ASD, the characteristics of these gradients in the cerebellar cortex, as well as the interconnections between the cerebellum and the cerebral cortex, remain unclear.

Objectives: This study aims to explore the characteristics of the functional connectivity gradient along the cerebellar cortical and cerebellar-cerebral pathways in individuals with ASD.

Methods: Subjects with acceptable T1-weighted magnetic resonance imaging (MRI) and resting-state MRI (rs-MRI) images were selected from the Autism Brain Imaging Data Exchange (ABIDE) I and II databases. We choose NettekovenAsym128 to down-sample voxel-based rs-MRI data considering the asymmetric nature of cerebellar functional organization and its dissociation from anatomical structure. For the cerebral cortex, we choose multimodal parcellation (MMP). After parcellating the preprocessed time series, we computed the rs-Function connectivity (FC) matrix for each individual using Fisher Z-transformed Pearson correlations between parcels. For the intra-cerebellar pattern, the first three eigenvectors reflect sensorimotor-association gradient (G1), VIII-vermis gradient (G2), and superior-ventral inferior gradient (G3). For the cerebellar-cerebral pattern, the first three eigenvectors are sensorimotor-association gradient (G1), left-right default gradient (G2), and visual-soma motor gradient (G3). We calculated three global measures that can quantify gradient developmental properties. The linear mixed model incorporated main effects of diagnostic group and age group, their interaction, and full-scale intelligence (FIQ) as covariates. We took a multivariate approach using Hotelling's T to discover shared effects across three eigenvectors.

Results: The final sample included 419 males aged 6 to 35 years (174 ASD vs. 245 typically developing controls [TDC]), which was further divided into three age groups: 218 children (6–12 years; 88 ASD, 130 TDC), 112 adolescents (12–18 years; 51 ASD, 61 TDC), and 89 young adults (18–35 years; 35 ASD, 54 TDC). We compared gradient scores along the first three functional organizational axes of cerebellar between individuals with ASD and TDC within the total sample, which indicated group differences in bilateral IX for intra-cerebellar patterns, and left lobules Crus I, VIIB-X, and right VI, VIIIA-X in cerebellar-cerebral patterns. Significant group differences were found in intra-cerebellar patterns, cerebellar-cerebral patterns and single-gradient analyses ($P_{FDR} < 0.05$), as refer to **Figure 1**. Furthermore, we found that the gradient changes in ASD were less pronounced with increasing age. The interaction effects of age group with the status of ASD primarily observed in left lobules VIIB-X and right lobules VI-VIIIB, IX for the intra-cerebellar pattern. In contrast, the cerebellar-cerebral pattern was evident in left the lobules VI-Crus I, VIIIA-VIIIB and right lobules VIIIA-IX.

Conclusions: Our findings indicated that there were significant differences in gradient scores on the cerebellar functional organizational axes between individuals with ASD and TDC, and these differences decrease with increasing age.

**402.134** Autism Subscores Are Correlated with Tuber Functional Connectivity to Right Cerebellar Crus V in Tuberous Sclerosis Complex

W. X. Herman¹, A. L. Cohen², J. Peters³, G. N. Miller⁴, M. Sahin⁵, H. Northrup⁶, M. Bebin⁷, D. A. Krueger⁸, J. Wu⁹, S. K. Warfield¹⁰ and M. D. Fox¹¹, (1)Neurology, Boston Children's Hospital, Boston, MA, (2)Neurology, Boston Children's Hospital, Boston, MA, (3)Department of Neurology, Boston Children's Hospital, Boston, MA, (4)2 Brookline Place, The University of Alabama, Brookline, MA, (5)Boston Children's Hospital / Harvard Medical School, Boston, MA, (6)McGovern Medical School, Univ. TX Health Sci Cntr-Houston, Houston, TX, (7)University of Alabama at Birmingham, Birmingham, AL, (8)Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (9)University of California Los Angeles, Los Angeles, CA, (10)Computational Radiology Laboratory, Department of Radiology, Boston Children's Hospital, Boston, MA, (11)Neurology, Brigham and Women's Hospital, Boston, MA

Background:

Autism spectrum disorder (ASD) is a neurodevelopmental condition affecting 1:54 people in the United States that results in altered social communication, restrictive/repetitive patterns of behavior, interests, and activities. Individuals with Tuberous Sclerosis Complex (TSC), a rare genetic disorder resulting from TSC1/TSC2 mutations, are at high risk of developing ASD (40%) and have focal brain lesions present from birth that affect surrounding brain tissue function. Because ASD in individuals with TSC is behaviorally indistinguishable from idiopathic/non-syndromic ASD, these individuals may provide unique lesion-based insight into the neuroanatomical substrate of ASD symptoms.

Objectives:

To examine networks in the brain related to autism severity and severity of different autism characteristics.

Methods:

This research draws on information from the TSC Autism Centers of Excellence Research Network (TACERN), comprising 115 individuals with Autism Diagnostic Observation Schedule (ADOS) data along with structural neuroimaging data. We applied lesion network mapping, a technique that identifies brain circuits associated with lesions like cortical tubers, to explore the relationship between specific ADOS variables and networks associated with these tubers. For comparative analysis, we referenced normative data from 1,000 nine-year-olds from the Adolescent Brain Cognitive Development Study.

Results:

We found that the localization of functional connectivity networks associated with the overall autism severity score was somewhat limited. However, when we analyzed the subscores for social affect (SA) and repetitive restrictive behaviors (RRB), we identified a correlation between SA scores and increased functional connectivity in the right cerebellar Crus V region, which is linked to both primary and secondary motor areas. Furthermore, the variance associated with RRB severity appeared to be largely independent of SA.

Conclusions:

We found a significant correlation between social affect and the activation of a specific network associated with bilateral somatomotor and cerebellar regions. In contrast, no correlation was observed when looking at total ADOS scores, which may help explain the diverse findings in neuroimaging studies that focus only on overall autism severity. Our findings emphasize a specific brain network tied to social affect in TSC-related autism, which could also be relevant for cases of idiopathic or non-syndromic ASD.

402.135 Brain Anatomical and Functional Study in Children Carrying De Novo Pathogenic ARID1B Mutations

A. Fabre^{1,2,3,4,5}, **K. Aljabali**^{1,5,6,7,8}, **L. Fillon**⁹, **A. Saitovitch**¹⁰, **J. Boigontier**⁹, **A. Munnich**¹¹, **M. Zilbovicius**¹² and **N. Boddaert**⁹, (1)Cerveau, Comportement, Cognition, Université Paris Cité, Paris, Île-de-France, France, (2)Consultation Mobile Régionale de Génétique, Paris, Île-de-France, France, (3)Image@Imagine, Institut Imagine, Paris, Île-de-France, France, (4)Trajectoires Développementales et Psychiatrie, INSERM Unité 1163 & U1299, Paris, Hôpital Necker Enfants Malades, Service de Radiologie Pédiatrique, France, (5)Pôle Autisme, Fondation Elan Retrouvé, Paris, Île-de-France, France, (6)Génétique, Consultation Mobile Régionale de Génétique, Paris, Île-de-France, France, (7)Unité 1163 & U1299, INSERM, Paris, Île-de-France, France, (8)Cerveau, Cognition, Comportement, Université Paris Cité, Paris, Île-de-France, France, (9)Service de radiologie pédiatrique Hôpital Necker, Institut Imagine / INSERM U1299, Paris, France, (10)Hôpital Necker service de radiologie pédiatrique, Institut Imagine / INSERM U1299, Paris, FRANCE, (11)Service d'Histologie-Embryologie et Cytogénétique, Université Paris Descartes Paris France, Paris, France, (12)Service de radiologie pédiatrique Hôpital Necker, INSERM, Paris, France

Background: Autism spectrum disorders (ASD) and intellectual disability (ID) are common neurodevelopmental conditions that present unique challenges. Mutations in the ARID1B gene can lead to various neurodevelopmental disorders, including Coffin-Siris syndrome or isolated ID, often accompanied by behavioral challenges like ASD and distinct physical features (e.g., underdeveloped fifth fingers or toenail abnormalities). Despite the established role of ARID1B in these conditions, MRI studies focusing on pediatric populations with ARID1B mutations remain limited.

Objectives: This study aims to investigate anatomical and perfusion abnormalities in the brains of children with ASD and de novo ARID1B pathogenic variants and to explore the relationship between these genetic mutations, the children's cognitive profiles, and their brain abnormalities.

Methods: We retrospectively included 24 ASD patients with de novo ARID1B pathogenic variants (mean age: 10.5 ± 8.9 years, range: 1–19 years), all of whom underwent MRI at Necker Children's Hospital. Of these, 7 patients (mean age: 12.56 ± 5.4 years) who underwent 3T MRI-scanning had both 3DT1 and Arterial Spin Labeling (ASL) sequences, which respectively measure brain structures and cerebral blood flow (CBF) at rest. Additionally, 25 healthy subjects (mean age: 11.51 ± 4.1 years) with 3T MRI scans were included from our database. A neuroradiologist conducted a visual analysis of the 3DT1 anatomical scans of the 24 patients. To examine grey matter differences between patients and controls, we performed voxel-based morphometry (VBM) using a whole-brain approach with 3DT1 images. We also assessed brain perfusion differences by comparing resting CBF using a voxel-wise analysis between the two groups. All statistical analyses were performed using SPM12 with age as a covariate, and significance was set at $p \leq 0.05$, FWE-corrected. Cognitive assessments included the Wechsler Intelligence Scale for Children (WISC-V) and a Developmental Neuropsychological Evaluation (NEPSY-II) to assess delayed memory.

Results: Visual analysis identified corpus callosum abnormalities in all 24 patients, with 18 showing also a posterior fossa arachnoid cyst. VBM analysis revealed a significant bilateral increase in grey matter in the posterior cingulate of patients with ARID1B pathogenic variants compared to healthy controls ($p < 0.05$). The ASL study indicated a significant increase in CBF in bilateral hippocampal regions in patients compared to controls ($p < 0.05$ cor). Cognitive assessments revealed that all 7 patients had ID but demonstrated strong memory performance, with all scoring above the 50th percentile in visual memory and 4 scoring above the 75th percentile.

Conclusions: Our findings show increased grey matter density in the posterior cingulate, a critical region of the Papez circuit, and heightened CBF in both hippocampi, which is associated with visual and spatial memory. These anatomical and functional results align with the observed neuropsychological profiles. The high memory scores suggest a significant dissociation between visual memory performance and overall cognitive abilities. An ongoing larger prospective study, including episodic memory tests, aims to further investigate phenotype-genotype correlations and will provide a comprehensive understanding of the clinico-radiological aspects of ARID1B pathogenic variations.

402.136 Brain Function Underlying Naturalistic Motor Observation and Imitation in Autistic and Non-Autistic Individuals

D. Yang¹, T. G. George², C. M. Sobolewski¹, S. R. McMorro¹, S. M. Park³, M. B. Nebel⁴, B. Tuncgenç⁵, R. Vidal⁶, N. Marrus⁷, S. H. Mostofsky⁴ and A. T. Eggebrecht¹, (1)Washington University School of Medicine, St. Louis, MO, (2)Mallinckrodt Institute of Radiology, Washington University in St. Louis School of Medicine, St. Louis, MO, (3)Washington University School of Medicine in St. Louis, Saint Louis, MO, (4)Center for Neurodevelopmental and Imaging Research, Kennedy Krieger Institute, Baltimore, MD, (5)Psychology, University of Nottingham, Nottingham, Nottinghamshire, United Kingdom, (6)Johns Hopkins University, Baltimore, MD, (7)Washington University in St. Louis, St. Louis, MO

Background: While autism spectrum disorder (ASD) is principally defined by deficits in social-communicative functioning with restricted interests and repetitive behaviors, autistic individuals often show early motor impairments that persist through childhood and into adulthood. Especially prominent among these ASD-associated motor features is difficulty imitating others' actions. Elucidating brain function underlying autism-associated behavioral differences in motor imitation has proved challenging due to constraints with functional MRI (fMRI). High-density diffuse optical tomography (HD-DOT) overcomes logistical challenges of fMRI, providing an open scanning environment conducive to neuroimaging during gross motor imitation.

Objectives: We aim to investigate brain-behavior associations underlying motor observation (OBS) and imitation (IM) in autistic and non-autistic control (NAC) adults and school-age children.

Methods: Participants, including 72 children (7-17 years; 32 ASD) and 103 adults (18-74 years; 19 ASD), performed OBS and IM tasks while being imaged with HD-DOT (**Table 1 and Fig. 1A-C**). Participants observed or imitated videos of an actor completing sequences of meaningless arm movements while being recorded using Kinect 3D cameras for computer-vision-based assessment of motor imitation (CAMI, **Fig. 1D**). General linear models were used to compute beta values of the HD-DOT-measured brain responses relative to rest (e.g., task>rest) with group-level random effects t-tests calculated for OBS, IM, and their contrast (IM>OBS). False discovery rate correction was used to control for multiple comparisons. We also applied multiple regression to investigate brain-behavior associations with both autistic traits, using the Social Responsiveness Scale - Version 2 (SRS-2), and CAMI (**Fig. 1E**).

Results: The adult group statistical maps for both tasks exhibit expected activations in visual and temporal cortex, with additional motor cortex activation during imitation (**Fig. 1F, G**). Additionally, we observed a negative correlation between SRS-2 t-scores and brain activation in the temporoparietal junction and superior temporal gyrus in the right hemisphere during the OBS task, and a similar negative correlation in the left hemisphere during the IM task (**Fig. 1H**). Further, during the IM task, motor cortex activation showed a positive correlation with CAMI scores (**Fig. 1I**). Notably, NAC children displayed a consistent pattern of OBS brain activation as the adult participants. In contrast, ASD children showed different activity in visual, temporal, parietal, and motor cortex (**Fig. 1J**), which may reflect brain activation differences in how visual attention is processed between autistic and non-autistic individuals. Finally, across the groups of children, there were strong relationships between SRS scores and brain activity during OBS, e.g., a negative correlation in the premotor cortex (**Fig. 1K**) - suggesting potential differences in the mirror neuron system during motor observation in individuals with stronger autism traits.

Conclusions: Using simultaneous HD-DOT and CAMI, we investigated brain function during both motor observation and naturalistic motor imitation (not possible in an fMRI) and observed key group differences as well as neural correlates between autism traits and brain function underlying both OBS and IM. Future directions include ongoing studies extending HD-DOT and CAMI to pre-school-age children to investigate early developmental patterns and improve intervention strategies at a critical neurodevelopmental age.

**402.137 Cerebellar Contributions to Social Learning in Typically Developing and Autistic Adolescence**

Y. W. Chen^{1,2}, S. Cahalan^{1,2}, J. Eilbott², C. Korn³, G. Rosenblau^{1,2} and A. Jack⁴, (1)Autism and Neurodevelopmental Disorders Institute, The George Washington University, Washington, DC, (2)Department of Psychological and Brain Sciences, The George Washington University, Washington, DC, (3)Section Social Neuroscience, Department of General Psychiatry, Heidelberg University, Heidelberg, Germany, (4)Psychology Department, George Mason University, Fairfax, VA

Background: Adolescence marks a critical stage in social development, during which individuals experience increasing social demands. While adolescents generally display less optimal social learning strategies compared to adults (Rosenblau et al., 2018), autistic teens face even greater difficulties in navigating these social challenges (Picci et al., 2014). These social challenges have been tied to altered predictive abilities. Autistic adolescents seem to use and encode prediction errors (PEs), the discrepancy between predicted and actual consequence, less compared to nonautistic peers (Rosenblau et al., 2020). A possible neural mechanism for this encoding difference involves cerebellar posterior lobe (CPL), a structure thought to generate predictions and encode PEs (Ramnani, 2006), and its densely connected cortical region, medial prefrontal cortex (mPFC) (Stoodley, 2016). However, this has been insufficiently studied across neurotypes, including in non-autistic adolescents.

Objectives: This study investigates cerebellar contributions to social learning in autistic (AUT) and nonautistic (N-AUT) adolescents. We hypothesize that the cerebellum encodes PEs in adolescents and expect differential cerebellar involvement in PE encoding between N-AUT and AUT.

Methods: Participants inferred a peer's preferences for 60 food and activity items in two runs and received feedback on actual preferences after each trial. PEs are the difference between ratings and feedback, with learning defined as PE reductions over time. fMRI data was preprocessed with fMRIPrep (Esteban et al., 2019), and the cerebellum was processed with SUIT (Diedrichsen, 2006). PEs were used as parametric regressors in a linear mixed effects model in FSL's FEAT to investigate cerebellar activity modulation.

Results: A preliminary sample of N-AUT adolescents (N = 14, 9 - 17 years old, 6 females), who completed the social learning task, showed a trend of PE reductions over time, and PEs were negatively associated with age. As predicted, the region of interest (CPL: Lobule VI, Crus I, Crus II) analysis revealed PEs scaled with activity in CPL. Furthermore, a non-linear relationship between age and PEs activity in CPL aligns with non-linear neural development throughout adolescence. A whole brain analysis with an overlapping N-AUT sample (N = 18, 9 - 17 years old, 5 females) revealed PEs scaled with activity in mPFC (Fig. 1). Further analyses are planned to expand on these initial findings, by analyzing PEs scaled CPL activity and functional connectivity between the CPL and mPFC during social learning with a larger sample of 18 N-AUT and 17 AUT participants.

Conclusions: Our reported findings highlight the role of CPL and mPFC in encoding PEs during social learning in adolescence. Follow up analyses in a larger sample of N-AUT and AUT participants can clarify the role of the cerebellum and of fronto-cerebellar connectivity in social learning of adolescents. Our study can not only shed light on brain development and social learning in adolescence, potentially identify this period as a sensitive period for cerebellum and fronto-cerebellar connectivity for social learning; it can also inform our understanding of predictive framework and cerebellar function in autism pathology and symptomatology.

This study is supported by the National Institute of Mental Health (R01MH116252).

402.138 Cerebellar Modulation of Brain Activation during Cognitive Flexibility in Autism: A Tdcs-fMRI Study

J. Dust¹, R. F. Tegiachchi¹, M. M. Lee², A. Schwartz², M. Paknejad³, H. Younesie³ and C. J. Stoodley^{1,4}, (1)Neuroscience, American University, Washington, DC, (2)Tufts University, Medford, MA, (3)American University, Washington, DC, (4)Developing Brain Institute, Children's National Medical Center, Washington, DC

Background: While inflexible behaviors are a core feature of autism, the neural bases of inflexible behaviors are less often investigated than social behaviors. In pre-clinical rodent models, modulating autism-relevant cerebellar subregions leads to inflexible behaviors (Kelly et al. 2020). The Flexible Item Selection Task (FIST), a cognitive flexibility task, robustly engages the cerebellum, with right cerebellar lobule VII showing the most statistically significant activation in the entire brain (Dajani et al. 2020). While autistic individuals have poorer FIST performance on flexibility trials (Yerys et al. 2012, Campbell et al. 2017), the neural bases of these differences are not clear. Further, the impact of cerebellar neuromodulation on cognitive flexibility has not yet been investigated in human participants. In this study, autistic young adults performed the FIST task after transcranial direct current stimulation (tDCS) targeting right cerebellar VII. We measured both task performance and functional MRI activation patterns.

Objectives: We hypothesized that: 1) the cerebellum will show less engagement during Flexibility trials than in neurotypical cohorts; 2) active tDCS will selectively impact performance during Flexibility trials; 3) active tDCS will modulate cerebellar activation during Flexibility trials.

Methods: Ten autistic adults (23±5 years; 6 Male, 4 Female) received 20min of 1.5mA excitatory (anodal), inhibitory (cathodal) or sham tDCS targeted right cerebellar lobule VII during separate neuroimaging sessions. The FIST task was performed at each session following neuromodulation. The effect of tDCS on task performance was modeled using linear mixed models in R Studio. Neuroimaging data were preprocessed and denoised with the CONN toolbox and statistical modeling was performed using SPM12.

Results: Based on the linear mixed models, there was no significant impact of tDCS condition on task performance, though there was a trend for inhibitory tDCS to decrease performance on Flexibility trials, with no impact on Control trials. At baseline, the autistic group showed increased cerebellar engagement in the posterior midline and during Flexibility trials compared to Control trials ($p < 0.001$, FDR cluster $p < 0.05$), in line with prior studies (Dajani et al. 2020), but no statistically significant engagement of right VII. Active tDCS targeting cerebellar RVII increased Flexibility-related activation both in the cerebellum (bilaterally) and throughout the rest of the brain.

Conclusions: This ongoing study indicated that, while there were no statistically significant tDCS effects on task performance, there was a general trend of decreased task performance on Flexibility trials after active cerebellar modulation relative to sham. At baseline (sham), the autistic group showed robust posterior midline cerebellar activation during Flexibility trials relative to the Control trials, but no statistically significant activation in right lobule VII, which is consistent with prior studies revealing structural and functional differences in right VII in autism. Active tDCS resulted in greater cerebellar activation during the Flexibility trials, including bilateral lobule VII. Interestingly, when comparing both tDCS conditions to sham, flex trials were correlated with greater activations in the inferior olive, a main input pathway to the cerebellum that modulates cerebellar activity. These preliminary imaging findings support the hypothesis that the cerebellum supports cognitive flexibility in autistic individuals.

402.139 Cerebellar Social Reinforcement Learning in Autistic and Neurotypical Adolescents

H. Popal¹, H. Xie², V. Alleluia Shenge¹, R. M. Jones³, H. A. Yarger¹, C. J. Charpentier¹ and E. Redcay¹, (1)Department of Psychology, University of Maryland, College Park, MD, (2)Children's National Hospital, Washington, DC, (3)Weill Cornell Medicine, New York, NY

Background: Prenatal cerebellar damage is one of the highest known risk factors for autism spectrum disorders (ASD). While traditionally thought to be exclusively a motor region, the cerebellum is now known to be involved in a host of cognitive domains, including social cognition. The posterior cerebellum has been shown to be structurally connected to the striatum and is thought to play a role in reinforcement learning. This cerebellum-striatum pathway has been shown to be critical for pro-social behaviors in rodents. While there has been significant attention given to the ventral striatum in examining social reinforcement in adolescents, the posterior cerebellum has not been examined in this work.

Objectives: In the present study, the sensitivity of the cerebellum to social reinforcement learning signals was examined in a sample of autistic and neurotypical adolescents.

Methods: 85 neurotypical and 28 autistic adolescent participants, aged 11-14, engaged in a social learning fMRI task in which they viewed their own responses to a survey about their likes and dislikes, followed by an option to push a button to learn about their peers preferences (or computer for a nonsocial control). The similar peer responded with positive feedback (thumbs up) 75% of the time and negative feedback (thumbs down) 25% of the time. The dissimilar peer was the reverse while the computer condition had a 50% probability of positive or negative feedback. This event-related design task had 24 trials in each of the four runs.

Results: Behavioral, we found that participants thought of the similar peer as more similar to themselves than the dissimilar peer ($b = 35.3$, $CI = [14.04-56.56]$, $p < .001$), indicating that participants were able to learn about the peers. This is despite no differences in reaction times between similar and dissimilar peer conditions in either group. Neuronally, we found that regions of the default mode network, the ventral striatum, and the posterior cerebellum were significantly more active for similar peer vs computer positive feedback. A preliminary reinforcement learning modeling analysis indicates that the posterior cerebellum is unique from the ventral striatum in that it significantly correlates with the absolute value of a reward prediction error parameter. This effect was true only for the neurotypical adolescents, and not the autistic adolescents.

Conclusions: Overall, these results suggest that similar brain regions contribute to social reward processing in neurotypical and autistic adolescents, but in the former group the posterior cerebellum maybe be contributing a valence-general error signal to social reinforcement learning. Despite these neuronal findings, there were no differences in how neurotypical and autistic adolescents behaviorally responded to learning about similar and dissimilar peers.

402.140 Characterisation of the Face Inversion Effect in Visual ERP Components

M. van der Vaart¹, M. Cooke², E. Jones³, D. Murphy⁴ and L. Mason¹, (1)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (2)King's College London, London, Greater London, United Kingdom, (3)Centre for Brain and Cognitive Development, Birkbeck University of London, London, United Kingdom, (4)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, UNITED KINGDOM

Background:

Face processing is fundamental to social information processing and social behaviour. Autistic people may process faces differently to neurotypical controls but the mechanisms responsible are poorly understood. The face inversion effect – that upside-down faces are harder to process than upright faces – may shed mechanistic light on these differences. A diminished inversion effect in autism has been reported on the N170 face sensitive ERP component, but little is known about how face inversion affects earlier (P1) and later (N2, P2) visual ERP components.

Objectives:

To characterise the face inversion effect in autistic and neurotypical individuals across the P1, N170, P2 and N2 components.

Methods:

We analysed EEG data acquired as part of the multi-site LEAP study. Autistic ($N = 246$) and neurotypical ($N = 190$) participants aged 6-30 years viewed pictures of upright and inverted faces (Fig 1a). Following data cleaning, we extracted the mean P1, N170, P2 and N2 amplitude for each participant and for the upright and inverted condition. We took the amplitude difference between the two conditions (upright-inverted) to calculate the inversion effect. We used linear mixed models to investigate the effect of participant group (autistic or neurotypical) and stimulus condition (upright or inverted), and their interaction, on the amplitude of each component. Age and electrode site were included as covariates and a random intercept model with was used to account for multiple observations per participant.

Results:

Viewing faces evoked a characteristic response consisting of P1, N170, P2 and N2 components (Fig 1B). Visually, the morphology of the ERP to upright faces differed across both groups from the ERP to inverted faces after N170 (Fig 1B). There was no main effect of participant group, however a main effect of stimulus condition (larger amplitude for inverted faces; face inversion effect) was present for all components except P2. This effect differed between autistic and neurotypical groups for the N170 (smaller in autistic group compared to neurotypical group) and P2 component (larger in autistic group compared to neurotypical group, Fig 1C, Table 1).

Conclusions:

The inversion effect was present in both groups, but smaller in the autistic group for N170 and larger in the autistic group for P2. This indicates that disruptions to configural processing caused by face inversion are pervasive across the chain of visually evoked potentials. The altered response in autism may indicate greater difficulties with configural processing in that group.

402.141 Neural Connectivity Effects on Competitive and Cooperative Task Outcomes in Children with and without ASD

M. Sabag¹, J. Yarmolovsky¹, S. Sadon² and R. Geva^{1,2}, (1)Psychology Department, Bar-Ilan University, Ramat-Gan, Israel, (2)Gonda Brain Research Center, Bar-Ilan University, Ramat Gan, Israel

Background: Autism spectrum disorder (ASD) core deficits include social cognitive deficits that extend to difficulties in Theory of Mind (ToM). Previous research shows that competitive manipulations enhance ToM understanding in ASD, yet the neural mechanism underlining this improvement is not yet understood. Individuals with ASD have exhibited resting-state hypo-connectivity; it is plausible that neural connectivity during competition, but not during cooperation, may explain enhanced social performance in ASD.

Objectives: To assess connectivity patterns in ASD, their relation to ASD symptom severity, and the effect of hyper-/hypo-connectivity on accuracy during cooperative and competitive peer play.

Methods: 51 children (ASD=27; TD=24) ages 8.18-16.61 years ($M_{ASD}=12.50\pm2.54$; $M_{TD}=11.74\pm3.02$) were paired with same-group and same-gender peers to perform cooperative and competitive interactive day-night inhibitory control tasks. The tasks require joint and individual actions and inhibitions. Individual (competition) and joint success (cooperation) were displayed on monitors to increase condition priming. Accuracy was recorded via E-prime 2.0. ASD symptom severity was assessed with the ADOS social scale. Participants were fitted with EEG sets, focusing on 7 attentive-social hubs, placing electrodes at the bilateral prefrontal cortex (PFC), and mid-frontal cortex (midFC) for the executive attention network, bilateral ventrolateral prefrontal cortex (VLPFC), and bilateral temporoparietal junction (TPJ) for the orienting attention network and ToM functions. Children were screened for IQ (WISC-IV_{HEB}).

Results: ASD participants demonstrated overall frontal-prefrontal hypo-connectivity in cooperation ($p=.034$) and competition ($p=.002$) as compared with TD, with a unique three-way interaction for hyper-connectivity during competition ($p=.017$), such that children with ASD demonstrate elevated connectivity of the midFC to bilateral TPJ and PFC to right TPJ, in individual compared to joint action, whereas TD children demonstrated elevated connectivity of the midFC to left TPJ and PFC to right TPJ in individual compared to joint inhibition (Figure 1). ASD symptom severity was correlated to cooperative joint action connectivity of the left PFC with midFC ($r=-.63$, $p<.001$) and right TPJ ($r=-.39$, $p=.044$) and individual action of the midFC with left ($r=-.40$, $p=.040$) and right PFC ($r=-.44$, $p=.022$), as well as joint inhibition connectivity of the bilateral VLPFC ($r=-.53$, $p=.004$), such that hypo-connectivity was linked to increased ASD symptoms. Similar links were found for competitive joint inhibition connectivity of bilateral VLPFC ($r=-.40$, $p=.041$) and individual inhibition connectivity of left PFC with right VLPFC ($r=-.44$, $p=.020$). Examination of connectivity relations with accuracy demonstrated positive relations of hyper-connectivity on accuracy during cooperation in both populations, yet more broadly in individual responses for the TD group and the joint responses in the ASD group. These effects were complemented by a unique pattern of hypo-connectivity promoting accuracy in competitive individual actions of ASD (Figure 2).

Conclusions: Findings extend the current body of literature, demonstrating frontal-prefrontal hypo-connectivity in ASD during dyadic play. Furthermore, hypo-connectivity patterns in the ASD group during competitive play and their negative correlations with accuracy may explain increased ToM performance previously found under similar manipulations. Hypo-connectivity relations to ASD symptom severity emphasize the importance of neural connectivity deviances in this population, pointing to possible advantages of competitive social play interventions for ASD.

402.142 Inter-Trial Variability Informs Autism Diagnosis in Machine Learning-Based Power Spectral Feature Analysis of EEG

M. Su¹, D. M. Shama^{2,3}, S. Beeler-Duden¹, J. D. Van Horn³, K. A. Pelphrey⁴ and A. Venkataraman¹, (1)Boston University, Boston, MA, (2)Electrical and Computer Engineering, Johns Hopkins University, Baltimore, MD, (3)Electrical and Computer Engineering, Boston University, Boston, MA, (4)University of Virginia School of Medicine, Charlottesville, VA, (5)School of Data Science, University of Virginia, Charlottesville, VA, (6)Department of Neurology, University of Virginia School of Medicine, Charlottesville, VA

Background: Biomarkers are essential for autism diagnosis, providing objective indicators that enhance assessment accuracy and facilitate earlier detection and targeted interventions. Electroencephalography (EEG) is a valuable tool for identifying biomarkers due to its non-invasiveness and scalability. Given the complexity and high dimensionality of EEG data, machine learning methods are better suited for developing biomarkers, as they can uncover intricate patterns that traditional analyses might miss, resulting in more accurate and reliable indicators. Recent studies indicate that increased intra-individual trial-to-trial variability in EEG responses may reflect distinctive brain differences associated with autism and serve as a potentially important diagnostic biomarker (Dong et al., 2024; Magnuson et al., 2020).

Objectives: The objective of this study is to identify whether trial-to-trial variability features serve more diagnostic value in machine learning methods than traditional “mean-EEG” features.

Methods: We analyzed multi-trial resting-state EEG scans from youth with ASD ($N=94$, age 12.5 ± 2.9 years) and without ASD ($N=96$, age 12.9 ± 2.8 years). We extracted two types of features from preprocessed EEG scans: (i) the conventional “mean-EEG” features with power spectral density (PSD) values extracted from the averaged EEG and (ii) “across-trial” features with summary statistics of PSD values extracted from each trial separately. The latter approach allows for assessing the relevance of distributional features across multiple trials of a subject. We trained four machine learning models (logistic regression, support vector machine, random forest, and an artificial neural network) for each of the two feature types separately.

Results: For all four models, using across-trial features resulted in higher overall performance ($p<0.05$). The across-trial logistic regression model achieved the highest accuracy (0.678 ± 0.083), AUROC (0.748 ± 0.082), and AUPRC (0.751 ± 0.086) with repeated 5-fold cross-validation.

Furthermore, we analyzed the weights of the across-trial logistic regression model to interpret performance. We observed that the standard deviation showed higher feature importance than the mean across trials, and delta-theta frequency bands exhibited higher feature importance than other bands ($p<0.05$). Power spectral density (PSD) analysis revealed significant differences between ASD and control groups across frontal, temporo-parietal, and occipital regions. Notably, higher frequency features were highly correlated across subjects, explaining why our machine learning model prioritized lower frequency bands (delta-theta) for diagnosis. These key features also showed strong correlations with behavioral scores (SRS-T and BRIEF Inhibit). In a separate analysis of male and female subgroups, while classification accuracy remained similar, we observed a shift in feature importance: higher frequencies were more relevant in males uniformly across all regions, whereas lower frequencies were more prominent in females, particularly in parietal, temporal, and central regions.

Conclusions: Our study emphasizes the diagnostic value of EEG power spectral density (PSD) and the potential of machine learning for autism classification and biomarker discovery. Analyzing feature variability across trials reveals distinctive biomarkers more effectively than traditional ERP averaging. Key features correspond with significant PSD differences and correlate with behavioral phenotypes in both the overall cohort and male/female subgroups, offering deeper insights into the biological aspects of ASD.

402.143 Community Vs. Lab EEG: Feasibility in Diverse Developmental Populations of Color

S. R. Perry¹, A. H. Dickinson² and C. Kasari³, (1)UCLA, Los Angeles, CA, (2)University of California, Los Angeles, Los Angeles, CA, (3)Education and Psychiatry, University of California Los Angeles, Los Angeles, CA

Background:

EEG holds significant promise for enhancing our understanding of neural differences associated with autism. However, communities of color have historically been underrepresented in research due to systemic barriers, distrust, and cultural hesitancy in engaging with institutions. This is particularly evident in terms of laboratory-based EEG collection, where logistical and cultural barriers have contributed to the underrepresentation of children of color in EEG research. To help address these challenges, this study aimed to examine the feasibility of community EEG in diverse populations, which may pave the way for future community-based EEG studies in autism.

Objectives:

This study aims to a) determine the consistency of data collected in lab vs. community settings, b) particularly among low-income and families of color.

Methods:

Ten participants (Mean age: 2.52 years; *SD*: 0.74; Range: 0.97 – 3.36) were recruited from an existing research database in the greater LA region. Laboratory based EEG sessions were collected prior to the community EEG. EEG recordings occurred within 30 days of one another (avg days apart=18.2, *SD*=27.03). Participants were diverse: (*M* age: 2.68 years; *SD*: 0.56; Range: 1.65-3.36; 70% male; 40% Hispanic (*N* = 4), 30% Black (*N* = 3), 20% Caucasian (*N* = 2), and 10% Asian (*N* = 1). Lab EEGs were collected with participants sitting on a caregiver's lap in a soundproofed, electrically shielded room. We utilized a 129-channel HydroCel Geodesic Sensor Net as well as a Net Amps 300 amplifier, powered by Net Station 4.4.5 software. Community EEGs were collected in locations chosen by the family (8 in home, 2 in community settings). EEG data were recorded from 32 active gel-based electrodes using a BrainVision LiveAmp amplifier and BrainVision Recorder software.

Results:

EEG data were successfully collected from ten participants in both lab and community settings. On average, the recording length of the EEG was 356 seconds. The data collected was considered viable and consistent. A paired samples t-test revealed no significant difference in the recording duration for community (*M* = 367.89 seconds, *SD* = 34.43) and lab EEGs (*M* = 344.34 seconds, *SD* = 44.50; *t*(9) = 1.25, *p* = .244, See Figure 1A). Noise estimates, including 60Hz signal power and 60Hz SNR, indicated minimal and comparable line noise across conditions (see Figure 1B).

Conclusions:

Our findings demonstrate that community-based EEG is feasible in a diverse developmental sample, highlighting its potential for increasing research accessibility. By expanding research beyond traditional settings, community-based data collection could enhance the representativeness of studies and improve the applicability of findings. Specifically, this approach could help researchers increase engagement among underrepresented communities, and prioritize the perspectives and experiences of families of color to promote equitable participation. These findings have particular relevance in autism research, where community-based EEG could improve the representativeness of samples, ensuring that our research better serves and benefits the full spectrum of individuals with autism, especially those from underrepresented communities.

**402.144 Comparable Visual Responses in Autistic and Non-Autistic Adults: Analysis across fMRI, EEG, and Psychophysics**

D. L. Seczon¹, H. M. Rea², K. M. Woodard¹, T. Kolodny³, S. J. Webb³ and S. O. Murray¹, (1)Psychology, University of Washington, Seattle, WA, (2)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (3)Psychology, Ben-Gurion University of the Negev, Be'er Sheva, Israel

Background: Visual sensory processing in autism is often characterized by heightened sensitivity, which may reflect differences in neural responses to visual stimuli. Prior research has suggested that these sensitivities might be due to heightened neural responses, though the mechanisms underlying such responses remain unclear.

Objectives: To investigate behavioral and neural responses to visual stimuli in autistic and non-autistic adults using a unique approach that integrates three independent measurement techniques — fMRI, EEG (steady-state visual evoked potentials, SSVEPs), and psychophysics. By applying a consistent visual stimulus across all methods and manipulating contrast sensitivity (high vs. low), we aimed to directly compare neural response magnitudes and sensitivity effects across these distinct but complementary methods.

Methods: Autistic (*N*=27) and non-autistic (*N*=31) adults participated in a multi-session experimental procedure involving fMRI, EEG, and psychophysics experiments. Across all methods, individuals were presented with the same stimuli, bilaterally presented circular counterphase 6Hz-flickering checkerboards, in high (100%) and low contrast (2%) conditions. Circular counterphase flickering checkerboards are effective in eliciting visual responses, making them ideal for multi-method investigations. In the fMRI session, BOLD responses were measured while participants fixated to the center of the screen and the bilateral checkerboards were presented, following a block-design that alternated 10 seconds of stimulus with 20 seconds of blank-fixation. Responses were measured in retinotopically-defined regions of early visual cortex including V1, V2, and V3. For the EEG recordings, a 129-channel cap was used to measure SSVEPs to the same flickering stimuli presentation. SSVEP amplitudes were extracted and analyzed for peak amplitudes across a pre-selected set of electrodes. For the psychophysics experiment, participants underwent three versions of a detection task to the same stimuli; a no adapter, low contrast adapter and high contrast adapter condition. Adapter conditions presented the flickering checkerboards before presenting a subsequent lateralized target checkerboard in one of the two (left or right) hemifields. The contrast of the target was adjusted following a stair-case procedure. Behavioral data was extracted and used to estimate individual contrast detection thresholds across the different conditions. All data were aggregated and tested for group differences.

Results: Stimulus contrast had a significant effect across experiments; the high contrast condition had higher fMRI and SSVEP responses than the low contrast condition. For the psychophysics experiment, a high contrast adapter led to higher contrast detection thresholds than the low contrast adapter and the no adapter conditions. No significant group differences were observed in visual responses across methods. Autistic and non-autistic individuals had comparable BOLD responses, SSVEP amplitudes and contrast detection thresholds across all conditions of the flickering stimuli.

Conclusions: This study provides evidence that behavioral and neural responses to visual stimuli in autistic adults are similar to those in non-autistic adults, as measured by BOLD responses, SSVEP amplitudes and contrast detection thresholds. The use of a consistent stimuli across methods strengthens the reliability of these results. These findings challenge the hypothesis of heightened neural activity to visual input in explaining visual sensitivities in autism.

402.145 Cortical Tracking of Speech in Autism Spectrum Disorder: A MEG Study of Speech Processing Under Different Audio-Visual Conditions

L. Piermatti¹, M. Gillis², M. Bourguignon³, S. Gander⁴, F. Merken⁵, G. Deliens⁶, J. Bertels⁷, C. Urbain⁷, V. Delvenne⁸ and X. De Tiège⁹,
 (1)Laboratoire de Neuroanatomie et Neuroscience Translationnelles (LN2T), Université Libre de Bruxelles, Bruxelles, Bruxelles, Belgium,
 (2)Université Libre de Bruxelles, Bruxelles, Bruxelles, Belgium, (3)Faculté des Sciences de la Motricité humaine, Université Libre de Bruxelles, Bruxelles, Bruxelles, Belgium, (4)Laboratoire de Neuroanatomie et Neurosciences Translationnelles (LN2T), Université Libre de Bruxelles, Bruxelles, Bruxelles, Belgium, (5)ACTE, Université libre de Bruxelles, Brussels, Belgium, (6)ACTE — Center of research in Linguistics — ULB Neuroscience Institute, Université libre de Bruxelles, Brussels, Belgium, (7)Faculté de Psychologie, Sciences de l'Éducation et Logopédie, Université Libre de Bruxelles, Bruxelles, Bruxelles, Belgium, (8)Service de Psychiatrie du bébé, de l'enfant, de l'adolescent et du jeune adulte, Université Libre de Bruxelles, Bruxelles, Bruxelles, Belgium, (9)Laboratoire de Laboratoire de Neuroanatomie et Neuroscience Translationnelles (LN2T), Université Libre de Bruxelles, Bruxelles, Bruxelles, Belgium

Background:

Social and communication difficulties are pervasive characteristics of autism spectrum disorder (ASD). Autistic individuals often struggle to integrate auditory and visual information. This challenge becomes especially pronounced in noisy auditory scenes, where they frequently report difficulties with speech comprehension. The neuronal underpinnings of these difficulties remain poorly understood.

Objectives:

To further explore speech processing in ASD, this magnetoencephalography (MEG) study assessed the cortical tracking of speech (CTS) in noiseless and noisy conditions in neurotypical and autistic adults with and without access to visual speech (i.e., attended speaker's lip movements). CTS evaluates how the human brain tracks the amplitude fluctuations of speech (the temporal envelope), at syllabic and phrasal frequencies.

Methods:

Twenty-two high-functioning autistic adults and 25 age- and gender-matched neurotypical adults (age range: 18–35 years, mean age: 26) were included. MEG signals were recorded as participants listened to naturalistic stories presented under different visual (with access to lip movements, images, or blindness) and noise (noiseless, cocktail party noise) conditions. Coherence was evaluated between MEG and speech temporal envelope in two frequency bands: syllabic (4–8 Hz) and phrasal (0.5 Hz).

CTS values were derived from the maximum coherence value across 5 symmetric temporo-parietal sensors showing the largest grand-average per hemisphere. An ANOVA assessed the effect of group, visual condition, noise condition and hemisphere on CTS.

Results:

CTS analyses revealed significant coupling between parieto-temporal neural activity and the attended speech in both populations, at both syllabic and phrasal rates.

The ANOVA did not disclose a significant group effect on CTS at either frequency.

A significant interaction was found between noise, hemisphere, and group on phrasal CTS ($p = 0.013$), reflecting distinct hemispheric lateralization patterns for each group. Specifically, autistic adults exhibited higher phrasal CTS in the left hemisphere, while neurotypical adults showed higher phrasal CTS in the right hemisphere, within the multi-talker background. A significant interaction was also found between visual conditions and group for syllabic CTS ($p = 0.04$), explained by increased CTS in the visual speech condition with lips visibility for autistic individuals compared to neurotypicals, regardless of noise presence.

Conclusions:

The brain of autistic adults tracks the attended speech similarly than those of neurotypical adults but differences emerge based on complex, context-dependent factors. First, left-lateralization of phrasal CTS observed in autistic adults in a multi-talker background may relate to an effect of selective attention on the low-frequency CTS of the attended speech stream to compensate for the sensory or cognitive challenges associated with speech in noise processing. Second, autistic adults show a more efficient tracking of syllable rhythmicity when visual cues are available, compared to neurotypicals. Lip movements and facial expressions may thus provide dynamic temporal and linguistic cues that support the syllabic tracking of the attended speech stream to a greater extent than in neurotypicals. This more efficient audio-visual integration may have developed throughout their lifespan as an adaptive mechanism supporting speech processing.

This study emphasizes the need to consider multiple interacting, rather than isolated, factors to fully understand the neural underpinning of speech processing in ASD.

402.146 Basic Sensory Risk Markers of Schizophrenia in Autism Spectrum Disorder: A Systematic Review and Meta-Analysis

F. Ragalmuto¹, B. Oranje² and **T. Ziermans³**, (1)Psychology, formerly affiliated with University of Amsterdam, Cologne, North Rhine-Westphalia, Germany, (2)Center for Neuropsychiatric Schizophrenia Research (CNSR) & Center for Clinical Intervention and Neuropsychiatric Schizophrenia Research (CINS), Copenhagen University Hospital, Psychiatric Center Glostrup, Copenhagen, Denmark, (3)Department of Psychology, University of Amsterdam, Amsterdam, Noord-Holland, Netherlands

Background: Schizophrenia (SZ) and autism spectrum disorders (ASD) share multiple features, including impairments in basic sensory processes. These deficits have also been found in groups at-risk of developing SZ. It is well-known that a diagnosis of ASD predisposes an individual to a higher risk of developing SZ, yet it remains unclear whether neurophysiological risk markers for SZ are also commonly observed in ASD. If present, this could point to common neurological mechanisms underlying transdiagnostic development of psychopathology.

Objectives: Perform a systematic review and subsequent meta-analyses for common neurophysiological risk markers for schizophrenia in ASD.

Methods: A literature search was conducted up to June 2024 for studies on prepulse inhibition of the startle reflex (PPI), P50 suppression, mismatch negativity (MMN), N100 and P200 amplitude, and smooth pursuit eye movement (SPEM). PRISMA guidelines were followed, and meta-analyses were performed for datasets comprising five or more studies using similar methodologies.

Results: In total 48 studies met predefined inclusion criteria, and meta-analyses were conducted for three paradigms: PPI, P50 suppression, and MMN. A statistically significant reduction was observed for P50 amplitude to the first stimulus of paired-click paradigms and duration MMN, while no significant differences were found for PPI parameters. For N100, P200 and SPEM paradigms insufficient comparable studies were available for meta-analysis. Overall, results for all measures displayed a high degree of heterogeneity.

Conclusions: These results indicate that some, but not all, basic risk markers for SZ may be present in ASD. However, the observed heterogeneity strongly suggests the presence of neurophysiological subgroups within the ASD spectrum. This highlights the need for targeted research on such subgroups to determine their clinical relevance, such as determining whether individuals with a higher number of disrupted neurophysiological measures are at greater risk for developing schizophrenia spectrum disorders.

402.147 Developmental Differences in Working Memory and Underlying Frontoparietal Activation in Autism Spectrum Disorder and Typical Development: An fNIRS Study

J. Bai¹ and M. K. Yeung², (1)Department of Psychology, The Education University of Hong Kong, Hong Kong, Hong Kong, Hong Kong,

(2)Department of Psychology, The Education University of Hong Kong, Hong Kong, Hong Kong, Hong Kong (China)

Background: Individuals diagnosed with autism spectrum disorder (ASD) often encounter difficulties in executive function skills, including working memory (WM), compared to their typically developing (TD) peers. Age is generally associated with WM improvement, especially during childhood and adolescence. However, few studies have compared the age-related difference in WM between autistic and TD individuals.

Additionally, details about the exact neural mechanisms underlying this phenomenon are currently lacking, preventing the development of effective neurological rehabilitation as a means to improve WM development in ASD.

Objectives: The objective of the study was to investigate the age-related difference in WM between autistic and TD children and teenagers.

Besides, the study aimed to reveal the brain mechanisms underlying this possible difference using functional near-infrared spectroscopy (fNIRS).

Methods: Twenty autistic and 20 TD children and teenagers aged 8 to 17, matched in age, gender, and IQ ($ps > .40$), were recruited. Participants were instructed to perform a spatial n -back task with three difficulty levels (0-back, 1-back, 2-back) while their brain activities were recorded by a NIRx NIRScout 16x16 device. A mixed ANCOVA was conducted to examine the effects of group (TD vs ASD) and age, which were between-subjects factors, and difficulty level (0-back vs 1-back vs 2-back), which was a within-subjects factor, on participants' accuracy and mean reaction time (RT). Additionally, the frontoparietal brain network was divided into four regions of interest (ROIs), namely the left frontal, right frontal, left parietal, and right parietal regions. A similar mixed ANCOVA was used to analyze brain activation patterns in both groups.

Results: No significant difference in accuracy or mean RT was observed between the TD and ASD groups, $ps > .25$. Besides, older participants responded significantly more accurately, particularly at 2-back (Figure 1), and were faster than younger ones, $F_s > 15.9$, $ps < .001$. Although the group-by-age interaction was of moderate size for mean RT, $\eta_p^2 = .08$, no age effect significantly differed between groups, $ps > .10$. Similarly, the TD and ASD groups showed comparable brain activation, $ps > .53$, except in the left parietal area, where the TD group exhibited higher activation than the ASD group, $F(1, 35) = 5.04$, $p = .03$. Moreover, a significant age difference in activation was found for the bilateral frontal and right parietal regions (Figure 2), where younger participants displayed higher brain activation than older ones, $F_s > 4.12$, $ps < .05$. Although the group-by-age interaction was of moderate size for the right frontal region, $p = .16$, $\eta_p^2 = .06$, the age effect significantly differed between groups for none of the ROIs, $ps > .16$.

Conclusions: There is insufficient evidence to suggest that children and teenagers with and without ASD demonstrate developmental differences in WM capacity and brain activation yet. More evidence will inform whether the age effects on task performance and right frontal activation during WM performance are different in ASD. Although older children outperform younger ones, they recruit less brain activities, implying an age-related decrease in effort for both autistic and TD individuals to perform the task.

402.148 Directional Anisotropy in the Neural Representation of Human Movement Kinematics and Its Relationship to Autistic Features in Children: Results from the Autism Biomarkers Consortium for Clinical Trials (ABC-CT)

J. P. Momsen¹, A. Naples¹, S. Faja², S. Jeste³, G. Dawson⁴, N. Kleinmans⁵, J. Dziura⁶, F. Shic⁷, S. J. Webb⁸, C. Sugar⁹ and J. McPartland¹⁰, (1)Yale Child Study Center, Yale University School of Medicine, New Haven, CT, (2)Boston Children's Hospital, Harvard, Boston, MA, (3)Children's Hospital Los Angeles, Los Angeles, CA, (4)Department of Psychiatry and Behavioral Sciences, Duke University, Durham, NC, (5)University of Washington, Seattle, WA, (6)Yale University, New Haven, CT, (7)Center for Child Health, Behavior and Development, Seattle Children's Research Institute, Seattle, WA, (8)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (9)University of California, Los Angeles, Los Angeles, CA, (10)Yale Child Study Center, Yale Child Study Center, New Haven, CT

Background:

Atypical biological motion (BM) perception has been hypothesized to be a core feature of ASD. A critical source of information carried in BM patterns involves asymmetric acceleration along the vertical plane, and predictively modeling the influence of gravity is critical for organizing spatial and temporal predictions about visual motion trajectories, including BM information. Despite the variety of methods and tasks used to study BM processing in ASD, no study has investigated whether sensitivity to implicit force-related information can offer a mechanistic explanation for BM processing differences in ASD.

Objectives:

The current study uses neural decoders trained on EEG collected during a BM task to examine how human movement is represented in neural activity in autistic and age-matched non-autistic individuals. We test for differences in the neural representation of motion dynamics according to directional axis (horizontal vs vertical) to assess the hypothesis that perceptual sensitivity to vertical motion during BM processing is relevant to neurocognitive profile of ASD.

Methods:

EEG was recorded as 166 autistic (36 females; μ age= 8.62) and 76 non-autistic (20 females; μ age= 8.43) participants passively watched videos of point-light walkers that either preserved the human form or were spatially and temporally scrambled (factor: motion type). Within each participant and motion type condition, a rotating leave-one-out training procedure generated decoders that transformed EEG data into predicted motion representations, which were then compared against the veridical stimulus to yield a metric (Pearson correlation) for decoding performance. This procedure was run twice using varied stimulus representations that isolated vertical or horizontal motion dynamics. Regression analyses tested for interactions between motion type, motion axis, and diagnostic group on decoder performance and the relative degree of predictive neural activity relevant for visual tracking. The latter was achieved by modeling the difference in decoder weights summed across -200ms to 0ms and across 0ms to 200ms (pre- minus post-video frame onset). Participant-level random slopes of motion type were also used to investigate relationships with symptom features.

Results:

While no effects of diagnostic group emerged on decoder scores, the analysis of decoder weights revealed a main effect of diagnosis ($b=-138.0$; $SE = 54.65$; $p=0.01$), and interactions between diagnosis and motion type ($b=186.25$; $SE = 22.25$; $p<0.0001$), and diagnosis and motion axis ($b=-70.0$; $SE = 22.31$ $p<0.01$). Participant-level effects of motion type on the temporal organization of decoder weights were positively associated with autism features (Social Responsiveness Scale total raw score ($p=0.004$), only in models trained on vertical motion trajectories).

Conclusions:

Although the degree to which neural activity tracked visual motion dynamics (decoder performance) was comparable across autistic and non-autistic individuals, robust group differences were apparent in the composition of decoders—specifically, how much utility was assigned to predictive versus postdictive neural activity. Across non-autistic participants, the contribution of predictive neural activity for motion tracking was enhanced for biological relative to scrambled motion. This effect was disrupted in the ASD cohort, and the magnitude of this effect during vertical movement tracking was associated with clinical features at the individual level.

402.149 Dissecting the Corticostriatal Functional Circuits to Parse out the Heterogeneity of Autism and ADHD Symptoms

H. B. Cho¹, H. An², S. Park² and S. J. Hong^{1,2,4,5}, (1)Center for Neuroscience Imaging Research, Institute for Basic Science, Suwon, Gyeonggi-do, Korea, Republic of (South), (2)Department of Biomedical Engineering, Sungkyunkwan University, Suwon, Gyeonggi-do, Korea, Republic of (South), (3)Autism Center, Child Mind Institute, New York, NY, (4)Life-inspired Neural network for Prediction and Optimization Research Group, Suwon, Gyeonggi-do, Korea, Republic of (South), (5)Center for the Developing Brain, Child Mind Institute, NY, NY

Background: Autism spectrum condition (ASC) and attention-deficit/hyperactivity disorder (ADHD) are two prevailing developmental conditions that are frequently co-occurring. Their commonalities can be found across many behavioral symptoms but are particularly highlighted for 'executive dysfunction'. Previous studies often referred to an altered corticostriatal circuit, a key brain network modulating flexibility, motor persistence, and attention as a common biological substrate for this dysfunction. Despite such importance, the details of circuit-level mechanisms underlying how this circuit dysfunction could lead to both common and distinct behaviors/cognitive symptoms in ASC and ADHD, and how they generate substantial phenotypic heterogeneity in each condition remain largely unknown.

Objectives: Here we tackled these questions by leveraging dimensional approaches to describe their clinical symptoms, executive functions, and corticostriatal functional connectivity (FC) along an integrated common axis to explain the comorbidity and heterogeneity of ASC and ADHD.

Methods: We analyzed the Healthy Brain Network data of clinically diagnosed ASC, ADHD, and neurotypical (NT) individuals (all male; 35 NT, 23 ASC, 111 ADHD, and 61 ASC+ADHD), targeting behavioral symptoms, cognitive performance (assessed by NIH toolbox) and neuroimaging data. Specifically, we have conducted: i) a factor analysis to identify the latent components commonly underlying behavioral symptoms of ASC and ADHD and ii) a partial least squares (PLS) analysis to investigate a multivariate relationship between these symptoms and corticostriatal FCs.

Results: The factor analysis identified four major symptom components across individuals with ASC and ADHD: 'social problems (Factor1)', 'impulsive behavior (Factor2)', 'emotional problems (Factor3)', and 'repetitive behavior (Factor4)' (Fig. 1A). Group comparisons based on diagnostic labels revealed that Factors 1, 3 and 4 were primarily associated with ASC-traits, while Factor2 with an ADHD trait (Fig. 1B). Notably, as expected, the ASC-trait Factors 3 and 4 revealed a negative correlation with a performance of cognitive flexibility, inhibition control, and working memory, whereas the ADHD-trait Factor2 did not show any similar effect with executive function scores (Fig. 1C). Next, associating these factors with corticostriatal FCs based on PLS, we further revealed a significant brain-symptom relationship in Factors 1 and 2 (Fig. 2A, B). Posthoc FC loading analyses localized this significance within the corticostriatal circuit, suggesting that the putamen and sensory-motor cortices may be common pathological substrates to describe various transdiagnostic symptoms between ASC and ADHD.

Conclusions: Our findings suggest that the corticostriatal alterations may be a core transdiagnostic feature, which variation could parsimoniously explain the heterogeneous behavioral symptoms commonly observed in ASC and ADHD. Our approach provides a promising Research Domain Criteria framework to discover a potential biological axis that may underlie the manifestation of ASC and ADHD, the two major developmental conditions.

402.150 Do Cognitive and Motor Skills Predict EEG Data Quality in 6 Month Olds at Higher Likelihood of an Autism Diagnosis?

M. Booth¹, **A. H. Dickinson**², **S. Huberty**³, **M. Daniel**⁴, **A. Campbell**⁵, **B. K. Lau**⁶, **J. Zempel**⁷, **S. J. Webb**⁸, **J. T. Ellison**⁹, **A. K. Lee**¹⁰, **A. M. Estes**¹¹, **S. R. Dager**¹², **H. Hazlett**¹³, **J. J. Wolff**¹⁴, **R. T. Schultz**¹⁴, **N. Marrus**⁷, **J. Piven**¹³, **J. R. Pruett**¹⁵ and **S. Jeste**¹⁶, (1)Children's Hospital of Los Angeles, Los Angeles, CA, (2)University of California, Los Angeles, Los Angeles, CA, (3)McGill University, Montreal, QC, Canada, (4)Semel Institute for Neuroscience, UCLA Center for Autism Research and Treatment, Los Angeles, CA, (5)UNC Chapel Hill, Chapel Hill, NC, (6)Otolaryngology-HNS, University of Washington, Seattle, WA, (7)Washington University in St. Louis, St. Louis, MO, (8)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (9)University of Minnesota, Minneapolis, MN, (10)Speech and Hearing Sciences, University of Washington, Seattle, WA, (11)Speech and Hearing Sciences, UW Autism Center, Seattle, WA, (12)Radiology, University of Washington, Seattle, WA, (13)University of North Carolina, Chapel Hill, NC, (14)The Center for Autism Research/CHOP, Philadelphia, PA, (15)Washington University School of Medicine, St. Louis, MO, (16)Children's Hospital Los Angeles, Los Angeles, CA

Background: Autism spectrum disorder (ASD) is characterized by core social communication and behavioral deficits that emerge after the first year of life. The Infant Brain Imaging Study (IBIS) was established to examine structural and functional brain differences in infants at a higher likelihood of developing ASD (HL; denoted by the presence of an older diagnosed sibling). We recently published a manuscript detailing the addition of electroencephalography (EEG) to this MRI and behavioral based study (Dickinson et al., 2024). Protocol feasibility metrics demonstrated that 72.5% of all infants successfully completed the entire protocol at 6 and 12 months. Data quality remained high with 77.6% and 81.5% of resting state data retained after artifact removal across 6 and 12-month infants, respectively. Nevertheless, behavioral characteristics of each infant were not yet evaluated in relation to EEG data quality.

Objectives: After establishing and testing a standardized protocol to acquire EEG data from HL infants, we asked whether developmental abilities, assessed by the Bayley Scales of Infant and Toddler Development (Bayley-4) at age 6-months, predicted EEG data quality in these infants. The cognitive and motor domains of the Bayley were assessed in relation to clean resting state EEG data to investigate the efficacy of EEG use across developmental abilities.

Methods: Developmental domains were measured through the Bayley-4 in 60 6-month-old infants at HL for ASD. Percentile rank on the cognitive and motor domains were extracted. Correlations between the percentage of clean EEG time and both the cognitive and motor domains were conducted. A multivariate regression was performed to investigate whether cognitive and motor Bayley subscale scores predicted total seconds of clean EEG time and total number of clean EEG channels after artifact removal.

Results: The Pearson correlation coefficients for neither the Bayley-4 cognitive nor motor subscores were significantly correlated to EEG data quality in this 6-month-old cohort. Additionally, multivariate regression showed that neither cognitive or motor scores were a statistically significant predictors of clean EEG data, measured in time and channel count (Tables 1 & 2).

Conclusions: Analyses revealed that neither cognitive nor motor scores, as measured by the Bayley Scales of Infant and Toddler Development at 6-months of age predicted EEG data quality. These findings suggest that data quality may remain independent of developmental level and support the continued use of EEG as a measure to examine infants that may have developmental delays. While a significant effect was not found here, computing the Bayes Factor may help to determine based on our sample size what association is relevant to this population. It is also possible that specific features of the EEG signal, such as spectral power or event related potentials will hold predictive value for infant development. In addition to confirming the above results at 12-month timepoints, we plan to investigate how specific spectral characteristics map onto cognitive and motor scores for these infants, as well as those with greater developmental delay.

402.151 Effects of a Social Skills Intervention on Restrictive and Repetitive Behaviors and Interests in Autistic Adolescents

V. De La Rosa¹, **L. S. Caldera Aguayo**¹, **R. Jalal**¹, **H. R. Gutierrez**¹ and **A. Nair**², (1)Psychology, Loma Linda University, Loma Linda, CA, (2)Loma Linda University, Loma Linda, CA

Background: To our knowledge, group-based social skills interventions (GSSIs) have not been extensively studied for their impact on restrictive and repetitive behaviors and interests (RRBIs), central features of autism. Limited behavioral research using the Program for the Education and Enrichment of Relational Skills (PEERS), a GSSI, on autistic adolescents revealed overall reductions in RRBIs and increased social competence scores post-intervention (Hong et al., 2019). Prior research on the neural basis of autistic symptomatology suggests overconnectivity in cortico-basal ganglia circuits (BG) is linked to higher RRBIs (Traynor et al., 2018). However, few imaging studies have examined the effects of GSSIs on BG circuitry and subsequently RRBIs.

Objectives: To examine whole-brain functional connectivity of the BG and its relationship to RRBIs in autistic adolescents, compared to typically developing (TD) controls after a social skills intervention.

Methods: Parents of autistic adolescents completed the Social Responsiveness Scale, Second Edition, Restrictive and Repetitive Behavior subscale (SRS-2 RRB; Constantino & Gruber, 2012), before and after the standardized 14-week PEERS (Laugeson et al., 2015) intervention. Resting-state functional MRI data obtained via a Siemens 3T PRISMA for 15 autistic adolescents ($M_{age} = 14$, 73.3% male) and 11 TD controls ($M_{age} = 15$, 58.3% male) pre- and post-PEERS intervention. FSL (Smith et al., 2004) and AFNI (Cox, 1996) were used for data preprocessing and bandpass filtering ($0.008 < f < .08$ Hz). ICA-AROMA (Pruim et al., 2015) removed potential motion confounds. A bilateral BG mask was created using the Harvard-Oxford atlas (Desikan et al., 2006). Global time series extracted from this mask were correlated with whole-brain signal. Fisher r-to-z transformations normalized final connectivity maps. AFNI's 3dClustSim (Cox et al., 2017a, 2017b) was used to estimate the probability of false positives while running paired t-tests group-level comparisons. Z' (prime) scores from clusters of significance for groups were extracted to calculate change scores from pre- and post-intervention connectivity clusters. Change scores were created for autistic adolescents from pre- and post-intervention SRS-2 RRB scores. Pearson's correlations were run to examine relationships between BG connectivity change scores and SRS-2 RRB change scores.

Results: There was a significant difference between SRS-2 RRBs scores pre ($M = 77.20$, $SD = 8.55$), and post- ($M = 69.66$, $SD = 8.56$) the PEERS intervention in autistic adolescents, $t(14) = 2.80$, $p = .007$. Pre-intervention, between-group whole-brain comparisons revealed no significant differences with BG connectivity across groups, $p > .05$. Between-group comparisons revealed whole-brain underconnectivity of the BG with the left lingual gyrus (LLG) in autistic participants compared to TD controls post-intervention, $p = .01$. Autistic adolescent BG underconnectivity was negatively correlated with SRS-2 RRB subscale change scores, $r = -.48$, $p = .037$, indicating greater BG underconnectivity with the LLG was associated with reduced RRBIs post-intervention.

Conclusions: Consistent with previous research, participation in a social skills intervention was associated with lower RRBIs in autistic individuals. Findings suggest underconnectivity of the BG with a primary sensory (visual) processing area post-intervention may reflect compensatory mechanisms in enhancing sensory processing, thus suggesting broader implications for treatment.

402.152 Electroencephalographic Correlates of Sleep Onset in Preschool Autism

A. Vasista¹, A. M. Maria², M. W. James³, S. M. Kaku⁴, S. Gosala⁵, A. Mysore⁶ and S. Rajagopalan^{7,8}, (1)St. John's Medical College Hospital, Bangalore, India, (2)St. John's Medical College Hospital and Research Institute, Bangalore, Karnataka, India, (3)Center for Advanced Research and Excellence in Autism and Developmental Disorders, St. John's Medical College Hospital and Research Institute, Bengaluru, Karnataka, India, (4)JSS Superspecialty Hospitals, Bangalore, Karnataka, India, (5)Neurology, St John's Medical College Hospital, Bangalore, India, (6)CAREADD St. John's National Academy of Health Sciences, Bangalore, Karnataka, India, (7)Institute of Bioinformatics and Applied Biotechnology, Bengaluru, Karnataka, India, (8)Center for Advanced Research and Excellence in Autism and Developmental Disorders, St. John's Medical College Hospital and Research Institute, Bengaluru, Karnataka, India

Background:

The earliest stage of non-rapid eye movement sleep cycle (N1) is the lightest sleep marked by the transition from wakefulness, known as drowsiness or sleep onset. Electroencephalography (EEG) during N1 is characterized by gradual reduction of posterior dominant alpha [8-13Hz] activity with diffused theta [4-8Hz] waves. It is fairly common for autistic individuals to experience parasomnia and sleep disturbances which have been adequately captured by sleep questionnaires [1]. The neural markers of such behaviors are much to be explored, particularly during sleep onset.

Objectives:

Given the prevalence of sleep problems in ASD, we hypothesized that they exhibit higher ATR particularly around posterior region with atypical peak alpha frequency (PAF). We aimed to compute EEG correlates of sleep behaviors captured during N1 and establish a relationship with ASD symptoms. Our target population is preschool children with autism and age-matched non-autistic children with other developmental disorders as a control group.

Methods:

EEG was recorded from 25 preschool children (2-6 years) during daytime sleep, out of which 15 were diagnosed with ASD and 10 were diagnosed with other neurodevelopmental disorders except ASD. The annotations of clean N1 segments were performed manually by medical professionals. All segments underwent 0.5-70Hz bandpass followed by a 50Hz notch filter. Power spectral density was computed from Welch's method and subsequently theta and alpha powers were estimated through Simpson's integral within each's frequency bounds. ATR and PAF were computed for each non-overlapping N1 epoch of 8s and averaged across all epochs. Children's Sleep Habit Questionnaire (CSHQ) was administered to all children to quantify their sleep pattern and behavior. The Indian Scale for Assessment of Autism (ISAA) was used to assess the severity of autism. All children in the ASD group exhibited mild or moderate autism. Statistical analysis involved topographically charting significant group differences for each measure and correlating them with ISAA and CSHQ domains. Generalized linear models were used to predict autism severity and sleep onset in autism from bilaterally derived EEG over anterior, central and posterior regions.

Results:

ASD displayed significantly higher ATR in central, occipital and in the right parieto-occipital regions. PAF in ASD was significantly lower around the right central region. Emotional responsiveness (ER) in ASD showed positive correlation ($r>0.8$) with high ATR and negative correlation ($r<-0.8$) with PAF. Sleep-disordered breathing (SDB) also correlated positively with ATR and ER in ASD. Correlating CSHQ and ISAA, bed-time resistance came out strongly associated ($r>0.9$) with sleep anxiety. Significant negative association was found between occipital PAF with ER in ASD ($p<0.01$, $\text{adj-}r^2=0.63$, $\beta=-1.52$).

Conclusions:

Through this study, we have validated our hypothesis of reduced sleep quality in autistic preschoolers through the markers of EEG during sleep onset. These objective measures correlate very strongly with autism symptomatology and sleep behaviors. Sleep disorders directly impact the quality of life of both autistic individuals and their family/caregivers. Early detection of sleep anomalies could be an effective tool to guide intervention and sleep therapy, and in turn lead to mitigate ASD symptoms.

402.153 Electrophysiological Responses to Auditory Stimulus Salience in Autistic Children Correspond with Behavioral Observations of Sensory Responsiveness

K. Dunham-Carr¹, M. Shao², G. Parra², Y. Braverman³, S. R. Rogers³, R. M. Mankaryous³, L. Jones⁴, C. Serianni² and A. R. Levin⁵, (1)Boston Children's Hospital / Harvard Medical, Boston, MA, (2)Boston Children's Hospital, Boston, MA, (3)Neurology, Boston Children's Hospital, Brookline, MA, (4)Boston Children's Hospital/Harvard University, Boston, MA, (5)Neurology, Boston Children's Hospital / Harvard Medical School, Brookline, MA

Background: Differences in responses to sensory stimuli, including hyper- and hyporesponsivity to sounds, are highly prevalent in autistic children and can have negative impacts on development and quality of life. While several behavioral measures have quantified differences in sensory responsiveness and links with outcomes in autism, there is a need for improved understanding of underlying neural mechanisms of atypical sensory processing. Measuring neural responses to stimulus salience via electroencephalography (EEG) can provide non-invasive, objective indices of alterations in neural circuits driving both hyper- and hyporesponsivity to sounds at varying volumes that may serve as potential biomarkers.

Objectives: This study characterizes neural markers of altered auditory processing by determining a) whether autistic children show different event-related potential (ERP) responses to varying auditory stimulus salience, or volume levels, compared to typically developing (TD) children and b) whether individual changes in response magnitude over volume correspond to behaviorally observed sensory processing.

Methods: Data collection is ongoing, with 19 3-4 year old participants (12 TD, 7 Autism) who have completed study protocol. EEG data are collected while participants are presented with 150 trials of 500 ms tones at four volume levels: 50 dB, 60 dB, 70 dB, and 80 dB in random order. Data are collected using NetStation and a 128-channel Geodesic sensor net (Net Amps 400 amplifier, Hydrocel GSN 128 EEG cap, EGI systems Inc). EEG data are preprocessed using the Batch EEG Automated Preprocessing Platform (BEAPP) and Harvard Automated Preprocessing Pipeline (HAPPE), with data bandpass filtered from 0.1-30 Hz and rereferenced to average. The amplitudes of the P1 (defined a priori as occurring between 95 and 145 ms poststimulus) and N2 (defined a priori as occurring between 215 and 265 ms poststimulus) components measured at frontal electrodes (averaged responses at Fz, F4, and F3) were derived for analyses. Participants also completed the Sensory Assessment for Neurodevelopmental Disorders (SAND), a behavioral assessment of sensory responsiveness, and the Mullen Scales of Early Learning.

Results: Preliminary results show significant P1 and N2 amplitude enhancements for the loudest volume compared to the softest volumes, and a Volume x Group interaction effect for N2 amplitudes, $F = 3.12$, $p = .032$, $\eta^2 = .12$, such that there are significant volume effects for the TD group that are absent in the Autism group (Figure 1). Additionally, the Autism group shows a significantly reduced slope of N2 amplitudes over increasing volume compared to the TD group, $t = -3.22$, $p = .005$, $d = -2.61$. There is considerable individual variability in the slopes of P1 and N2 amplitudes, and associations between N2 slope and SAND scores are moderated by group and developmental level (Figure 2).

Conclusions: Our findings suggest that neural responses to auditory stimuli show dynamic change in response to increasing salience, autistic individuals show less dynamic change, and individual differences in dynamic change correspond to behaviorally observed sensory responsiveness. These findings can help further characterize neural mechanisms underlying altered sensory responsiveness in autism that may inform the development of more targeted diagnostic tools and interventions.

402.154 Elevated Information Conflict Processing during Visual Perspective Taking in Autism: Evidence from EEG

L. Polzer¹, **S. Boxhoorn¹**, **M. Schütz¹**, **A. Mühlherr¹**, **C. M. Freitag²** and **C. Luckhardt¹**, (1)Autism Research and Intervention Center of Excellence Frankfurt, Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, University Hospital Frankfurt, Goethe University, Frankfurt, Hessen, Germany, (2)Autism Research and Intervention Center of Excellence Frankfurt, Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, JW Goethe Universit, Frankfurt, Hessen, Germany

Background: Visual perspective taking (VPT) describes the ability to understand what a scene would look like from another person's vantage point. The necessity to ignore irrelevant information, such as information that is incongruently available to the self and another person, can increase the difficulty to judge visual perspectives. Previous studies indicated altered VPT performance in autism, especially with higher task difficulty. In non-autistic participants, the modulation of event-related potentials (ERPs) during VPT has been suggested to reflect attentional processes (P200), self-other distinctions (P3) and conflict processing during response selection (late frontal slow wave [LFSW]). ERPs are hence promising to reveal neurophysiological processes that may underly atypical VPT in autism.

Objectives: The aims were to 1) investigate whether autistic individuals show altered behavioral VPT, 2) examine altered ERPs and, by extension, associated underlying functions of VPT in autism and 3) investigate altered effects of information incongruency on behavior and neurophysiological processing.

Methods: We assessed behavioral responses and EEG of 84 participants (autistic: $n=46$, non-autistic: $n=38$) between 10 and 17 years during an established VPT paradigm (Samson et al., 2010). Participants were presented with a picture of an avatar facing one of two opposing walls, on which 1-3 disks were visible. Participants were instructed to judge whether a cue at trial start indicated the correct number of disks that could be seen from either their own or the avatar's perspective. The number of disks that was visible from the participants' perspective was either congruent or incongruent to the number of disks visible to the avatar. Interaction effects between group (autistic/non-autistic), perspective (self/avatar) and congruency (congruent/incongruent) on behavioral performance (reaction times [RT], accuracy) and mean amplitude of ERPs (P200, P3, LFSW) were analyzed with (generalized) linear mixed effect models on a trial-by-trial level.

Results: Autistic compared to non-autistic participants were less likely to respond correctly when rating the avatar's perspective in congruent trials ($p=.005$) and generally slower when responding to incongruent trials ($p=.039$). Only autistic participants were less likely to respond correctly and showed a smaller LFSW to incongruent compared to congruent trials when rating their own perspective ($p<.001$), while in both groups incongruent trials were associated with lower accuracy and smaller LFSW when rating the avatar's perspective (autistic: $p=.002$, non-autistic: $p<.001$). The P200 and P3 mean amplitude were larger for congruent compared to incongruent trials ($p<.001$, respectively) but did not differ between groups.

Conclusions: Results suggest altered VPT abilities in autistic youth. Elevated congruency effects in autistic individuals' rating of their own perspective may reflect an attenuated ability to disregard irrelevant information. Neurophysiological results did not support attentional or inherently social functions to underly attenuated VPT performance. Instead, differences in LFSW amplitudes indicated an altered cortical recruitment to resolve conflicting information during response selection in autism.

402.155 Evaluating Machine Learning Techniques for Autism Identification through Resting State EEG

Y. Emarat¹ and **Y. Zhang²**, (1)Department of Computer Science & Engineering, University of Minnesota, Minneapolis, MN, (2)Department of Speech-Language-Hearing Sciences, University of Minnesota, Minneapolis, MN

Background: Electroencephalography (EEG) has become a dominant method for identifying neural markers associated with autism spectrum disorder (ASD). Researchers have applied various computational modeling and machine learning approaches to improve our understanding of ASD. Most of the machine learning studies focused on children's EEG data with adult EEG data being less frequently assessed.

Objectives: The primary objective of this study was to test and compare different machine learning models for classifying ASD based on adult EEG signals. We aimed to optimize our approach by utilizing various EEG features that may contribute to the development of assistive tools for diagnosis and monitoring intervention effects in clinical settings.

Methods: We used a publicly available dataset from University of Sheffield, which contains resting state EEG data from 28 individuals with ASD and 28 neurotypical controls (age range: 18-68). After preprocessing for artifact removal, we extracted features in the time-domain, frequency-domain, and entropy-based measures. We trained and evaluated several machine learning algorithms, including Support Vector Machines (SVM), Random Forests, and K-Nearest Neighbors (KNN), employing an ensemble approach for participant classification. Cross-validation techniques were applied to verify the robustness of the models.

Results: Despite the wide age range in the participants, our base models achieved promising classification accuracy with specific EEG features. Feature selection and ensemble methods further improved model performance with an impressive accuracy of 98.85%, suggesting that certain EEG biomarkers could serve as reliable indicators for ASD classification. We further tested the models' resilience by introducing artificial noise to the data, which did not significantly affect accuracy, demonstrating their robustness against new and noisy inputs.

Conclusions: Our findings showcase the potential of data-driven computational modelling of ASD. Future research will focus on refining classification models by considering age-related differences and validating them with larger datasets to enhance generalizability.

402.156 Lactate and the Locus Coeruleus in Autism: Insights from Magnetic Resonance Spectroscopy and Pupillometry

B. Keehn¹, A. Edmondson², Y. Kim¹, R. McNally Keehn³ and U. Dydak⁴, (1)Speech, Language, and Hearing Sciences, Purdue University, West Lafayette, IN, (2)Radiology and Environmental and Public Health Sciences, Cincinnati Children's, Cincinnati, OH, (3)Pediatrics, Indiana University School of Medicine, Indianapolis, IN, (4)Health Sciences, Purdue University, West Lafayette, IN

Background: Lactate release by astrocytes fuels neuronal activity and functions as a signaling molecule critical for synaptic plasticity and memory. Prior research using magnetic resonance spectroscopy (MRS) has demonstrated that increased concentrations of cerebral lactate are present in autism. One driver of lactate production and mobilization from glucose and glycogen stores is norepinephrine (NE), which is released during firing of the locus coeruleus (LC). The LC-NE system, which also plays a critical role in arousal regulation and selective attention, has been shown to function differently in autistic individuals. Although prior research has shown elevated cortical lactate levels in autism, it remains unclear whether increased tonic LC-NE activity in autism contributes to these lactate differences.

Objectives: To examine cortical lactate levels in autistic and neurotypical children, and to determine whether persistently elevated LC-NE activity in autism, as indexed by resting pupil diameter, is associated with group differences in cortical lactate levels.

Methods: Participants included 20 autistic children and 20 age-, sex-, and nonverbal-IQ matched neurotypical (NT) children. 1H-MR spectroscopy data were obtained on a 3T Siemens Prisma MR Scanner using semi-LASER localization (TE = 35 ms, TR = 2000 ms, Averages = 64, Acquisition Time = 2:28) to measure lactate in the visual cortex (VIS; 30mm x 30mm x 20mm), temporal-parietal junction (TPJ; 30mm x 30mm x 20mm), and frontal eye fields (FEF; 30mm x 30mm x 20mm). Spectra were quantified using LCModel. Pupil diameter was monitored using an EyeLink 1000 Plus remote eye-tracking system. Children completed a baseline eye-tracking task to measure resting pupil diameter, which has been shown to indirectly index tonic LC-NE activity.

Results: For lactate measures, autistic children did not differ from NT children for FEF (autism=0.31 [0.07]; NT=0.28 [0.04]; $p=0.13$) or TPJ (autism=0.26 [0.06]; NT=0.24 [0.05]; $p=0.32$) lactate levels; however, autistic children did evidence significantly increased lactate levels in VIS (autism=0.35 [0.07]; NT=0.29 [0.06]; $p=0.004$) and average lactate levels across all three VOI (autism=0.31 [0.05]; NT=0.27 [0.03]; $p=0.003$). For the baseline eye-tracking paradigm, autistic children showed significantly increased pupil diameter compared to their NT peers (autism=4.24 [0.63]; NT=3.62 [0.55]; $p=0.002$). For both groups combined, the relationship between resting pupil diameter (i.e., tonic LC-NE activation) and average cortical lactate levels was significant ($r = 0.58, p < 0.0001$). This association was present in the autism group ($r = 0.55, p = 0.01$), but not the NT group ($r = 0.35, p = 0.13$).

Conclusions: Consistent with prior reports, our results show that autistic children exhibit both greater levels of cortical lactate and elevated tonic activation of the LC-NE system. Rather than arising due to metabolic dysfunction, our findings suggest that greater concentrations of cerebral lactate may be the consequence of persistently heightened LC-NE activity in autism. These findings provide further support for autistic differences in LC-NE activation and their association with cerebral lactate levels. Given the important role of lactate as a neuronal energy source and signaling molecule, future research should explore the neurofunctional and behavioral consequences of increased cerebral lactate in autism.

402.157 Evidence Towards a Sensorimotor Basis for Facial Expression Differences in Autism

K. S. Bress¹, J. Quinde Zlibut², C. A. Convery³, B. G. Travers⁴ and C. J. Cascio⁵, (1)Vanderbilt University School of Medicine, Nashville, TN, (2)Vanderbilt University, Nashville, TN, (3)Department of Psychiatry and Behavioral Science, VUMC, Nashville, TN, (4)The University of Wisconsin-Madison, Madison, WI, (5)Department of Psychiatry and Behavioral Science, Vanderbilt University Medical Center, Nashville, TN

Background: Nonverbal social communication depends on both spontaneous facial expressions which accurately represent one's internal sensations and emotions, and voluntary control of these expressions to adapt to social circumstances. Differences in facial expressivity are commonly observed in autism, even when the self-reported emotion is similar to non-autistic peers. Given that sensorimotor differences are common in autism, and that facial expression is a complex motor behavior, it is possible that facial expression differences in autism have a sensorimotor basis. Understanding this putative low-level source of altered facial expressivity would both inform evidence-based social skills interventions and address stigma based on non-autistic assumptions about autistic facial expressions.

Objectives: The goal of this study was to interrogate a sensorimotor basis for facial expressivity differences in autism by assessing group differences in functional connectivity among the somatotopic face areas of the primary sensory and motor cortices.

Methods: We performed a seed-based connectivity analysis on resting state functional magnetic resonance images from n=59 autistic (AUT, mean age=16.89, 28% female) and n=71 non-autistic (NA, mean age = 18.69, 25% female) individuals to interrogate pairwise connectivity between the upper and lower somatotopic face areas of the primary sensory (S1) and primary motor (M1) cortices. To test the hypothesis that somatotopic organization of functional connectivity across the facial sensory and motor cortices differs in autism compared to non-autistic peers, we fit a linear mixed effects model on the Fisher-transformed correlation (z-value) representing the correlation in BOLD signal for each ROI pair, including diagnostic group, ROI pair identity, diagnostic group * ROI pair identity, gender, and age as fixed effects. Individual subject identity was included as a random effect. We then replicated these analyses using data from n=106 non-autistic and n=106 autistic adults from the Autism Brain Imaging Data Exchange (ABIDE).

Results: In both the AUT and NA groups, we observed that: (1) The upper face areas of S1 have equivalent functional connectivity (FC) with the upper and lower face areas of M1, and (2) The lower face areas of S1 have greater FC with the lower face areas of M1, compared to the upper face areas of M1 (contrast estimate= 4.29, SE=0.39, t-ratio=10.86, p-value<2e-16). These findings were replicated in the ABIDE dataset (contrast estimate=4.29, SE=0.40, t-ratio=10.72 p-value<2e-16).

Conclusions: These data suggest that FC between the primary sensory and motor cortex is organized with somatotopic specificity for the lower face, but not for the upper face, and that this organization does not differ in autistic compared to non-autistic individuals. Somatotopic specificity in lower face S1-to-M1 FC may reflect the fine sensorimotor control required for complex lower face actions such as vocalization and mastication. A broad network of cortical and subcortical regions support the balance between spontaneous and voluntary facial expression control. Thus, the next steps for this work will involve mapping and comparing the structure of this broader network across autistic and non-autistic individuals. Future work should also consider how camouflaging impacts the balance between neural systems for voluntary versus involuntary facial expression.

402.158 Evoked and Induced Gamma Power in VEPs from Children with ASD-Related Synaptopathies

TX Health Sci Cntr-Houston, Houston, TX, (19)Psychiatry, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (20)Department of Psychiatry, Rush University Medical Center, Chicago, IL, (21)Office of the Clinical Director, National Institutes of Health - National Institute of Mental Health, Bethesda, MD, (22)Boston Children's Hospital / Harvard Medical School, Boston, MA, (23)Neurology, Boston Children's Hospital / Harvard Medical School, Brookline, MA

Background: Autism Spectrum Disorder (ASD) can alter neural circuit dynamics at multiple levels, including "lower-level" processing of basic sensory stimuli and "higher-level" complex cognition. Prior literature associates disorders of mTOR, a neurologic signaling pathway, with increased likelihood of ASD diagnosis. Visually Evoked Potentials (VEP) on electroencephalography (EEG) can enhance understanding of the neural dynamics of mTOR and its relationship to cognitive processing may be valuable in identifying biomarkers for ASD. Within the VEP, comparisons between phase locked (evoked) gamma responses, which correspond to a stimulus-driven, lower-level neural reaction, and non-phase locked (induced) gamma responses, which represent nuanced, higher-level processing, illustrate these differences. Although previous research suggests children with ASD have significant differences in evoked and induced VEP gamma responses compared to their TD counterparts, this has not been previously studied among populations with mTOR pathway disorders. By focusing on neurogenetic disorders of the mTOR pathway, this project aims to identify additional biologically-based insights into the neural dynamics influencing ASD.

Objectives: We compared both evoked and induced VEP gamma responses (30-59Hz) between children with Phelan-McDermid Syndrome (PMS), PTEN Hamartoma Tumor Syndrome (PHTS), and Tuberous Sclerosis Complex (TSC), and age-matched TD peers.

Methods: We collected VEP EEG data from children (2-11 years) with PMS (n=31), PHTS (n=14), and TSC (n=21), and a TD group (n=28) as part of a multisite study. Data were preprocessed using the Batch EEG Automated Processing Platform (BEAPP) and Harvard Automated Preprocessing Pipeline (HAPPE). Evoked and induced gamma power were calculated using a wavelet-based time-frequency analysis methodology from established literature (Figure 1). The time-frequency decomposition was taken from each trial in the 50-100ms time window, then averaged to calculate total power. Induced power was calculated by subtracting the event related potential (ERP) from each trial, followed by performing time-frequency decomposition across trials; evoked power was computed by subtracting the induced power from the total power. Kruskal-Wallis tests with a post-hoc Dunn's test were applied to average evoked and induced gamma power between 50ms to 100ms to compare groups.

Results: There is a significant difference in evoked gamma power between groups, $X^2(3, N=94)=10.17, p=.017$. Dunn's post hoc test indicates those group differences were driven by the PMS cohort, such that children with PMS show significantly less evoked gamma power compared to TD (adj $p=.009$) (Figure 2). TSC and PHTS evoked responses were not significantly different from TD. There were no significant group differences in induced gamma power.

Conclusions: Reduced evoked gamma power in the PMS cohort is consistent with previous findings in children with ASD. These results suggest there are differences in the initial circuit processing of children with PMS, which may impact sensory processing. Future directions for this work include investigating whether reduced evoked power correlates with clinical phenotypes of ASD and PMS. Our work highlights the potential to connect deviant mTOR pathway activity and abnormal cognitive processing that may both converge across and distinguish neurodevelopmental disorders, including autism.

402.159 Examining Associations between Neural Sensitivity to Social Feedback and Loneliness in Autistic and Non-Autistic Adolescents

V. Alleluia Shenge¹, H. Xie², H. Popal¹, J. Merchant¹, P. Munshell¹, H. A. Yarger¹ and E. Redcay¹, (1)Department of Psychology, University of Maryland, College Park, MD, (2)Children's National Hospital, Washington, DC, (3)University of Maryland, College Park, MD

Background: Loneliness increases during adolescence and is higher in individuals on the autism spectrum, which can result in multiple negative psychological such as depression and self-harm. Thus, there is crucial to understand factors that contribute to the development of loneliness among autistic and nonautistic youth. Theoretical models of loneliness based on research with nonautistic adults have identified factors that create and sustain loneliness and suggested social stimuli are perceived as more threatening and less rewarding by lonely individuals affecting brain regions encoding reward, social salience, and social cognition.

Objectives: To examine the relation between neural sensitivity to social feedback and loneliness and whether this relationship is different between autistic and non-autistic adolescents.

Methods: Our sample included 94 youth (ages 11-14, 22 autistic (AUT), 72 non-autistic (non-AUT), 37 female, 54 female, 3 gender fluid/other). Participants completed an fMRI task where they received feedback about how similar their likes and dislikes were to that of two other peers (or a computer for a nonsocial control). The positive social feedback (thumbs up) occurred when participant and peer agree, and negative social feedback (thumbs down) was given when they disagree. A nonsocial control included positive and negative nonsocial feedback. Loneliness was assessed using an adapted version of the Loneliness Rating Scale. Contrasts of interest were positive social feedback (peer positive vs computer positive) and negative social feedback (peer negative vs computer negative). Analyses focused on a-priori defined ROIs encompassing regions associated with social cognition, reward and salience. Regressions examined the effect of neural sensitivity to feedback, group, and their interaction on loneliness while controlling for age and sex for positive and negative social feedback separately.

Results: For both positive and negative social feedback models, group was a significant predictor of loneliness with AUT showing higher rates of loneliness than non-AUT (neg: $b = -13.37, t(80) = -5.12, p < 0.001$; pos: $b = -13.64, t(80) = -3.91, p < 0.001$). Neural sensitivity to negative social feedback was also positively associated with loneliness scores ($b = 80.67, t(80) = 2.09, p = 0.04$). Importantly, the interaction between neural sensitivity and group was significant for negative feedback ($b = -93.83, t(80) = -2.26, p = 0.026$). In both models this interaction was due to a strong positive relation between neural sensitivity to social feedback and loneliness in the AUT group but not in the non-AUT group.

Conclusions: Our results highlight higher rates of loneliness among autistic youth. Further, they show that adolescents who are more sensitive to social feedback, either positive or negative, have higher rates of loneliness. This relation was strongest for the autistic group and for negative feedback. AUT youth may be at greater risk of social rejection and bullying and those who are most sensitive to peer feedback may be most affected. These findings counter hypotheses of reduced reward sensitivity in autism by highlighting that autistic individuals display typical levels of neural sensitivity to social feedback and this sensitivity may be a risk factor in the development of loneliness.

402.160 Examining Emotion Dysregulation Profiles in Relation to Reward Positivity and Feedback-Related Negativity in Autistic and Non-Autistic Youth.

N. Cifuentes¹, H. Garcia¹, R. Ahmad¹, A. C. Castillo¹, R. G. McDonald² and E. Kang², (1)Montclair State University, Montclair, NJ, (2)Department of Psychology, Montclair State University, Montclair, NJ

Background: Emotion dysregulation (ED) refers to difficulty controlling or modulating emotions, internally and externally, which may lead to difficulties in many areas of functioning (Gross, 2008; Conner et al., 2020). ED has been proposed as a transdiagnostic mechanism that may contribute to the co-occurrence among autism and other psychiatric disorders (White et al., 2014). Electrophysiological indices of ED may be valuable in understanding ED development and associated challenges. Irritability, thought to precede ED, has been linked to neural correlates like feedback-related negativity (FRN) and reward positivity (RewP; Malhi et al., 2017; Deveney, 2019). FRN and RewP have also been associated with negative affect and difficulties improving mood (Gehring & Willoughby, 2002; Gill et al., 2024), and hence may be associated with higher rates of ED. However, there is limited research on these neural mechanisms and their relation to ED in autistic youth.

Objectives: The current study seeks to clarify the relationship of FRN or RewP with ED dysphoria (e.g., negative affect) and reactivity (e.g., externalized outbursts), and how these relationships differ across autistic and non-autistic youth.

Methods: Fifty-seven youth (39 autistic; $M_{age}=10.38$, $SD_{age}=2.99$; 50.9% male; 57.9% White, 14.1% Asian/South Asian/MENA, 7% Black, 14% Multiracial) from Northeastern US participated in this study. Parents completed a measure of ED dysphoria (EDD) and reactivity (EDR; Emotion Dysregulation Inventory; Mazefsky et al., 2018). An electroencephalogram (EEG) was recorded while youth completed a computer task of a developmentally-appropriate adaptation of the Wisconsin Card Sorting Task, where children were instructed to match the stimulus to an unannounced, changing rule (Kessel, 2019). Youth were given either positive or negative feedback based on their adherence to the rule. RewP was measured between 250 and 300 ms, while FRN was measured between 200 and 300 ms following negative feedback that might elicit an emotional response.

Results: Bivariate correlations indicated more negative FRN amplitudes related to greater EDR ($r=-.389$, $p<.01$) and greater EDD ($r=-.303$, $p<.05$) in the full sample. No associations were found between RewP and ED. When examined separately by diagnostic group, no significant relationships were found across FRN, RewP, and ED in non-autistic children. Associations between FRN and EDR ($r=-.403$, $p<.05$) remained in the autistic sample only.

Conclusions: Our findings that larger (i.e., more negative) FRN amplitudes may relate to greater ED, but not RewP, suggest that youth with more ED may have an increased response to negative feedback, and this relationship may be particularly more relevant for autistic children who are more emotionally reactive. It is possible that children with ED profiles who are exposed to repeated criticism may experience more emotional sensitivity, and thus more dysregulation (Wall et al., 2018). These findings could offer a window into the neural mechanisms of ED, and how learned behaviors from the environment may relate to brain functionality. Future research should further explore neurophysiological mechanisms of ED, especially in the context of autistic youth, which will allow for a more comprehensive understanding of ED presentation and better tailored treatment options.

402.161 Examining the Effects of Temperament on Neuroimaging Scan “Success” in Children with Autism

K. Eggen¹, **M. Kim²**, **K. Mol³**, **M. McNamee⁴**, **M. DiPiero⁵**, **L. Bloy⁶**, **Y. Chen⁶**, **J. C. Edgar⁶**, **T. Roberts⁶** and **E. S. Kushner⁷**, (1)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (2)Lurie Family Foundations MEG Imaging Center, Department of Radiology, The Children's Hospital of Philadelphia, Philadelphia, PA, (3)Northeastern University, Boston, MA, (4)Texas A&M, College Station, TX, (5)University of North Carolina, Chapel Hill, NC, (6)Lurie Family Foundations MEG Imaging Center, Department of Radiology, Children's Hospital of Philadelphia, Philadelphia, PA, (7)Departments of Radiology and Psychiatry, The Children's Hospital of Philadelphia, Philadelphia, PA

Background: Clinical and behavioral protocols to enable brain imaging with children with autism and intellectual disability or higher support needs (Gabrielsen et al., 2018; Nordahl et al., 2016; Kushner et al., 2019) have expanded inclusion in neuroimaging research. Identification of characteristics associated with scan completion and collection of evaluable data will support the tailoring of support protocols to maximize scan success and the child and family experience. Previous literature suggests that temperament can be associated with success of other medical procedures, such as dental exams and sedation success for MRI/CT (e.g., Voepel-Lewis et al., 2001; Radis et al., 1994).

Objectives: To consider temperament as a child trait that will help optimize protocols and predict likelihood of scan success.

Methods: Participants included 43 children with a diagnosis of autism across two cohorts: 13 children ages 2-5 years (mean =3.9 years, $SD=0.8$; mean nonverbal IQ (NVIQ)=68.7, $SD=19.4$; 9M:4F) and 30 children ages 8-12 years (mean age=9.9 years, $SD=1.3$; mean NVIQ=54.3, $SD=16.1$; 25M:5F). Parents completed the Carey Temperament Scales (Carey & McDevitt, 1995) to report their child's behavioral style across nine categories of temperament. Questionnaire version was chosen based on nonverbal mental age, with 38 parents completing the Behavioral Style Questionnaire (3-7yrs) and 5 parents completing the Toddler Temperament Scale (1-35mos). Scan “success” was operationalized as acquiring magnetoencephalography (MEG) data (i.e., MEG machine turned on, paradigm administered) across tasks obtained using a 275-channel CTF MEG system. Dependent variables were Carey temperament z-scores across nine scales (activity level, adaptability, approach to novelty, distractibility, emotional intensity, persistence, quality of mood, rhythmicity, sensory sensitivity) and an overall manageability rating. Binary logistic regression was used to examine temperament factors associated with MEG data acquisition status.

Results: Across both cohorts, 28 (65%) children had acquired MEG data (86% in the preschool cohort and 76% in school-age cohort). There were no differences in age, $F(1,41)=0.85$, $p=0.36$, or nonverbal IQ, $F(1,41)=2.93$, $p=0.09$ for acquired status, therefore age and nonverbal IQ were removed from the regression model. Collinearity was identified between age and two of the temperament scales (emotional intensity, $r=-0.37$, $p=0.014$; distractibility, $r=-0.35$, $p=0.021$), so those scales were also excluded from the model; no collinearity was identified between nonverbal IQ and the temperament scales. Logistic regression revealed that children rated by parents as more difficult to manage (overall manageability scale) were significantly less likely to have acquired MEG data, with a COR of 2.28 (95% CI, 1.06-4.90, $p=0.03$). There was also a trend toward children with a higher ability to continue an activity in the face of distractions (persistence scale) being more likely to have acquired MEG data, with a COR of 0.38 (95% CI, 0.13-1.1, $p=0.07$).

Conclusions: Broad temperament ratings of manageability and persistence with tasks in the face of obstacles or distractions may be associated with neuroimaging scan completion. If predictive of scan outcome, there is particularly high utility in brief screening questions for manageability that can guide support protocol development for brain imaging visits.

402.162 Examining the Social Visual Pathway in Children with Autism Spectrum Disorder

C. Li¹, **H. Park¹**, **J. Awasthi¹**, **M. J. Rolison²**, **M. Li³**, **D. Scheinost⁴**, **K. Chawarska²** and **M. Hampson⁵**, (1)Yale University, New Haven, CT, (2)Child Study Center, Yale University School of Medicine, New Haven, CT, (3)Bentley University, Waltham, MA, (4)Radiology & Biomedical Imaging, Yale University School of Medicine, New Haven, CT, (5)Yale School of Medicine, Yale University, New Haven, CT

Background: The social visual pathway, including the visual motion area (MT/V5) and the posterior to anterior portions of the superior temporal sulcus (STS), specializes in processing dynamic social information (Pitcher & Ungerleider, 2021, *Trends Cogn Sci*). While aberrant STS function is well-documented in autism spectrum disorder (ASD, autism), connectivity specifically along the social visual pathway in ASD has not been explored.

Objectives: This study aimed to investigate resting-state functional connectivity within the social visual pathway in children with autism compared to typically developing (TD) children, and to explore associations between connectivity strength and clinical measures of autistic symptoms. We hypothesized that children with autism would have decreased connectivity within the social visual pathway and that the strength of the connectivity between the nodes would be associated with the severity of social but not restricted and repetitive behaviors symptoms of autism.

Methods: Resting-state fMRI data from 281 children with autism and 428 TD children (aged 6-14 years) were obtained from the Autism Brain Imaging Data Exchange (ABIDE) repository. Functional connectivity between regions along the social visual pathway (MT/V5, posterior STS, middle STS, and anterior STS - see Figure 1 for a schematic representation of these regions of interest) was examined using partial correlation models, controlling for age, data collection site, sex, IQ, and head motion. Associations between functional connectivity strength and symptom severity measured by the Autism Diagnostic Observation Schedule (ADOS) and the Social Responsiveness Scale (SRS) were analyzed using generalized linear models.

Results: Children with autism showed significantly lower connectivity between the right posterior STS (rpSTS) and right middle STS (rmSTS) compared to TD children ($p = .006$, Bonferroni-corrected threshold $p < .008$). No significant group differences were found for other connections within the social visual pathway before or after correction for multiple comparisons. Reduced rpSTS-rmSTS connectivity was significantly associated with higher social symptoms as measured by ADOS Social Affect raw scores in children with autism ($p = .044$) and SRS Social Communication Index raw scores across both children with autism and TD children ($p = .006$). No significant associations were found with ADOS Restricted and Repetitive Behavior raw scores or SRS Restricted and Repetitive Behavior Index raw scores.

Conclusions: These findings demonstrate that connectivity within the right-lateralized social visual pathway is disrupted in school-aged children with autism, specifically between the posterior and middle STS. This disruption is associated with social impairment severity but not with restricted and repetitive behaviors, suggesting its specific role in the social deficits observed in ASD.

402.163 Exploring the Biological Mechanisms Underlying Co-Occurance of Autism and Epilepsy

W. Gaetz¹, C. Birnbaum², L. Blaskey³, M. Kim⁴, E. S. Kuschner⁵, V. Kaufman⁶, L. Bloy³, M. Saleh⁷, E. Marsh¹ and T. Roberts³, (1)Children's Hospital of Philadelphia, Philadelphia, PA, (2)Radiology, Children's Hospital of Philadelphia, Philadelphia, PA, (3)Lurie Family Foundations MEG Imaging Center, Department of Radiology, Children's Hospital of Philadelphia, Philadelphia, PA, (4)Lurie Family Foundations MEG Imaging Center, Department of Radiology, The Children's Hospital of Philadelphia, Philadelphia, PA, (5)Departments of Radiology and Psychiatry, The Children's Hospital of Philadelphia, Philadelphia, PA, (6)The Children's Hospital of Philadelphia, Bala Cynwyd, PA, (7)Neurology, The Children's Hospital of Philadelphia, Bala Cynwyd, PA

Background:

Epilepsy and autism spectrum disorder (ASD) are clinically distinct disorders but have significant overlap. Comorbid epilepsy and ASD are predictive of more severe outcomes, hence, there may be a shared neurophysiological mechanism underlying these two conditions. Better definition of the mechanistic similarities between autism and epilepsy will expand our understanding of this comorbidity and may open new pathways for targeted therapies.

Objectives:

Male participants ages 8-17 years old both with and without ASD (and no history of clinical epilepsy) were recruited (21 TD; 20 ASD-) and underwent psychological evaluation followed by the collection of magnetoencephalographic (MEG) data during resting-state, somatosensory and motor task conditions, followed by a brain magnetic resonance imaging (MRI) scan including magnetic resonance spectroscopy (MRS).

Methods:

Dependent variables determined from MRS included gamma-aminobutyric acid (GABA) concentrations assessed from MEGAPRESS applied to voxels placed at regions of interest (left and right sensorimotor hand motor areas). We predicted that children with ASD would show reduced in vivo (MRS) GABA levels and be directly associated with atypical epileptiform activity in children with ASD.

Results:

Consistent with previously published findings, the current study showed that MRS GABA levels are significantly lower in children with ASD, compared to controls (TD: $5.64E \pm 0.15$; ASD $5.16E \pm 0.16$; $p < 0.05$) in a linear mixed model (LMM) with Group and Hemisphere as fixed effects and Subject as a random effect.

MEG analysis using the SAMg2 "spike-detection" algorithm identified epileptiform activity in the resting MEG data from 11 of 20 participants with ASD (55%; 3 x higher than 4/21 TD with sharply contoured resting activity (18.75%; chi-squared $p < 0.05$). SAMg2 analysis of each 2-minute resting MEG data segment yields localized brain areas where "sharp" features can be identified in time (left virtual sensors) and space (brain color maps). Note that there are common "sensorimotor" brain areas active between the ASD- subjects where significant "spikiness" was observed.

ASD cases with epileptiform activity show reduced GABA levels vs. ASD cases without epileptiform activity 4.9 ± 0.2 vs. 5.9 ± 0.2 (LMM) with epileptiform activity present/absent as a fixed effect and subject as a random effect $p = 0.048$. A nonsignificant trend suggests that the presence of epileptiform activity, and low GABA levels, may be associated with elevated SRS scores, suggesting a clinically-relevant correlate.

Conclusions:

We replicated the demonstration that MRS measures of GABA levels from sensorimotor brain areas are reduced in ASD vs TD. Participants with ASD were significantly less likely to fall asleep during our 40-minute resting MEG recordings. Despite sleep differences, participants with ASD exhibited 3x the epileptiform activity than observed in TD (55% of ASD-). The observation of epileptiform activity was not straightforwardly associated significantly associated with any of the acquired clinical measures, and thus the consequence of this activity for the individual remains an open area for future research. ASD participants who showed epileptiform activity had significantly lower GABA levels than those who did not, hinting at a potential mechanism whereby relatively low GABA levels may result in hyperexcitable (i.e., epileptiform) signaling.

402.164 Feasibility of Measurements of Cerebral 3-[¹⁸F]Fluoro-5-(2-pyridinylethynyl)Benzonitrile Uptake and Fragile X Messenger Ribonucleoprotein and Neuropsychological Measurements in Men with Fragile X Syndrome

J. R. Brasic¹, A. Nandi², T. Sedlak³, K. Slifer⁴, E. Berry-Kravis⁵, D. F. Wong⁶ and D. B. Budimirovic⁷, (1)Department of Psychiatry, NYU Grossman School of Medicine, New York, NY, (2)The Russell H. Morgan Department of Radiology and Radiological Science, Johns Hopkins University School of Medicine, Baltimore, MD, (3)Psychiatry and Behavioral Sciences, Johns Hopkins University School of Medicine, Baltimore, MD, (4)Kennedy-Krieger Institute, Baltimore, MD, (5)Pediatrics, Neurological Sciences, & Biochemistry, Rush University Medical Center, Chicago, IL, (6)Washington University in Saint Louis, Saint Louis, MO, (7)Psychiatry, Kennedy Krieger Institute, Baltimore, MD

Background: Multiple lines of investigation provide evidence of glutamatergic dysfunction in people with fragile X syndrome (FXS). Although animal models of FXS demonstrated amelioration of behavioral symptoms after the administration of glutamatergic agents, multiple clinical trials of glutamatergic agents demonstrated no beneficial effects on humans with FXS. A comprehensive review of unsuccessful clinical trials of glutamatergic agents for humans with FXS identified the lack of a biomarker as a key component for successful clinical trials. A quantitative measurement of target engagement of the metabotropic glutamate receptor subtype 5 (mGluR₅) in the living human brain can be obtained by means of positron emission tomography (PET) after the intravenous (IV) bolus injection of 3-[¹⁸F]fluoro-5-(2-pyridinylethynyl)benzonitrile ([¹⁸F]FPEB). **Objectives:** We seek to determine the feasibility of comprehensive measurements of fragile X messenger ribonucleoprotein (FMRP), genetic tests for FXS, and neuropsychological tests [Stanford-Binet Intelligence Scales, 5th Edition (SB-5), Hopkins Verbal Learning Test-Revised (HVLRT), Vineland Adaptive Behavior Scales, 3rd Edition (Vineland-3), Autism Diagnostic Observation Schedule, 2nd Edition (ADOS-2), and the Intra-Extra Dimensional Set Shift (IED), a test of visual discrimination and attentional set formation maintenance, shifting, and flexibility of attention, and the One Touch Stockings of Cambridge (OTS), a test of executive function that assesses spatial planning and working memory subdomains, from the Cambridge Neuropsychological Test Automated Battery (CANTAB)], along with MRI and PET to measure mGluR₅ target engagement in men with FXS.

Methods: Two men with the full mutation of FXS (>200 CGG repeats) aged 19 to 41 (mean 27.6 ± 9.4) years underwent determination of FMRP, genetic testing for FXS, a neuropsychological battery, and mock scanner training before PET for 90 minutes after the IV bolus injection of V bolus injection of 178.9 ± 7.06 MBq [¹⁸F]FPEB with specific activity of 722.7 ± 114.8 MBq/millimole, and a mass of 0.055 ± 0.007 micrograms.

Results: The Image demonstrates transverse, sagittal, and coronal timages of [¹⁸F]FPEB in a 24-year-old man with FXS, a 27-year-old man with FXS, and a 27-year-old man with typical development (TD). Nondisplaceable binding potentials (BP_{ND}) with the multilinear reference tissue method with two parameters (MRTM2) in cortical regions [medial temporal (mTp) and posterior cingulate (pCg)] and subcortical regions [caudate nucleus (CN), putamen (Pu), and thalamus (Th)] were markedly lower than those in age- and sex-matched participants with typical development. Neuropsychological scores confirm deficits in spatial planning, working memory, rule acquisition and reversal, and socialization, as well as intellectual disability and autism spectrum disorder.

Conclusions: A comprehensive assessment of men with FXS including genetic and FMRP measurements, MRI and PET scans, and a thorough neuropsychological battery is feasible when performed by investigators who are experienced in assessing adults with neurodevelopmental disorders. The utilization of mock scanner training by behavioral psychologists is a crucial step to train participants to be able to complete MRI and PET scans. The proposed protocol will provide investigators the crucial information (mGluR₅ target engagement and measurements of FRMP, genetic tests for FXS, and crucial neuropsychological variables) for optimal clinical trials of glutamatergic agents for people with FXS and related conditions.

**402.165** Functional Connectivity and Sensory Processing in Autism: A Systematic Review of Neural Correlates and Behavioral Relationships

G. Feisel¹, R. Sahu¹, K. Garibian¹, T. Chakraborty¹, C. DeLong¹, A. Watson-Grace¹ and **J. E. Crasta²**, (1)The Ohio State University, Columbus, OH, (2)Physical Medicine and Rehabilitation, The Ohio State University, Baltimore, MD

Background: Advances in neuroimaging have facilitated a deeper understanding of the neural mechanisms underlying sensory processing differences in individuals on the autism spectrum. Sensory processing differences are a common feature of autism and can significantly impact daily functioning and quality of life. There is a need to synthesize findings related to brain regions and networks involved in the brain-behavior relationships of sensory processing differences.

Objectives: This systematic review aims to synthesize current research on the relationship between functional connectivity and behavioral measures of sensory processing in individuals on the autism spectrum. The review seeks to identify common neural networks and brain regions associated with sensory processing and examine the strength and consistency of the correlations reported across studies.

Methods: The review was conducted in accordance with the Preferred Reporting Items for Systematic Reviews (PRISMA) guidelines.

Comprehensive searches were performed across six databases: PubMed, PsychINFO, Embase, CINAHL, Scopus, and Web of Science. Articles were imported into Covidence for screening. Two independent reviewers screened titles, abstracts, and full texts using the following inclusion criteria: (1) peer-reviewed journal articles published in English, (2) participants diagnosed with autism, (3) use of functional connectivity measures, including functional MRI (fMRI), functional near-infrared spectroscopy (fNIRS), diffusion tensor imaging (DTI), and diffusion-weighted imaging (DWI), (4) use of standardized sensory processing measures, and (5) statistical correlation between functional connectivity outcomes and sensory processing measures.

Results: Out of 6,549 studies screened, 15 studies met the inclusion criteria. Most studies ($n=11$, 73%) used fMRI, with two utilizing DTI and one using proton spectroscopy. The majority of studies (80%) were conducted in the United States. Sample sizes ranged from 15 to 78 participants, with an average sample size of 35.86. Participants' ages ranged from 3.5 to 55 years, with 67% of studies focusing on children aged 7 to 18 years. Resting-state paradigms were employed in 73% of studies, while 20% used task-based paradigms. Sensory processing was most frequently assessed using the Sensory Profile (including the Adolescent/Adult Sensory Profile and Short Sensory Profile). All but one study reported significant correlations between functional connectivity and sensory processing measures. Brain regions and networks associated with sensory processing included the sensorimotor cortex ($n=4$), insular cortex ($n=5$), visual cortex ($n=3$), amygdala ($n=3$), thalamocortical connectivity ($n=3$), and occipital cortex ($n=2$). Networks implicated included the Default Mode Network ($n=2$) and the Salience Network ($n=3$). However, the strength and direction of correlations between these regions varied across all studies limiting the ability to draw cohesive conclusions, especially regarding specific and localized connectivity patterns.

Conclusions: Taken together, studies show that sensory processing behaviors in autism are associated with differences in functional connectivity patterns. These findings also underscore the complexity of brain-behavior relationships in sensory processing among autistic individuals. However, inconsistencies in connectivity patterns highlight the need for further research to refine our understanding of these relationships. Future studies would benefit from increased sample sizes and open data sharing to facilitate meta-analyses and promote a more cohesive understanding of the neural underpinnings of sensory processing differences in autism.

402.166 Functional Connectivity between Regions Implicated By Acquired Prosopagnosia Predict Emotional Face Processing Ability in Autism

G. N. Miller¹, C. Steeby¹ and A. L. Cohen², (1)Boston Children's Hospital, Brookline, MA, (2)Neurology, Boston Children Hospital, Boston, MA

Background: Difficulty with social communication and joint attention are hallmark features of autism and may be linked to atypical processing of facial information. Neuroimaging studies have identified numerous brain regions that demonstrate group-level differences in autistic participants during face processing tasks; however, it remains unclear if these observations are causal or compensatory. Previous work from our lab has used lesion network mapping (LNM) to identify a brain network causally associated with face recognition deficits in patients with acquired prosopagnosia (i.e., face blindness after stroke). While there is increasing evidence that consistent brain regions are involved in generating similar symptoms across clinical populations, the generalization of these findings to developmental disorders remains an empiric question.

Objectives: Here, we determine whether the brain network implicated by acquired prosopagnosia is associated with variation in face processing abilities in adolescents with and without autism.

Methods: We collected fMRI and behavioral data (including the Reading the Mind in the Eyes test (RMIE)) from 45 adolescent participants, 21 with a diagnosis of autism spectrum disorder. Using resting-state data and RMIE scores, we localized a cohort-specific right fusiform face area (rFFA), as well as frontal regions of interest (ROIs) that were also implicated by our LNM of prosopagnosia. For each participant, we then calculated the functional connectivity/temporal correlation between the rFFA with each of the frontal ROIs. Using multivariate linear regression, we assessed whether these ROI-ROI correlations were predictive of face processing ability, controlling for autism diagnosis, ADHD diagnosis, sex, full-scale IQ (FSIQ), and age.

Results: Participants with autism performed significantly worse on the RMIE ($t(43)=-3.778$, $p\text{-value}<0.0005$). The cohort-specific rFFA was localized to MNI coordinates 30, -64, -14; this ROI was significantly functionally connected to two frontal ROIs: the Anterior Cingulate Cortex (ACC:-4,30,43) and left Middle Frontal Gyrus (MFG:-25,16,54). The total regression model was significant ($F(7,37)=7.9$, $p<0.001$) and explained approximately 52.3% of the variance in RMIE score. In this model, rFFA-ACC functional connectivity was a significant predictor of RMIE score ($b=-13.04$, $t(37)=-2.5$, $p=0.017$), as were age ($b=0.17$, $t(37)=4.7$, $p<0.001$) and FSIQ ($b=0.11$, $t(37)=2.47$, $p=0.010$). Interestingly, while the interaction between rFFA-ACC connectivity and diagnostic group membership was not statistically significant ($p=0.733$), separate analyses for each group revealed that rFFA-ACC correlation ($p=0.034$) and age ($p=0.001$) were significant predictors of RMIE score for the autism group, but not in the non-autism group.

Conclusions: Lesion network mapping of acquired prosopagnosia suggested the importance of connectivity between the rFFA and multiple regions of the frontoparietal control network. In the current study, we identified that differences in rFFA-ACC functional connectivity predict differences in face processing ability independent of age and IQ. Of note, these differences appeared to be potentially stronger or even unique to the group of participants with autism.

402.167 Hyperconnectivity between Thalamic Subregions and Functional Brain Networks in Autistic Adults

J. T. Luna¹, J. Y. Peters², A. Van De Water² and D. Kliemann¹, (1)The University of Iowa, Iowa City, IA, (2)The University Of Iowa, Iowa City, IA

Background: Autism Spectrum Disorder (ASD) has been associated with atypical brain connectivity (Geschwind & Levitt, 2007). The thalamus is a crucial hub integrating information across multiple functional brain networks (Hwang et al., 2017) and may contribute to atypical brain connectivity in autism. Previous work mostly focused on connectivity between the whole thalamus or functionally defined thalamic subregions with broad cortical regions. Prior results suggest atypical sensory information filtering and somatosensory-motor integration. It is unclear how specific thalamic nuclei may contribute to atypical connectivity profiles.

Objectives: The main goal was to characterize the functional role of anatomical thalamic subregions within large-scale brain network organization in autism. To increase spatial specificity, we subdivided the thalamus into seven individual and five grouped nuclei to investigate differences in volumes and functional connectivity to seven cortical brain networks. We hypothesized reduced thalamic volumes, and atypical functional connectivity (particularly to sensory and somatosensory-motor networks) in autistic compared to neurotypical adults.

Methods: We used magnetic resonance imaging (MRI) to measure brain structure and functional connectivity (FC, timeseries correlation of resting-state functional MRI) in adult autistic ($n = 32$, female = 11) and neurotypical comparison participants ($n = 47$, females = 30). Since the total sample differed in age, sex, intellectual functioning, and head motion, we conducted matched sample analyses (volume: $n = 69$, 30 ASD; FC: $n = 52$, 27 ASD). We subdivided the thalamus into 13 subregions per hemisphere (anteroventral (AV), laterodorsal (LD), ventral anterior (VA), lateral posterior (LP), ventral lateral (VL), ventral lateral posterior (VLp), ventral posterior (VP), centromedian and intralaminar (CeM), medial, pulvinar, midline, lateral geniculate (LGN), medial geniculate (MGN)) using a probabilistic atlas in native space (Iglesias et al., 2018). Functional data was preprocessed and denoised following previously outlined procedures (Kliemann et al. 2024). We assessed FC between thalamic subregions and seven functional networks (Yeo et al., 2011) averaged across hemispheres. Main effects and interactions were assessed with repeated measures analyses of variances, while interactions with the factor group were further explored with Bayesian analyses to estimate evidence for the null and alternative hypotheses.

Results: Structural analyses (corrected for intracranial volume) suggested similar subregion volumes across groups ($F(1) = 0.014$, $p = 0.9$). Functional analyses (corrected for head motion) showed overall increased FC in the autistic group ($F(1) = 6.891$, $p = 0.012$), as well as an interaction between nuclei, network, and group ($F(72) = 1.623$, $p = 7.7e-4$). Post-hoc analyses suggested strongest evidence for group differences in visual (AV, LGN, Midline, VL, VLp, Pulvinar), somatosensory-motor (midline, VA, VL, VLp), dorsal-attention (LGN, midline, VLp) and default mode (AV, Pulvinar) networks.

Conclusions: Thalamic subregion volume did not differ significantly between groups, while thalamo-cortical connectivity was generally increased in the autistic group with idiosyncratic effects across subregions and networks. Our preliminary results suggest that atypical functional connectivity of thalamic subregions may contribute to large-scale brain network organization in autistic adults. Future work should characterize heterogeneity (within and across individuals, and samples) as well as brain-behavior relationships of thalamo-cortical connectivity.

402.168 Identifying Differences in Resting State Brain Network Activity between Children Diagnosed with Autism Versus ADHD Using Deep Domain Generalization

W. E. Carson¹, S. Major², H. Akkineni³, H. Fung³, E. Peters⁴, K. L. Carpenter⁴, G. Dawson⁶ and D. Carlson⁷, (1)Department of Biomedical Engineering, Duke University, Durham, NC, (2)Psychiatry and Behavioral Sciences, Duke Center for Autism and Brain Development, Durham, NC, (3)Duke University, Durham, NC, (4)Department of Psychiatry and Behavioral Sciences, Duke Center for Autism and Brain Development, Durham, NC, (5)Department of Psychiatry and Behavioral Sciences, Duke University Medical Center, Durham, NC, (6)Department of Psychiatry and Behavioral Sciences, Duke University, Durham, NC, (7)Department of Civil and Environmental Engineering, Duke University, Durham, NC

Background: Researchers aim to identify features of brain activity associated with neurodevelopmental conditions to better understand their etiology and biological bases. Issues that preclude the identification of generalizable associations include highly correlated features and high-dimensional feature spaces. Factor models provide a natural way to parse high-dimensional, correlated feature spaces by learning compressed representations with respect to orthogonal groupings of features (i.e., factors). A common approach is to first apply a dimensionality reduction technique that decomposes data into a compressed representation and then regress on the reduced space. However, such approaches may fail to generalize if a large portion of feature variance is related to individual-specific variation, rather than variance related to group differences. Recent machine learning approaches (e.g., domain generalization) attempt to provide a solution wherein representations invariant to variance specific to individuals (i.e., “domains”) are learned.

Objectives: Autism and attention-deficit hyperactivity disorder (ADHD) are neurodevelopmental conditions that often co-occur. Understanding the neural basis of the overlaps and distinctions between these two conditions could help lead to improved therapies and outcomes. Our objective was to identify factors of neural features that differentiate between brain activity of children diagnosed with autism versus children diagnosed with ADHD using a domain generalization approach.

Methods: Resting state (RS) electroencephalography (EEG) was recorded from 93 children (75 male, 18 female) ages 3-8 years old, 46 of whom were diagnosed with autism and 47 of whom were diagnosed with ADHD. EEG was preprocessed via an automated, multi-step process and partitioned into 1-second-long windows. Power spectral density and cross-power spectral density features were generated for each window for frequencies 1-55 Hz. We employed a factor model parameterized by neural networks to separately model both shared group variance and variance specific to individuals. Our model decomposed features into a lower-dimensional, domain-invariant representation. Subsequently, a logistic regression classifier was trained using the lower-dimensional “scores” as input to predict diagnosis. This process was evaluated via a group 5-fold cross-validation scheme. Classifier accuracy was quantified using area under the receiving operator characteristic (AUROC) curve. This process was repeated using principal component analysis (PCA) for the factor model to provide a benchmark. We qualitatively evaluated the learned representations by visualizing factors weighted by the learned logistic regression coefficients.

Results: Diagnostic prediction using scores produced by our domain-invariant factor model resulted in an AUROC of 0.64 ± 0.05 . Prediction using scores produced by PCA produced an AUROC of 0.61 ± 0.04 . Visualization of the learned representations (Figure 1) revealed that children diagnosed with ADHD exhibited greater global theta (5-7 Hz), alpha (8-10 Hz), and beta1 (11-20 Hz) activity. Children diagnosed with autism exhibited more prominent frontal beta2 (21-30 Hz) and gamma (> 30 Hz) activity as well as greater posterior delta (1-4 Hz) activity.

Conclusions: Our approach improved downstream prediction of autism versus ADHD diagnoses, indicating that representations learned via our domain generalization approach were less correlated with individual-specific variance. These results demonstrate that domain generalization may provide a way for researchers to mitigate the effects of individual-specific variance in neural association studies.

402.169 Increased Medial Prefrontal Activation during Introspective Evaluation of Emotion in Autistic Adolescents

Y. Takarae¹, G. Lo², B. Heath², D. G. Amaral², C. W. Nordahl², S. Ghetti³, A. E. Guyer³ and M. Solomon², (1)Department of Psychiatry and Behavioral Sciences, UC Davis, Sacramento, CA, (2)Department of Psychiatry and Behavioral Sciences, UC Davis MIND Institute, Sacramento, CA, (3)Psychology, University of California, Davis, Davis, CA

Background: Adolescence is marked by significant neuroplasticity involving gray and white matter pruning that refines connectivity among widely distributed brain systems. These changes support more complex social and adaptive behaviors. This substantial growth in adolescence, however, may also produce imbalances between neural systems due to their potentially different growth trajectories. In particular, imbalances between the subcortical reward/affect system and the prefrontal cortical system are considered to predispose adolescents to increased emotional reactivity, sensitivity to peer influence/criticism, and negative affect, which are linked to affective mental health problems, including depression. Given past evidence of atypical prefrontal development in autism, it is possible that such imbalances are more pronounced in autistic adolescents predisposing them to greater risk of affective problems.

Objectives: Evaluate severity of affective problems and brain activity during a well-validated paradigm for affective processing, Sadness Introspection Paradigm (SIP), in autistic and non-autistic adolescents.

Methods: Participants were 15-18 year old autistic and non-autistic adolescents. The severity of affective problems was assessed using the Emotion Dysregulation Inventory (EDI). T1 and echo planar images (EPI) during the SIP were acquired. The SIP was implemented as a mixed design with two conditions involving evaluation of either affective (sadness) or physical (nose length) features of face stimuli. The stimulus pictures included male and female faces with sad, happy, angry, or neutral expressions. Participants were instructed to rate, on a 4-point scale, how sad they felt when they looked at each picture or how long the nose was. The EPI images were preprocessed using the Analysis of Functional NeuroImages (AFNI). The images were time shifted and motion corrected. Participants with fewer than 80% of images remaining after censoring images >0.9 mm framewise displacement were excluded. 14 autistic and 21 non-autistic participants were included in the further analysis. 3dDeconvolve from AFNI was used to model individual level data, and 3dMVM was used to examine group-level responses related to the conditions and their interactions with group.

Results: The autistic group reported greater dysphoria and emotion reactivity problems on the EDI. Several prefrontal areas showed differential activation by group during the SIP. During the introspection of sadness, the autistic group showed higher ventromedial and dorsomedial prefrontal activation compared to the non-autistic group. During the evaluation of physical features of faces, the autistic group showed reduced activation in the canonical attention-related areas, including the frontal eye field and intraparietal sulcus.

Conclusions: The observed increase in medial prefrontal activation in the autistic group is consistent with activation patterns associated with depressive disorders and negative mood. The dorsomedial prefrontal area has been implicated in emotion regulation via emotional awareness and self-referencing, and elevated activation in the area has been reported in adolescents and adults with major depressive disorders. The ventral prefrontal area has been implicated in regulation of negative moods due to its connection to the amygdala. These findings point to the significant role of prefrontal cortical brain regions in the emergence of affective problems in autistic adolescents.

402.170 Individualised Mapping of Neural EEG Responses for Neurodevelopmental Populations in a Multiverse Space

R. Haartsen¹, L. Mason², P. Garces³, E. Loth⁴, D. Murphy⁵, S. Lippe⁶, R. Leech⁷, E. Jones¹ and E. U. AIMS LEAP⁸, (1)Centre for Brain and Cognitive Development, Birkbeck University of London, London, United Kingdom, (2)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (3)Neuroscience and Rare Diseases, Roche Pharma Research and Early Development, Roche Innovation Center Basel, Basel, Switzerland, (4)Department of Forensic and Neurodevelopmental Sciences, Flat 2, 116, South Hill Park, London, London, United Kingdom, (5)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, UNITED KINGDOM, (6)Neurosciences of Early Development Lab, CHU Sainte-Justine University of Montreal, Montreal, QC, Canada, (7)Imperial College London, London, United Kingdom, (8)EU-AIMS Consortium, London, United Kingdom

Background:

Autism studies have traditionally focused on group differences while ignoring individualised approaches. Studies furthermore focus on one or two brain functioning metrics, for example the latency of the neural response to faces. This narrow focus hinders advancement of individualised approaches. One solution is using machine learning to create a multiverse space of brain responses where metrics from similar mechanisms are located at close distances. This method further allows for modelling individualised maps of brain responses across the multiverse space and examine how someone's responses vary across the space.

Objectives:

We aimed to create a multiverse space of electroencephalography (EEG) measures from social neuroimaging tasks in a large neurodiverse sample.

Methods:

We extracted 382 EEG metrics from 2 EEG tasks collected within the Longitudinal European Autism Project in 500 6 to 30-year-old autistic and non-autistic people. From the FaceERP task, we extracted ERP latency and amplitude (P1, N170), spectral power, and event-related oscillations. From the dynamic videos task, we calculated spectral power, aperiodic slope and exponent, and functional connectivity.

To create the space, we applied multidimensional scaling to the EEG metrics from a subset of 120 people. We validated the space by generating individual computational models of responses across the space within a different subset of 109 people using Gaussian Process Regression modelling. We correlated the model predicted values with the observed values for the metrics excluded from training.

Finally, we correlated the metrics within the space with IQ, adaptive skills, and autistic traits (using the Vineland Adaptive Behaviour Scales-Second Edition: VABS-II, the Social Responsiveness Scales, Second Edition: SRS-2, and Repetitive Behaviours Scale-Revised: RBS-R) to examine the meaningfulness of the space.

Results:

The multiverse space revealed EEG metrics for different tasks are spread across the space. Metrics from similar analytic signal processing approaches are clustered together (Figure left).

For the validation, computational models for brain responses across the space revealed intra-individual variability in patterns (Figure middle). Correlations between model-predicted and observed values for the metrics were above 0 suggesting meaningful information is embedded within the space (*median* = .58, $Z = 9.06$, $p < .0001$).

The topography of the multiverse space varied by age where correlations with EEG metric values varied between -.83 and .46, and revealed a gradient from a negative to positive association diagonally (bottom left to top right) across the multiverse space (Figure right). No such strong associations across topography were observed for IQ ($-.34 \leq r's \leq .28$), adaptive skills ($-.51 \leq r's \leq .56$), or autistic traits (SRS SCI domain ($-.34 \leq r's \leq .32$); RBS-R total ($-.35 \leq r's \leq .32$)).

Conclusions:

Metrics based on similar analytic approaches provide similar information across social tasks. In addition, there is variation between individuals in neural responses across the multidimensional space individual variation among these. Future research may implement this approach to select metrics of interest for discovery research or clinical research for developing personalised support via neuro-adaptive sampling and real-time EEG techniques.

402.171 Integrating Automated Artifact Detection and Expert Review in EEG Signal Processing

S. Huberty¹, M. Hare², S. Jeste² and C. DiStefano², (1)University of Southern California, Los Angeles, CA, (2)Children's Hospital Los Angeles, Los Angeles, CA

Background:

Electroencephalography (EEG) is widely used in studies involving children, including those with neurodevelopmental disorders such as autism, due to its non-invasive nature, high temporal resolution, and relative robustness to motion artifacts compared to other imaging techniques. However, artifacts from eye movements, muscle activity, and other sources can still contaminate the EEG signal, especially in studies involving individuals who may have difficulty following instructions to minimize movement during data collection. The pyLossless EEG processing pipeline was developed to combine automated artifact identification with expert manual review, to efficiently remove artifacts from the EEG signal. This semi-automated approach, which includes manual review, may be particularly useful in studies involving children with neurodevelopmental disabilities, due to the frequent presence of artifacts and the effort required to collect the data.

Objectives:

Since the pyLossless pipeline was initially demonstrated on a sample of adults, we sought to evaluate its performance on a cohort of children with neurodevelopmental disorders and with typical development, to determine its effectiveness in removing artifacts from relatively noisy EEG data.

Methods:

We applied the pyLossless EEG processing pipeline to EEG data from a heterogeneous sample of 75 children, including children with autism (n=46; a subset of whom were minimally verbal, n=22), typically developing children (n=23), and children with Angelman Syndrome (n=5). The EEG data were collected using a 128-channel system with a sampling rate of 500 Hz. The data were pre-processed in Python using the PyLossless pipeline, followed by expert manual review. The pipeline flagged potential noisy channels, time segments, and independent components, and the manual review served to confirm or reject the identified artifacts. We computed a proxy metric of the signal-to-noise ratio (SNR) data after processing to evaluate the effectiveness of the artifact identification process.

Results:

To evaluate the pipeline, we compared the evoked potentials between the raw and pre-processed data after automated and manual review. First, we segmented the data at the onset of the stimulus of interest and computed the maximum peak-to-peak (PTP) amplitude of each channel for each epoch. For the processed data, we took the mean across epochs of these PTP values, whereas for the raw data, we used the median to account for the presence of artifacts. The root mean squared error (RMSE) was computed between the aforementioned mean and median values as a measure of the signal-to-noise ratio. A lower RMSE indicates a better match between the processed and raw data. The results showed that both the fully automated and manual review steps improved the signal-to-noise ratio compared to the raw data. However, incorporating manual review improved the SNR particularly in noisier datasets.

Conclusions:

We evaluated the performance of the semi-automated pyLossless pipeline on EEG data from a cohort of children with autism. While many EEG processing pipelines are designed for data from adult neurotypical populations, the results suggest that manual review of EEG data is especially beneficial for noisy datasets. This work provides a framework for future studies to evaluate the effectiveness of automated pre-processing pipelines on data from neurodevelopmental populations.

402.172 Cleaning EEG Data By Combining Automated Artifact Identification with Expert Manual Review.

S. Huberty¹, **M. Hare**², **S. Jeste**² and **C. DiStefano**², (1)McGill University, Montreal, QC, Canada, (2)Children's Hospital Los Angeles, Los Angeles, CA

Background:

Electroencephalography (EEG) is widely used in studies involving children, including those with neurodevelopmental disorders such as autism, due to its non-invasive nature, high temporal resolution, and relative robustness to motion artifacts compared to other imaging techniques. However, artifacts from eye movements, muscle activity, and other sources can still contaminate the EEG signal, especially in studies involving individuals who may have difficulty following instructions to minimize movement during data collection. The pyLossless EEG processing pipeline was developed to combine automated artifact identification with expert manual review, to efficiently remove artifacts from the EEG signal. This semi-automated approach, which includes manual review, may be particularly useful in studies involving children with neurodevelopmental disabilities, due to the frequent presence of artifacts and the effort required to collect the data.

Objectives:

Since the pyLossless pipeline was initially demonstrated on a sample of adults, we sought to evaluate its performance on a cohort of children with neurodevelopmental disorders and with typical development, to determine its effectiveness in removing artifacts from relatively noisy EEG data.

Methods:

We applied the pyLossless EEG processing pipeline to EEG data from a heterogeneous sample of 75 children, including children with autism (n=46; a subset of whom were minimally verbal, n=22), typically developing children (n=23), and children with Angelman Syndrome (n=5). The EEG data were collected using a 128-channel system with a sampling rate of 500 Hz. The data were pre-processed in Python using the PyLossless pipeline, followed by expert manual review. The pipeline flagged potential noisy channels, time segments, and independent components, and the manual review served to confirm or reject the identified artifacts. We computed a proxy metric of the signal-to-noise ratio (SNR) data after processing to evaluate the effectiveness of the artifact identification process.

Results:

To evaluate the pipeline, we compared the evoked potentials between the raw and pre-processed data after automated and manual review. First, we segmented the data at the onset of the stimulus of interest and computed the maximum peak-to-peak (PTP) amplitude of each channel for each epoch. For the processed data, we took the mean across epochs of these PTP values, whereas for the raw data, we used the median to account for the presence of artifacts. The root mean squared error (RMSE) was computed between the aforementioned mean and median values as a measure of the signal-to-noise ratio. A lower RMSE indicates a better match between the processed and raw data. The results showed that both the fully automated and manual review steps improved the signal-to-noise ratio compared to the raw data. However, incorporating manual review improved the SNR particularly in noisier datasets.

Conclusions:

We evaluated the performance of the semi-automated pyLossless pipeline on EEG data from a cohort of children with autism. While many EEG processing pipelines are designed for data from adult neurotypical populations, the results suggest that manual review of EEG data is especially beneficial for noisy datasets. This work provides a framework for future studies to evaluate the effectiveness of automated pre-processing pipelines on data from neurodevelopmental populations.

402.173 Evaluating the Association between Early Changes in EEG Aperiodic Components and Language Outcomes in Infants with and without Autism

H. Chung¹, **C. L. Wilkinson**², **A. Dave**³, **A. Job Said**⁴, **H. Tager-Flusberg**⁵ and **C. A. Nelson**¹, (1)Department of Developmental Medicine, Boston Children's Hospital, Boston, MA, (2)Department of Developmental Medicine, Boston Children's Hospital / Harvard Medical, Boston, MA, (3)Texas A&M University, Austin, TX, (4)Boston Children's Hospital, Brookline, MA, (5)Psychological and Brain Sciences, Boston University, Boston, MA

Background:

Toddlers with autism often experience co-occurring language delays, with 30% remaining minimally verbal. Despite the prevalence of language impairments, the neurobiology underlying language challenges in autism is poorly understood. Previous research, including ours, has shown reduced EEG power across multiple frequency bands (e.g., theta, alpha, gamma) in 3-6 month-old infants with autism siblings, followed by accelerated increases in later years. This pattern may reflect changes in aperiodic components that give rise to broad-band power differences. Moreover, it remains unclear whether changes in aperiodic components contribute to later language delays in autistic infants. Here, we apply new methods to parametrize the power spectra into aperiodic (broad-band neuronal firing) and periodic (oscillatory activity) components to examine whether changes in aperiodic components during the first year of life are linked to autism and later language outcomes.

Objectives:

Leveraging data from three prospective longitudinal studies—two focused on infants with an elevated familial likelihood (EFL) of autism due to having a sibling with autism (Sibling projects) and one focused on elevated likelihood of autism due to living in a low-resource household (Low-Resource project)—we aimed to assess whether infants later diagnosed with autism exhibit altered changes in EEG aperiodic components during the first year of life. Furthermore, we examined whether these developmental changes in EEG features are associated with language outcomes.

Methods:

Frontal aperiodic and periodic components were calculated using SpecParam from 5-minute resting-state EEG data at 3 or 4 months and at 12m, and language scores were assessed via the Mullen Scales of Early Learning at 18 or 24 months. Autism diagnosis was evaluated by Autism Diagnostic Observation Schedule-Second Edition. Linear mixed-effects models were used to assess changes in EEG components over time, and linear regression, with age and sex as covariates, was employed to examine associations between EEG features and language outcomes.

Results:

First, from the Sibling projects, at 3-months of age, EFL infants, regardless of autism diagnosis exhibited significantly lower aperiodic activity from 6.6-55Hz ($p < 0.05$; Figure 1A). However, infants with later autism diagnosis exhibited significantly greater increases in aperiodic activity (e.g. total aperiodic power and aperiodic offset) from 3-to-12 months, compared to both EFL-noAutism and Low-likelihood-noAutism infants (Figure 1B). Similarly, from the Low-Resource project, infants later diagnosed with autism also exhibited reduced aperiodic activity at 4 months old, and showed significantly greater increases in aperiodic activity with age compared to non-autistic infants. (Figure 1C). Finally, exploratory analyses from the Sibling project showed that greater changes in aperiodic offset and slope from 3-to-12 months were associated with lower language abilities at 18 months in infants with autistic siblings, and this relationship was stronger in the autism group (Figure 1D).

Conclusions:

Early age-dependent changes in EEG aperiodic power may serve as a potential biomarker for autism and/or language development. We hypothesize that greater increases in early aperiodic activity may reflect over compensation of early aberrant neural activity, resulting in decreased ability to process language inputs during early learning.

**402.174 Characterizing Functional Brain Networks in Children with and without Autism**

H. Chung¹, W. An², C. L. Wilkinson³, H. Tager-Flusberg⁴ and C. A. Nelson¹, (1)Department of Developmental Medicine, Boston Children's Hospital, Boston, MA, (2)Pediatrics, Division of Developmental Medicine, Boston Children's Hospital, Boston, MA, (3)Department of Developmental Medicine, Boston Children's Hospital / Harvard Medical, Boston, MA, (4)Psychological and Brain Sciences, Boston University, Boston, MA

Background:

Autism is a heterogeneous neurodevelopmental disorder, with common co-occurring challenges such as language and cognitive delays. However, the underlying neurobiology of autism as it relates to behavioral challenges remains poorly understood. One promising framework for understanding the neurobiology of autism focuses on abnormal brain oscillations, which are thought to arise from an altered balance between excitation and inhibition. This balance is essential for shaping neural connectivity, and previous studies have found inefficient, suboptimal connectivity and disorganized large-scale brain networks in individuals with autism. Notably, prior EEG studies have reported significant differences in the alpha frequency range, which may reflect a cascading effect of early disruptions in thalamocortical connections. Early disrupted network organization may compromise complex functions, such as language, which depend on flexible communication between brain regions. However, most studies investigating these neural alterations have been cross-sectional and focused on older children or adults, which overlooks the dynamic development of brain networks during early childhood.

Objectives:

Building on previous research demonstrating sub-optimal networks among older children and adults with autism, this study aims to: 1) characterize EEG graph-theory-based functional network trajectories in children with and without autism in the first three years of life and 2) assess whether differences in the trajectory of functional networks help explain behavioral challenges of autism, such as language delays.

Methods:

High density resting-state EEG data was collected from 243 participants (63 Autism; 180 no-Autism) from two prospective longitudinal projects spanning 3-to-36 months. Whole-brain functional connectivity (e.g. coherence) and graph theory metrics (e.g. local efficiency - clustering coefficient; global efficiency - path length) were computed. Standardized assessments (i.e., Autism Diagnostic Observation Schedule, Mullen Scales of Early Learning) were administered to assess autism outcomes at 24 or 36 months. Generalized additive mixed models was used to assess changes in EEG components over time, and linear regression, will be employed to examine associations between EEG features and language/cognitive outcomes.

Results:

Preliminary analyses reveal that peak alpha (4-11 Hz) connectivity increases with age from 3 to 36 months in both children with and without autism (Figure 1A). However, the trajectory of alpha connectivity magnitude differs between the two groups. While both autistic and non-autistic toddlers show increases in alpha connectivity up to 2 years of age, by 36 months, toddlers with autism demonstrate reduced global alpha connectivity (Figure 1B, C), particularly between frontal-temporal and central-posterior regions, compared to their non-autistic peers. This trend is also evident in network topology, where toddlers with autism exhibit reduced local network efficiency (e.g. lower clustering coefficient; Figure 1D), indicating less efficient communication within localized regions of the brain compared to non-autistic children.

Conclusions:

These preliminary findings highlight age-related changes in peak alpha connectivity, alongside group-level differences in network organization at 36 months. Developmental changes in alpha oscillations may reflect the maturation and refinement of neural networks, with our results suggesting reduced efficiency and less flexible communication between distributed brain regions in autism.

**Poster Session****403 - Early Development (< 48 months) I**

May 1st, 2025, 12:30 PM - 1:30 PM - Hall 4A

403.175 A Systematic Review and Meta-Analysis of Atypical Visual Attention Towards Non-Social Stimuli in Preschoolers with Autism

J. R. Hinz^{1,2}, F. F. Eikeseth¹, K. Chawarska⁴ and S. Eikeseth³, (1)Department of Behavioural Science, OsloMet – Oslo Metropolitan University, Oslo, Oslo kommune, (2)Child Study Center, Yale - School of Medicine, New Haven, CT, (3)Department of Research and Development, Oslo University Hospital, Oslo, Norway, (4)Child Study Center, Yale University School of Medicine, New Haven, CT, (5)Department of Behavioural Sciences, Oslo Metropolitan University, Oslo, Norway

Background: Research on attention towards non-social stimuli in preschoolers with autism has increased over the past decade, as more studies investigate visual non-social stimuli as a potential biomarker. However, studies show mixed results—some report elevated non-social attention in children with autism, while others do not. This could potentially be due to stimulus content utilized across studies. It has been suggested that stimuli relating to common circumscribed interests (CIs) (machines, fractals etc.) elicit more attention than non-CI related stimuli. Currently it is unclear if this special status of CI-related stimuli is already present in preschoolers with autism, with CIs typically being observed in older children.

Objectives: A meta-analysis was conducted to gauge the extent of potential attentional biases towards non-social stimuli in preschoolers with autism. We examined eye-tracking studies on children with autism between 8 and 60 months of age, which deployed stimuli depicting content related to common CIs, and studies using non-CI non-social stimuli. We hypothesized that (1) non-social stimuli would attract more visual attention in children with autism than in typically developing (TD) controls; (2) CI stimuli elicit more attention from children with autism compared to non-CI non-social stimuli; (3) attention to CIs is associated with more severe autism symptoms.

Methods: 31 eye-tracking studies including attentional measures (gaze duration, number of fixations etc.) towards non-social stimuli were identified, and effect sizes were standardized into Hedges g . First an overall meta-analysis for general non-social attention including all studies was conducted. Both traditional restricted maximum likelihood as well as a novel robust Bayesian meta-analysis (RoBMA-PSMA) models were used for study synthesis. A follow-up subgroup analysis, splitting studies based on stimulus employed (CI, non-CI), was performed to measure the effect of stimulus content. Lastly a series of meta-regressions was performed to control for unaccounted heterogeneity and test for associations between age, sex, stimulus dimension (static / dynamic), non-verbal DQ, symptom severity and effect sizes. Variables were analyzed separately due to the small number of studies, by including them as covariates to the previous model.

Results: The initial overall sample showed small ($g = 0.39$) but significantly higher attention towards non-social stimuli for the autism group than in TD. However, the follow-up subgroup analysis where studies were split based on stimulus type revealed no significant differences for non-CI stimuli, but significant large effects on attention allocation when CI related stimuli were used ($g = 0.69$). No associations were found between attention to CI stimuli and age, sex, stimulus type, nonverbal skills and autism severity. Sensitivity for the symptom severity regression was limited due to underreporting of clinical measures in included studies.

Conclusions: Our findings show that CIs-related stimuli contribute to elevated non-social attention in autism. None of our regressions explained meaningful variance, suggesting a universal effect not limited to children with specific characteristics. Results emphasize the need for evaluation of stimulus content in study design, especially in research focused on identifying attentional biomarkers. It further highlights the potential role of CIs in biomarker development, calling for more research into an understudied symptom area.

403.176 ASD Identification in Early Intervention: Exploring Optimal M-CHAT-R/F Thresholds in Children with Developmental Delays

A. Morell¹, S. O'Kelley², A. B. Barber³, K. R. Tomeny⁴, M. B. Vick⁵, W. D. Pittard⁶, L. C. Hackney⁷, K. Goff⁸ and G. Dooley⁸, (1)The University of Alabama at Birmingham, Birmingham, AL, (2)Department of Psychology, The University of Alabama at Birmingham, Birmingham, AL, (3)Communicative Disorders, Samford University, Tuscaloosa, AL, (4)University of Alabama, Tuscaloosa, AL, (5)Alabama Department of Rehabilitation Services, Tuscaloosa, AL, (6)Alabama's Early Intervention System, Alabama's Department of Rehabilitation Services, Huntsville, AL, (7)Alabama Department of Mental Health, Decatur, AL, (8)The University of Alabama, Tuscaloosa, AL

Background:

The Modified Checklist for Autism in Toddlers, Revised, with Follow-up (M-CHAT-R/F), is widely used in early intervention settings to identify children with an increased likelihood for autism spectrum disorder (ASD). Identifying the optimal threshold for maximizing sensitivity in populations of children with identified delays is warranted.

Objectives:

This study aimed to evaluate the predictors of ASD diagnosis and the screening performance of the M-CHAT-R/F in a sample of children referred to Part C, with a focus on identifying an M-CHAT-R/F threshold to improve the accurate identification of children with likely ASD.

Methods:

The sample included 114 children (71.1% male), with an average age of 23.04 months (SD=4.89). The racial composition was 49.1% White/Caucasian, 42.1% Black/African American, 2.6% Hispanic/Latino, 1.8% Asian, and 4.4% identifying as 2+ races. After identification through Part C and subsequent referral for evaluation, 84.2% were diagnosed with ASD based on external clinical evaluations.

Binary logistic regression was conducted to assess the predictive value of gender, race, areas of delay (i.e., social-emotional, cognitive, communication, physical, and adaptive), parent/provider autism concerns, and M-CHAT-R/F scores. A Receiver Operating Characteristic (ROC) analysis was performed to examine the ability of the M-CHAT-R/F to discriminate between ASD and non-ASD cases. The Area Under the Curve (AUC) and sensitivity and specificity values were analyzed across different threshold scores.

Results:

The final logistic regression model was statistically significant ($\chi^2=28.20$, $p=.013$), explaining between 22.3% (Cox & Snell R^2) and 39.8% (Nagelkerke R^2) of the variance in ASD diagnosis. The model correctly classified 90.2% of cases, with high sensitivity (99%) but lower specificity (37.5%). Communication delay was the strongest predictor of ASD diagnosis, with affected children being 79 times more likely to be diagnosed with ASD (OR=78.789, $p=.003$).

ROC analysis revealed an AUC of 0.591 (95% CI: 0.463-0.720, $p=.243$), indicating limited discriminatory capacity of the M-CHAT-R/F to differentiate between ASD and non-ASD cases in this sample. At the standard cutoff of 8, sensitivity was 66.7% and specificity was 50%. Lowering the cutoff to 5 increased sensitivity to 80.2%, but reduced specificity to 18.7%, leading to more false positives. Further reducing the threshold to 4 maximized sensitivity at 86.5%, but dropped specificity to 12.5%. Raising the cutoff to 9 decreased sensitivity to 62.5%, while maintaining specificity at 50%. At a cutoff of 10, sensitivity fell to 51%, while specificity increased to 56%, potentially missing nearly half of ASD cases.

Conclusions:

In early intervention contexts, where sensitivity is prioritized to ensure that more children receive appropriate support, lowering the M-CHAT-R/F threshold may be beneficial. While this would increase false positives, follow-up assessments can help clarify diagnosis over time. Lowering the threshold to 5 from 8 may strike the best balance in this population, improving sensitivity and ensuring that more children with ASD are identified early, allowing for timely access to interventions. The low number of true negatives in this sample may limit the specificity of these analyses, further emphasizing the need to focus on sensitivity to reduce the under-identification of children in need of ASD-specific intervention.

403.177 Accommodation of Rrbs Among Young Autistic Children: A Cross-Sectional and Longitudinal Study

T. Matz Vaisman, T. Graucher and J. Koller, Seymour Fox School of Education, The Hebrew University of Jerusalem, Jerusalem, Israel

Background: Family accommodation consists of changes in behavior or routines made by family members of children with psychological or developmental conditions in an attempt to reduce the child's stress associated with the condition (Lebowitz, Panza, Su, & Bloch, 2012). Among children with anxiety disorders, studies have linked increased accommodation with higher symptom severity, lower psychosocial functioning, poorer response to intervention, increased parental distress, and elevated caregiver burden (Caporino et al., 2012; Lebowitz et al., 2012; Futh, Simonds, & Micali, 2012). Preliminary studies of family accommodation in the context of autism found a strong positive correlation between accommodation and restricted and repetitive behavior (RRBs) severity, anxiety levels, and disruptive behaviors, and a negative correlation between accommodation and adaptive functioning (Feldman et al., 2019; Koller et al., 2021; Matz Vaisman & Koller, under review). The current study focuses on accommodation among parents and teachers of young autistic children, both cross-sectionally and longitudinally, and the association between accommodation and various child clinical characteristics.

Objectives: To examine the role of accommodation of RRBs in young autistic children, across timepoints and caregivers, and to better understand its relationship with daily functioning.

Methods: 87 families of autistic children aged 2-4 who received a gold-standard autism evaluation participated in this study. Parents completed questionnaires on their child's RRB expression (RBS-R; Bodfish et al., 1999), their accommodation of the child's RRBs (FAS-RRB; Feldman et al., 2019), and child adaptive functioning (ABAS; Harrison & Oakland, 2015). Teachers completed a measure of their accommodation of the child's RRBs (TAS-RRB). Families completed the same questionnaires 6 and 12 months after the initial evaluation. Approximately one year after the initial assessment, families returned to the lab for a follow-up diagnostic evaluation.

Results: Analyses showed that, at diagnosis, over 75% of mothers, fathers, and teachers reported daily or weekly accommodation. Maternal accommodation correlated significantly and positively with child's RRBs ($r(85) = .487, p < .001$) and negatively with child adaptive functioning ($r(87) = -.253, p < .05$). Paternal accommodation correlated significantly and positively with child's RRBs ($r(76) = .313, p < .01$) but showed no significant correlation with child adaptive functioning. Maternal and paternal accommodation correlated significantly with each other ($r(77) = .369, p < .001$). Teacher accommodation did not correlate with any child characteristics, nor with parental accommodation. Analysis of the one-year follow-up data found that parents reported slightly less frequency of daily and weekly accommodation (69% mothers, 70% fathers), though their average accommodation scores were higher overall. Parents continued to correlate significantly with each other ($r(47) = .572, p < .01$). Teacher data were not analyzed at follow-up, as many of the children had transferred to a different educational framework over the course of the year.

Conclusions: This study shines light on accommodation in early childhood development of autistic children across caregivers and timepoints.

Accommodation should be further investigated with a more nuanced perspective on RRBs, distinguishing between accommodation of adaptive and maladaptive RRBs. Particular attention should be paid to trajectory analyses, to better understand the impact of time on accommodation.

403.178 Administering the CSBS in Collaboration with Caregivers in a Virtual Environment: Reliability, Fidelity, and Lessons Learned

J. Franco¹, J. Butler², A. Garza², E. Cho², E. Lidov², A. Glickman², A. Miller² and L. H. Hampton², (1)Department of Speech, Language, and Hearing Sciences, The University of Texas at Austin, Austin, TX, (2)The University of Texas at Austin, Austin, TX, (3)Communication Sciences and Disorders, Northwestern University, Evanston, IL

Background:

The Communication and Symbolic Behavior Scales Assessment (CSBS) has been shown to be valid and reliable (Wetherby et al. 2018) but is yet to be studied in telepractice. This study critically examines the coached-caregiver administration of the CSBS in a virtual environment. While parent-mediated interventions have been found effective in both in-person and telepractice (Hao et al, 2019), less is known about Parent-Mediated Assessment.

Objectives:

This study aimed to expand the scope of teleassessment with infants and toddler siblings of autistic children using the Communication and Symbolic Behavior Scales Assessment (i.e., CSBS; Wetherby & Prizant, 2002), which focuses on social communication in children ages 1-3. This study examined the following research questions: (1) Can caregivers administer the CSBS with virtual coaching with high rates of fidelity? (2) Can our assessors administer the CSBS virtually with high rates of fidelity? (3) Can naïve assessors achieve high levels of reliability when scoring the CSBS administered virtually? (4) Are the virtual assessment procedures, as designed, acceptable to families?

Methods:

We included participants from an ongoing clinical trial (NCT05307094). Caregivers with an older child diagnosed with autism and a younger, undiagnosed, toddler 11- 18 months of age were identified and recruited. A sample of thirty infant/toddler participants were randomly selected and of the ninety total CSBS administrations in this sample, three per participant across three timepoints, 20% were selected for reliability and fidelity. We included administration logistics regarding assessment material assembly and organization, procedures for modifications as well as characteristics and training of the assessors in this study.

Results:

Parent administration of the CSBS assessment procedures were consistently rated high ($M=95.61\%$, $SD=3.99$, range=85.94-100%) and agreement between raters on parent fidelity scores were strong ($ICC=0.89$). Assessor implementation of the CSBS protocol was high ($M=91.14\%$, $SD=8.8\%$, Range= 65.94%-100%). Two assessments scored below optimal fidelity levels (65.94% and 74.13%) were noted to be impacted by sibling(s) present, caregiver frustrated during assessment or assessment required multiple accommodations. Agreement between the raters of total social communication scores obtained from the telehealth CSBS was high ($ICC=.85$). There was notable variability ($CI= 0.64-0.94$) with camera/audio issues or confusion when protocol was not followed correctly by caregiver occurring more frequently. Results indicate that administering the CSBS in a telehealth environment is feasible for the clinician/parent to administer, reliable for the raters to score, and acceptable by parents. However, this type of administration may not be well-suited for all children.

Conclusions:

Future recommendations highlighting some technology and logistical demands as well as methods to adapt existing assessments for telehealth administration should be considered. Conducting CSBS assessment administrations with coaching via telehealth then comparing those administrations to others conducted via in-person clinical setting, could help researchers validate the accuracy of the tool, the nuance in coaching vs clinical judgement and how that translates across these contexts. Additionally, examining the moderators of these two contexts – the telehealth coaching model and the in-person administration model, could yield interesting results that may speak to some of the limitations we were unable to address.

403.179 Analyzing the Predictive Relationship of Early Motor Skills and Restricted and Repetitive Behaviors in Infancy

C. E. Thomas¹, A. Acosta², J. Yurkovic-Harding^{3,4} and J. Bradshaw², (1)Psychology, The University of South Carolina, Columbia, SC, (2)University of South Carolina, Columbia, SC, (3)Department of Psychology, University of South Carolina, Columbia, SC, (4)Carolina Autism and Neurodevelopment Research Center, University of South Carolina, Columbia, SC

Background: Restricted and repetitive behaviors (RRBs) are a core feature of autism spectrum disorder (ASD) and can include repetitive motor mannerisms that involve fine (hand/finger mannerisms/posturing) and gross motor (complex mannerisms; spinning, rocking, etc.) behaviors (Kim & Lord, 2010). In addition to RRBs, previous studies have found children with ASD to have co-occurring motor delays (Licari et al., 2019; Uljarević et al., 2017). Given motoric involvement in RRBs, it is possible that emerging RRBs and motor development are linked, and development in one area may affect or cascade into other domains (Bradshaw et al., 2022). It is possible that higher rates of RRBs, reflecting atypical motor movements, may emerge due to early motor difficulties. However, there is currently limited research on this association.

Objectives: The current study aims to identify the predictive relationship between early fine and gross motor skills in early infancy and later presentation of RRBs at age 2 years within infants at elevated (EL) and low (LL) genetic likelihood for ASD who were and were not diagnosed with ASD.

Methods: In a prospective, longitudinal study, infants ($N=61$; EL, $n=24$; LL, $n=37$) were seen in early infancy (between 4-6 months) and at outcome (2 years). Fine motor (FM) and gross motor (GM) skills were assessed using the Bayley-3 (Bayley, 2005) between 4-6 months. At 2 years, infants were seen for a diagnostic outcome visit. Selected RRB algorithm items from the ADOS-2 Toddler Module (Unusual Sensory Interest in Play Material/Person, Hand and Finger Movements/Posturing, and Unusually Repetitive Interests or Stereotyped Behaviors) were summed to generate our RRB outcome. General linear models were used to examine the relationship between infant motor skills and 2-year RRB scores across diagnostic outcome groups (ASD, $n=19$; TD, $n=42$).

Results: Overall, RRB scores at 2 years were higher for children with ASD than TD children ($F(1,57)=4.75$, $p=.001$). GM skills at 4-6m did not significantly predict RRB scores ($F(1,57)=0.38$, $p=.54$). However, FM skills did significantly predict RRB scores ($F(1,57)=5.94$, $p=.018$; see Figure 1.). Specifically for children with ASD, higher FM skills predicted higher RRB scores ($F(1,57)=4.80$, $p=.03$).

Conclusions: Contrary to our hypotheses, our findings indicate that more FM skills during infancy predicted higher RRB presentation later in development, especially for children with ASD. It is possible that infants with higher FM skills may have more opportunities to develop and engage in RRBs early in life that cascade to higher RRBs in toddlerhood. Additionally, we found no association between GM skills and later RRB presentation. Further research that characterizes RRBs more specifically may elucidate a relationship between early GM skills and later RRBs.

403.180 Test-Retest Reliability in Remote Assessment of Social Attention

M. Hare¹, C. Stone², M. H. Vu¹, M. C. Frank³, J. B. Wagner⁴, R. Landa⁵, R. A. Durazo- Arvizu^{6,7}, S. J. Sheinkopf⁸, E. Tenenbaum⁹ and S. Jeste¹, (1)Children's Hospital Los Angeles, Los Angeles, CA, (2)Department of Psychiatry and Behavioral Sciences, University of North Carolina Greensboro, Durham, NC, (3)Psychology, Stanford University, Stanford, CA, (4)Department of Psychology, College of Staten Island, CUNY, Staten Island, NY, (5)Center for Autism Services, Science and Innovation, Kennedy Krieger Institute, Baltimore, MD, (6)Department of Pediatrics, Children's Hospital Los Angeles, Los Angeles, CA, (7)University of Southern California, Los Angeles, CA, (8)Thompson Center for Autism & Neurodevelopment, University of Missouri, Columbia, MO, (9)Department of Psychiatry and Behavioral Sciences, Duke University, Durham, NC

Background:

Infant siblings of autistic children have a higher likelihood of developing autism (Ozonoff et al., 2024). However, research with this population has been largely limited by in-person assessment, resulting in reduced accessibility and generalizability. The RISE battery is a set of originally lab-based tasks which have been adapted to investigate infant cognitive and language development at home (Tenenbaum et al., 2024). Prior research has shown that infants and toddlers later diagnosed with autism show a reduced preference for social stimuli when presented alongside non-social stimuli (Campbell et al., 2019; Chawarska et al., 2016; Pierce et al., 2016). Here we are testing a social-attention task in low-likelihood infants (those without an autistic sibling) to determine whether social preference can be measured reliably in a remote task.

Objectives:

1. To examine preference for social stimuli among infants viewing social and non-social stimuli remotely. Hypothesis: Low-likelihood infants will show a reliable preference for social stimuli.
2. To examine test-retest reliability between the first presentation of the task and the follow up presentation one week later. Hypothesis: Preference for social stimuli will be positively correlated between the first and second time point.

Methods:

A preferential looking task contrasting colorful geometric animations with dancing children was shown via a computer to 6- and 12-month-old infants using the remote administration platform Children Helping Science. There were 10, 4-second trials with location of the social and non-social stimuli counterbalanced across trials. Gaze direction was automatically coded by iCatcher+, an open-source computer vision program. The infants were shown the same task one week later. Only participants with >33% tracked frames and no side bias were included in the final analysis, which utilized a linear mixed-effects model and Spearman's correlation.

Results:

111 participants were tested (49% female, 51% male). 8.3% were reported as Asian, 1.8% as Black, 52.3% as White, and 37.6% as more than one race. 14.7% of participants reported being of Hispanic or Latino descent. 39 6-month-olds and 48 12-month-olds were included in the final analysis. A subset of 54 infants repeated the task at time 2, 41 of whom were included in the analysis.

Both 6- and 12-month-old participants showed a preference (mean proportion >0.50) for the social stimuli (12-m: 0.62 [0.56 - 0.68], $p = 0.001$; 6-m: 0.62 [0.56 - 0.68], $p = 0.001$; m-diff: 0.0 [-0.06 - 0.06], $p = 0.919$) (see Figure 1). Collapsing across age groups, there was a significant positive correlation between the proportion of looks to the social stimuli at the two time points, $r(41) = [0.34]$, $p = [0.032]$ (see Figure 2).

Conclusions:

Consistent with prior research (Pierce et al., 2011), infants showed a preference for the social relative to non-social stimuli through a remotely administered task. This remote assessment strategy provides a key opportunity to track individual differences in infant social attention, with potentially divergent developmental trajectories heralding early markers of autism in a scalable way. Currently data is being collected from infant siblings of autistic children to address group differences.

**403.181** Autism Indicators at 12-Months Predict Autism Screening Results at 24 Months in a General Population Birth Cohort

S. J. Sheinkopf¹, E. M. Andres¹, C. M. Loncar², B. M. Lester³, G. Puggioni⁴, M. A. Clark⁵ and C. A. Cragin², (1)Thompson Center for Autism & Neurodevelopment, University of Missouri, Columbia, MO, (2)Brown University, Providence, RI, (3)Department of Psychiatry and Human Behavior, The Warren Alpert Medical School of Brown University, Providence, RI, (4)Department of Computer Science and Statistics, University of Rhode Island, Kingston, RI, (5)Brown University School of Public Health, Providence, RI

Background: Measurement of behaviors and autism symptoms prior to 24 months of age has the potential to identify behavioral signs suitable for early surveillance in general pediatric populations.

Objectives: To test whether caregiver-reported autism indicators at 12 months predict autism related behaviors, positive autism screen results, and social communication delays at 24 months in a general population of infants, and to examine the impact of caregiver minority status on predictive associations.

Methods: Participants were 511 children (246 females; 336 White/Non-Hispanic) from an ongoing longitudinal birth cohort study. At age 12 months, primary caregivers completed the First Year Inventory-Lite (FYI-Lite, v3.1b), a measure of early emerging autism indicators, yielding two subscales, Social Communication (SC) and Sensory Regulatory (SR), and an overall score with predefined thresholds for elevated scores. The 24-months measures were the Communication and Symbolic Behavior Scales Infant Toddler Checklist (CSBS) and the Modified Checklist for Autism in Toddlers, Revised with Follow-Up (M-CHAT-R/F). Regression models tested the association between continuous scores from the 12- and 24-month measures. Contingency models, stratified by racial/ethnic minority status, tested the prediction of positive M-CHAT-R/F results from the presence of above threshold FYI-Lite score at 12 months. These analyses expand on previously presented findings, now with a larger sample using stratified relative risk analyses.

Results: Controlling for infant sex and minority status, regression models revealed that higher FYI-Lite subscale scores positively predicted later M-CHAT-R/F ($R^2 = 0.33$, $F[4,506] = 63.18$, $p < 0.001$) and CSBS ($R^2 = 0.39$, $F[4,506] = 81.17$, $p < 0.001$) scores. The FYI-Lite SC subscale was a statistically significant predictor in both models, predicting higher M-CHAT-R/F scores ($\beta_2 = 2.6$, $p < 0.001$) and poorer communication scores on the CSBS ($\beta_2 = -10.5$, $p < 0.001$) (see Figure 1). Male sex ($\beta_3 = -1.84$, $p < 0.001$) and minority status ($\beta_2 = -1.81$, $p < 0.01$) were associated with CSBS scores. Contingency analyses revealed that above threshold FYI-Lite scores at 12 months predicted positive M-CHAT-R/F results at 24 months ($RR = 9.1$; 95% CI: 4.53, 18.35). Stratification analyses revealed effect modification for minority status (Table 1): elevated FYI-Lite scores were more strongly predictive of positive M-CHAT-R/F scores in non-minority infants ($RR = 24.5$; 95% CI: 8.94, 67.1) than in minority infants ($RR = 2.9$; 95% CI: 1.02, 8.27). Thus, although proportionally more minority participants had elevated autism indicators at 12-months, this did not directly result in higher rates of positive M-CHAT-R/F scores in these participants. The cell sizes for categorical CSBS results were too small to calculate relative risk.

Conclusions: In these updated results from an ongoing longitudinal birth cohort study, individual differences in autism-related social communication behaviors at 12 months of age predicted autism-related behaviors at 24 months. The association between above threshold elevations on the FYI-Lite at 12 months and positive screen results at 24 months supports the plausibility of screening for autism indicators prior to the age of formal diagnosis. Effect modification was found, indicating the need to account for demographic diversity in future predictive models.

403.182 Autism Symptoms More Closely Associated with Object Engaged Play Than Language Skills in Toddlers with Autism

N. Trujillo-Beltran¹, S. T. Seese², J. Panganiban³ and C. Kasari⁴, (1)UCLA Semel Institute for Neuroscience and Human Behavior, Los Angeles, CA, (2)University of California, Los Angeles, Los Angeles, CA, (3)Semel Institute, University of California Los Angeles, Los Angeles, CA, (4)Education and Psychiatry, University of California Los Angeles, Los Angeles, CA

Background: Joint engagement, where children share focus and interact with others, is crucial for language development (Roemer et al., 2022); however, toddlers with autism may have challenges with initiating and sustaining joint engagement (Shire et al., 2020). Research shows that toddlers with autism may spend more time in object-focused engagement more than in joint engagement. Longer periods of joint engagement have been associated with greater language learning in children with autism (Adamson et al; Kasari et al, 2008).

Objectives: To explore the relationship between toddler characteristics (including language abilities and autism symptoms) and engagement states during a play interaction between a caregiver and toddler with ASD.

Methods: This study is a secondary data analysis including 149 participants (M age= 21 months) with autism from two larger randomized control trials. At the start of the intervention, engagement states were coded during a 10-minute free play session between caregivers and their child.

Engagement was categorized into states, including (1) unengaged (e.g., wandering, looking around), (2) onlooking, (3) person engaged, (4) object engaged (OB) (e.g., intensely looking at or manipulating physical object), (5) supported jointly engaged, and (6) coordinated jointly engaged.

Bivariate correlations were conducted to explore the relationship between child demographic information, including language ability (from independent Mullen assessment) and autism symptoms (ADOS SC and RRB scores) and engagement states from caregiver-child interactions.

Results: The proportion of time spent in each engagement state was calculated (see Table 1). Toddlers, on average, spent the majority of the interaction in an object engaged state ($M=.50$, $SD=.23$). The proportion of time spent in OB focused engagement significantly related to ADOS Social communication scores (.184, $p=.025$) and ADOS RRB scores (.174, $p=.035$). Time spent in OB engagement did not relate to a child's language abilities (expressive: $-.082$, $p = .323$; receptive: $-.096$, $p=.246$). Children who spent more time OB engaged were more likely to have higher ADOS SC and RRB scores (greater symptoms).

Conclusions: The results indicate that ADOS symptoms, but not language, significantly relate to time spent object engaged. More autism symptoms were associated with more time in object engaged states. Object engaged states may limit language learning because the focus is on objects only and not people and objects. Future work is needed to explore the extent to which a primary focus on objects facilitates some skills but not others among young autistic children, and how targeted interventions can benefit both joint engagement and language learning.

403.183 Autism and Female Toddlers: Uncovering Subtle Differences in Social Affect and Self-Help

A. Furey^{1,2}, A. J. Schwartz³, C. Rice⁴ and M. South⁵, (1)College of Arts and Sciences, Emory University, Atlanta, GA, (2)Emory University School of Medicine, Emory Autism Center, Decatur, GA, (3)Department of Psychiatry & Behavioral Sciences, Emory University School of Medicine, Decatur, GA, (4)Division of Human Development and Disability, Centers for Disease Control and Prevention, Atlanta, GA, (5)Psychology & Neuroscience, Emory Autism Center, Decatur, GA

Background: Compared to males diagnosed with Autism Spectrum Disorder (ASD), females are more likely to be misdiagnosed, late-diagnosed, or undiagnosed. Thus, differences are expected and often attributed to cognitive and social development discrepancies between sexes. However, existing research remains inconclusive. Better understanding of predictive autism traits in young females can lead to better screening, diagnosis, and targeted early interventions to improve long-term successful outcomes.

Objectives: To explore sex differences in early autism trait presentation of very young toddlers with a high likelihood for diagnosis, to improve the understanding and identification of the female autism phenotype.

Methods: Data was part of a larger study piloted by the Emory Autism Center and the Georgia Department of Public Health to increase capacity for early diagnosis via outreach in mostly rural and micropolitan public health regions. All data was from toddlers aged 16-33 months who were enrolled in early intervention in Georgia. Those who screened as “High-Risk” on the Modified Checklist for Autism in Toddlers – Revised with Follow-Up (MCHAT-R/F) were referred for a telehealth assessment completed with standardized methodology. The impact of biological sex on trait presentation was examined via analysis of scores from the MCHAT-R/F and Developmental Profile 4 (DP-4), items from the standard intake and developmental history form, and final diagnostic outcomes. All analyses were completed through IBM SPSS Statistics Version 29.0.2.0. (20).

Results: Participants ($N = 163$) had an average age of 25.3 months ($SD = 4.2$) at referral. Females represented approximately one-third of the sample (107 male, 56 female). The sample was 40.5% White, 52.8% Black or African American, 2.5% Asian, and 4.3% More Than One Race. Significant differences between sexes for outcome variables included area of initial caregiver concern, with behavioral and motor concerns significantly over-represented in males ($p < .05$) while females had a significantly higher likelihood of having self-help and social skills concerns ($p < .05$). Additionally, females were reported by caregivers as significantly less likely to smile and laugh and less likely to have concern for others ($p < .05$). Caregivers also significantly reported males were more interested in learning new things, and clinicians reported males were more likely to meet B3 criteria of fixated interests ($p < .05$). No significant differences were found regarding demographic variables, M-CHAT-R/F or DP-4 scores, or other diagnostic outcomes.

Conclusions: Males were more likely to have observable and problematic initial concerns like behavioral and motor issues and intense interests. Contrastingly, females were more likely to show more subtle concerns with general social and self-help skills, as well as less obvious atypical social behaviors like minimal smiling or concern for others. Broad cognitive and social measures did not pick up on these smaller differences, which may suggest additional screening/assessment questions needed for females in the larger population. Significant differences in autism presentation between sexes are present but may easily go undetected. Further investigation of these subtle differences, especially in moderate-risk groups, are paramount for understanding autism in females to ensure early identification and maximize opportunities for success.

403.184 Capturing Emotion Dysregulation in Early Childhood: Exploring Associations between Parent-Report and Observational Measures in Autistic and Non-Autistic Preschoolers

J. B. Northrup, S. Eldeeb and C. A. Mazefsky, Department of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, PA

Background: Emotion dysregulation (ED) is more prevalent and severe in autistic children compared to non-autistic peers. Typically, ED is measured through either parent reports or observational methods (i.e., emotion-evoking tasks) during which behavior and/or physiological measures are captured. However, findings from these different measurement approaches do not always align, potentially reflecting different facets of ED. Furthermore, given social and communication differences in autism the relationship between these measurement methods may differ for autistic children compared to their peers.

Objectives: This study aimed to 1) analyze the associations between three different methods of ED measurement (parent report, examiner-rated parent interview, observed affect during frustration tasks) in autistic and non-autistic preschoolers and 2) identify subgroups of preschoolers who showed similar patterns of association across the three measures.

Methods: The sample consisted of 57 3- and 4-year-olds (24 autistic; 33 non-autistic; mean age: 4.15 ± 0.52). Parents completed the Emotion Dysregulation Inventory-Young Child (EDI-YC), a parent report measure characterizing ED across two dimensions: reactivity (fast, intense emotional reactions) and dysphoria (low positive affect, sadness). Parents were interviewed using the Early Childhood Irritability-Related Impairment Interview (E-CRI) and scored by the interviewer on impairment associated with child ED across five contexts: home life, out-and-about, with peers, with nonparental adults, and in school/daycare. Finally, parents and children were observed at home during a series of frustration tasks and child negative affect presence and intensity were coded in five second intervals.

We examined bivariate correlations between all measures within the autistic and non-autistic samples separately. We utilized a machine learning clustering technique (Random Forests) to identify subgroups of preschoolers who exhibited similar characteristics across the three measures.

Results: Figure 1 presents the correlation coefficients between observed dysregulation and parent reported dysregulation (EDI and E-CRI) for both the autistic and non-autistic groups. In the autistic group, there were stronger associations observed between parent reports and observational measures across several pairs. The machine learning analysis revealed three ED subgroups. One displaying high levels of ED across all measures (high ED group), one displaying low levels of ED across all measures (low ED group), and one displaying low levels of ED across parent report variables but moderate levels of *observed* dysregulation (mixed ED). Figure 1 shows the percent of the autistic and non-autistic samples within each of these ED subgroups. Notably, 42% of the non-autistic sample was in the “mixed ED” group, while only 2 autistic children were in this group.

Conclusions: These findings highlight differences in the relationship between parent-reported measures of emotion dysregulation and observational measures in autistic and non-autistic children. Notably, parent report and observational measures converged more strongly in autistic children than non-autistic peers. Such differences may stem from variations in parent interpretation of behavior and/or the diverse ways child ED manifests across different contexts. Understanding these differences is essential for future research aimed at characterizing ED in autism. The final presentation will incorporate a larger sample size (100 expected participants) and the addition of physiological data from the observational tasks to further understand these associations.

403.186 Comparison of Multiple Autism Screeners, Used Individually and in Combination, at 18 and 24 Months of Age

D. N. Gangi, C. Parikh, R. Ni, M. M. Hill, S. Maqbool, G. S. Young and S. Ozonoff, Psychiatry & Behavioral Sciences, UC Davis MIND Institute, Sacramento, CA

Background: Autism screening tools can aid in early detection of autism. Most screening studies are challenged to calculate psychometric indices of sensitivity and specificity because they typically assess only screen-positive cases and do not follow screen-negatives, thus not identifying missed cases of autism (Levy et al., 2020; McPheeters et al., 2016; Siu et al., 2016). We addressed this limitation of prior research in our study by using multiple screening measures, conducting repeat screenings, evaluating a random sample of approximately 10% of screen-negatives, and conducting surveillance at study conclusion.

Objectives: To examine psychometric properties of three autism screeners, when used independently and in combination, in a large community sample at 18 and 24 months, ages of common pediatric screening.

Methods: 838 families completed three screening measures online at 18 and 24 months of age: Video-referenced Infant Rating System for Autism (VIRSA; video-based measure in which caregivers rate which video clips depicting varying social-communication ability are most like their child, with no written descriptions of behavior), Infant-Toddler Checklist (ITC; written questionnaire in which caregivers rate social-communicative behaviors), and Modified Checklist for Autism in Toddlers-Revised (M-CHAT-R; written questionnaire in which caregivers answer 20 yes/no questions about autism-relevant behaviors). Screening positive was defined for each measure: VIRSA score ≤ 3 (Young et al., 2020), ITC composite score below 10th percentile (Wetherby & Prizant, 2002), and M-CHAT-R score ≥ 3 (Robins et al., 2014). Outcomes (ASD or no ASD) were determined at 36 months via telehealth diagnostic evaluation (including TELE-ASD-PEDS and Developmental Profile) for children who screened positive on any measure at any age and a random sample of children who screened negative on all screeners at every age. 86 (10%; 1 from screen-negative group) were classified with ASD at 36-month outcome.

Results: Sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV) for each screener when used in isolation at both ages are presented in Table 1. As can be seen from True Positives identified by each measure, our multi-screener approach identified cases that would have been screen-negatives if using only one screener. Logistic regressions to examine the unique predictive value of each measure (see Table 2) indicated that all three screeners were uniquely predictive at each age. We then examined sensitivity, specificity, PPV, and NPV at both ages for combinations of screeners (i.e., screening positive on 2 or 3 screeners), presented in Table 1.

Conclusions: Our study allowed for the calculation of all psychometric performance characteristics (not only PPV and NPV, but also sensitivity and specificity) through the use of multiple autism screeners and diagnostic follow-up on screen-negative cases, addressing limitations of previous work. Each screener provided non-redundant information at each age and identified true positive cases that were not detected by the other screeners. Our findings support the use of multiple screeners at the common ages of pediatric screening for autism, particularly the ITC and M-CHAT-R in combination.

403.187 Developing an Infant Reward Processing Scale from the Infant Behavior Questionnaire – Revised Short Form

Y. C. Kuo¹, M. McEllin¹, C. L. Wilkinson², M. Bosquet Enlow³, H. Tager-Flusberg⁴, C. A. Nelson⁵ and C. C. Clements¹, (1)University of Notre Dame, South Bend, IN, (2)Department of Developmental Medicine, Boston Children's Hospital / Harvard Medical, Boston, MA, (3)Boston Children's Hospital, Boston, MA, (4)Psychological and Brain Sciences, Boston University, Boston, MA, (5)Department of Developmental Medicine, Boston Children's Hospital, Boston, MA

Background: The Social Motivation Hypothesis of autism posits that autistic individuals may be less likely than neurotypical individuals to find social stimuli rewarding. Evidence suggests that school-age children, adolescents, and adults on the spectrum show diminished neural responses to rewarding social and nonsocial stimuli compared to neurotypical peers (Clements et al., 2018). Reward processing is commonly studied in school ages through adulthood, but rarely in infancy and toddlerhood, when reward circuitry begins developing and when autism becomes apparent. In this study, we explore a potential parent-report measure of reward processing for use during infancy. We leverage the commonly used Infant Behavior Questionnaire-Revised Short Form (IBQ-R-SF), a 91-item measure of infant temperament suitable for infants aged 3-12 months. Although some of the existing fourteen IBQ-R subscales tap aspects of reward processing, a subscale specific to reward processing does not yet exist. The derivation of a reward composite will facilitate collection of parent-report data to test the Social Motivation Hypothesis in the first year of life.

Objectives: To develop a reward composite scale from the IBQ-R-SF.

Methods: The IBQ-R-SF was reviewed by three authors to identify items that might comprise three novel subscales relevant to reward processing (effort, response, anticipation), mirroring methods of similar efforts (Irwin et al., 2024; Marrus et al., 2022). IBQ-R-SF data collected at Boston Children's Hospital were factor analyzed in a discovery sample of 692 infants (ages 5-12 months) and in an independent replication sample of n=173 9-month-olds. Exploratory factor, confirmatory factor, and reliability analyses were performed iteratively. Items with the lowest factor loadings and item-total correlations were pruned until goodness-of-fit indices reached acceptable levels in the discovery sample and all primary factor loadings exceeded 0.25.

Results: Of the 91 IBQ-R-SF items, 29 items were selected by two or more raters for inclusion in the reward processing composite. After pruning, 18 items remained. An exploratory factor analysis showed a three-factor solution as the best fit in the discovery sample. Fit indices in confirmatory factor analysis suggested adequate fit in the discovery sample (RMSEA=0.094, SRMR=0.071, CFI=0.709) and the replication sample (RMSEA=0.10, SRMR=0.069, CFI=0.827). Across samples, loadings ranged from 0.167-0.921. Although goodness-of-fit indices for these novel reward composite scales did not reach desired thresholds (RMSEA <0.05, CFI>0.90, SRMR<0.05), the standard IBQ-R-SF factor structure showed worse fit in both samples (discovery sample: RMSEA=0.073, SRMR=0.115, CFI=0.572; replication sample: RMSEA=0.115, SRMR=0.111, CFI=0.728), consistent with past efforts that failed to replicate the standard subscale structure (Gartstein et al., 2005; Bosquet Enlow et al., 2016). Items loading on the three reward composite factors appeared to tap constructs of approach, positive response to toys and books, and smile/laughter during physical play.

Conclusions: Three reward subscales were created from a subset of IBQ-R-SF items. These subscales may be used to track the development of reward-relevant behavior, informing the Social Motivation Hypothesis of autism. These novel subscales showed promising fit in two independent samples. Future directions include assessing construct validity, discriminant validity, and differences in reward composite scores for infants who do and do not develop autism.

403.188 Developmental Changes in the Remote Assessment of Prediction Abilities in Infants with and without a Sibling with Autism
M. Harris¹, E. Tenenbaum², A. Waterman², C. Lew-Williams³, M. H. Vu⁴, C. Stone⁵, M. Hare⁴, K. Gilyard⁶, R. Landa⁷, S. J. Sheinkopf⁸, J. B. Wagner⁹ and S. Jeste⁴, (1)*Duke University Medical School, Durham, NC*, (2)*Department of Psychiatry and Behavioral Sciences, Duke University, Durham, NC*, (3)*Princeton University, Princeton, NJ*, (4)*Children's Hospital Los Angeles, Los Angeles, CA*, (5)*Department of Psychiatry and Behavioral Sciences, University of North Carolina Greensboro, Durham, NC*, (6)*Psychology, Harvard University, Cambridge, MA*, (7)*Center for Autism Services, Science and Innovation, Kennedy Krieger Institute, Baltimore, MD*, (8)*Thompson Center for Autism & Neurodevelopment, University of Missouri, Columbia, MO*, (9)*Department of Psychology, College of Staten Island, CUNY, Staten Island, NY*

Background:

Previous research suggests a connection between autism and difficulties with prediction (Cannon et al., 2021; Sinha et al., 2014). Our understanding of the development of this critical skill in autism has been limited by the need for in-person assessment, which typically involves small samples. Examining developmental milestones such as prediction in large samples of infants, including those who will later receive an autism diagnosis, would help elucidate the relevance of these mechanisms for cognitive development in autism. The Remote Infant Studies on Early Learning (RISE) Battery was developed to address this need. Here, we present preliminary results from the RISE Prediction Task, which assesses anticipatory looks to cued spatial locations following familiarization. Previous research has shown correlations between this type of visual prediction and language abilities in toddlers without autism (Reuter et al., 2018).

Objectives:

1. To test a simplified version of a visual prediction task that can be administered in the infant's home for infants with and without an autistic sibling.
2. To test for developmental changes in visual prediction abilities during the first year of life.

Methods:

To date, 55 6-month-old infants and 56 12-month-old infants without an autistic sibling (49% female, 51% male; 8.3% Asian, 1.8% Black, 52.3% White, and 37.6% more than one race) have enrolled. We have also tested 35 infant siblings of autistic children (6 months, n = 23; 12 months, n = 12; target n = 100) for whom data analysis is underway. Infants view 16 trials on their home computer. In each trial, an animated central cue is displayed (2 sec), followed by a colorful animated pinwheel that appears on either the left or right side of the screen (2 sec). For Trials 1-8, the pinwheel appears on one side and for Trials 9-16, it appears on the opposite side (starting side counter-balanced between infants). The dependent measure is the proportion of trials with an anticipatory eye movement (AEM), defined as looks to the target side occurring 200 ms before the central cue disappears and up to 200 ms after the target appears.

Results:

In Block 1, 6-month-olds did not reliably demonstrate AEMs until Trial 7 (Fig 1). Twelve-month-olds did so starting at Trial 3 (Fig 2). In Block 2, 12-month-olds were able to update their predictions about the new location reliably by Trial 16, whereas 6-month-olds failed to do so on any trial.

Conclusions:

In the remote setting, we successfully measured infant abilities in the domain of visual prediction, objectively and in a scalable manner. We demonstrated a developmental shift between 6 and 12 months in the ability of infants to predict and update their predictions about a target location. This work has implications for our capacity to assess this important cognitive ability in large samples of infants and can help us track the trajectory of prediction in infants who will go on to receive an autism diagnosis.

403.189 Distinct Pathways to Anxiety: Early Behavioral Inhibition and Social Anxiety in Syndromic and Idiopathic Autism

K. B. Cortez¹, R. M. Hantman², E. A. Hunt³, H. Petee⁴, S. Serang¹, A. L. Hogan⁵, H. Arnold¹, X. Fu⁶ and J. Roberts¹, (1)*Department of Psychology, University of South Carolina, Columbia, SC*, (2)*Psychology, University of South Carolina, Columbia, SC*, (3)*Department of Psychology, University of South Carolina, Columbia, SC*, (4)*University of South Carolina School of Medicine, Columbia, SC*, (5)*Department of Communication Sciences and Disorders, University of South Carolina, Columbia, SC*, (6)*University of South Carolina, Columbia, SC*

Background: Anxiety affects ~40-50% of individuals with autism spectrum disorder (ASD).¹ Fragile X syndrome (FXS), the most common single-gene cause of ASD (i.e., 2-6% of ASD cases),^{2,3} is highly co-occurring with anxiety disorders, with 77-86% meeting criteria (e.g., social anxiety).⁴ ASD cases linked to known genetic conditions, like FXS, are referred to as "syndromic ASD," while those without a known genetic cause are "idiopathic ASD." Behavioral inhibition (BI), a temperament trait marked by heightened reactivity to novelty,⁵ increases risk for anxiety symptoms in childhood.⁶ Prior research identified differences in BI in ASD; autistic toddlers exhibit a muted fear response compared to neurotypical (NT) children.⁷ Yet, little is known how BI relates to later anxiety symptoms in ASD and how fear responses differ between idiopathic and syndromic ASD.

Objectives: To investigate differences in BI and explore the relationship between early (36 months) BI in and later (60 months) social anxiety in toddlers with syndromic ASD (FXS+ASD), toddlers with idiopathic ASD, and NT toddlers.

Methods: Participants included 46 children with ASD (85% male), 26 FXS+ASD children (85% male) and 30 NT children (71% male). The clinical best estimate (CBE) procedure⁸⁻¹² confirmed ASD diagnosis. At 36 months ($M(SD)_{ASD} = 37.01(1.73)$; $M(SD)_{FXS+ASD} = 37.28(1.75)$; $M(SD)_{NT} = 36.78(1.20)$), the Stranger Task¹³ was administered. Bodily fear, facial fear, and escape behaviors were coded from video. Social anxiety symptoms were measured at 60 months ($M(SD)_{ASD} = 59.27(2.63)$; $M(SD)_{FXS+ASD} = 59.60(3.36)$; $M(SD)_{NT} = 59.67(2.17)$) using the social anxiety subscale raw score from the Preschool Anxiety Scale-Revised.¹⁴ Path analysis¹⁵ was conducted to investigate how being part of the ASD or FXS+ASD group relates to fear behaviors at 36 months. Additionally, the analysis explored how fear behaviors, group membership, and their interaction were associated with social anxiety symptoms at 60 months. For skewness, social anxiety scores were log-transformed.

Results: Preliminary analyses showed more escape behaviors were observed in the FXS+ASD group compared to the NT group ($\beta = 0.36, p = .012$; Figure 1). Significant interactions were found between facial fear and both the ASD ($\beta = -7.21, p = .001$) and FXS+ASD groups ($\beta = -5.91, p = .005$), indicating that the relationship between early facial fear and later social anxiety differed from the NT group (Figure 2). While higher facial fear predicted more social anxiety in NT children, this association was reversed in children with ASD or FXS+ASD.

Conclusions: Preliminary findings suggest children with FXS+ASD exhibit more BI, as reflected in higher levels of escape behavior. However, the relationship between early facial fear and later social anxiety observed in NT children was not present in children with ASD or FXS+ASD. These different associations underscore the need for tailored approaches in identifying anxiety in ASD. This study's novel use of CBE to confirm diagnosis of ASD in FXS moves beyond merely examining the spectrum of ASD symptoms in FXS, addressing nuanced ways in which anxiety, fear behaviors, and ASD may interact in idiopathic and syndromic ASD, providing valuable insights into these distinct developmental pathways.

403.190 Dysregulation Is a Predictor of Time Unengaged in Toddlers with Autism

S. T. Seese^a, E. C. Hayashi^b and C. Kasari^c, (1)University of California, Los Angeles, Los Angeles, CA, (2)Kasari Lab, University of California, Los Angeles, Los Angeles, CA, (3)Education and Psychiatry, University of California Los Angeles, Los Angeles, CA

Background: Toddlers with autism often have challenges with joint attention and tend to have shorter durations of joint engagement compared to typically developing peers. Since joint engagement plays a key role in enhancing social communication skills (such as joint attention or language), it would be apparent that dysregulation in young toddlers may negatively affect their ability to engage with a play partner.

Objectives: This study aims to explore the relationship between dysregulation and joint engagement within the context of a free play interaction between toddlers with ASD and their caregivers.

Methods: Data were drawn from two larger randomized control trials including 149 infants/toddlers ($M \text{ age} = 21 \text{ months}$) with autism (see Table 1). At baseline of the intervention, dysregulation behaviors and engagement states were coded during a 10-minute free play caregiver-child interaction. Dysregulation behaviors were coded by (a) type and (b) proportion time (in seconds) dysregulated. Dysregulation behaviors include (a) negativity (b) physical venting (c) idiosyncratic behaviors (d) avoidance (e) distraction (f) verbal repetitive behaviors (g) self-soothing and (h) other-directed comfort seeking. Engagement is coded via states, which include (1) unengaged (e.g., wanders, looks around), (b) onlooking (c) person engaged (d) object engaged (e) supported jointly engaged and (f) coordinated jointly engaged. Proportion of time (in seconds) in the unengaged state is used for analysis.

Results: Total time dysregulated significantly and positively relates to time unengaged ($r(148) = .361, p < .001$), such that higher time dysregulated relates to higher time unengaged. A multiple regression analysis was conducted to examine if proportion of total time unengaged could be predicted by proportion time dysregulated, while controlling for child ADOS scores and nonverbal cognitive ability (NVDQ). The overall model was significant, $R^2 = .183, (F(4,143) = 8.013, p < .001)$. Proportion time dysregulated was the strongest predictor, $b = .454, t(143) = 4.275, p < .001$.

Conclusions: Results suggest that the duration of dysregulation is significantly related to time unengaged within the caregiver-child play interaction. While children can be engaged while also being dysregulated (they are not mutually exclusive), these results highlight that these toddlers are indeed *unengaged* while exhibiting dysregulation. Repercussions for less time spent jointly engaged has implications to other developmental outcomes, including social communication (Shih et al., 2021). Given that children with ASD are at risk for challenges with emotion regulation and have challenges with joint engagement, this work has implications for future intervention targets. This study has also implications for investigating the role of the caregiver within the interaction, specifically in terms of facilitating joint engagement and supporting the child's emotion regulation.

403.191 Early Developmental Pathways in Infants at Elevated Likelihood for Autism: Towards an Innovative Biomarker Approach to the Study of Social and Non-Social Audiovisual Processing

E. Capelli^a, M. Cassa^a, L. Billeci^a, E. M. Riboldi^a, C. Beretta^a, G. Procissi^a, E. Siri^a, C. Cantiani^a, C. Piazza^a, M. Molteni^a and V. Riva^a, (1)Scientific Institute IRCCS Medea, Bosisio Parini, Italy, (2)Scientific Institute, IRCCS E. Background: Autism is characterized by significant heterogeneity, with individual differences not only in the severity of core symptoms but also in cognitive, language, sensory, and behavioral domains, which follow distinct developmental trajectories. There is growing interest in identifying reliable behavioral and brain-based biomarkers that could serve as early detection tools for autism. Autistic individuals exhibit differences in integrating sensory information across multiple modalities, such as audiovisual (AV) integration, and they process social and non-social stimuli differently compared to neurotypical (NT) individuals. However, research exploring the potential interactions between sensory and social processing in early life is still limited, and no studies have investigated early social and sensory markers in infant siblings of autistic children (EL) using integrated experimental techniques.

Objectives: This study introduces a novel research protocol that integrates electroencephalography (EEG oscillations) and eye-tracking (pupillometry) to (1) characterize AV processing in social and non-social contexts in EL compared to NT toddlers and (2) examine the association between early developmental pathways of early social/non-social audiovisual integration and later clinical outcomes.

Methods: The study includes 34 EL toddlers and 31 NT toddlers, all recruited at 18 months, with follow-up assessments conducted at 24 months. At both time points, participants undergo a comprehensive experimental protocol that includes pupillometry and EEG measurements. The integrated EEG-eye-tracking task focuses on AV processing in both social and non-social conditions. Videos are presented in both synchronous and asynchronous modalities (with a 1000 ms audio delay), resulting in four conditions: SOC/SYNCH, SOC/ASYNCH, NONSOC/SYNCH, and NONSOC/ASYNCH.

Results: Preliminary results from pupillometry analysis using a general linear mixed (GLM) model revealed a significant interaction group X time-point ($F=3.434$; $p<.05$). EL toddlers exhibited smaller pupil dilation in response to social stimuli compared to NT toddlers at both 18 and 24 months, with a significant reduction in pupil size from 18 to 24 months in the EL group (Figure 1a). Notably, only EL toddlers with clinical signs of autism (ELAUT+) had significantly smaller pupil size changes at 24 months compared to both NT toddlers and EL toddlers without clinical signs of autism (ELAUT-; $F=4.170$, $p=.020$; see Figure 1b). Furthermore, preliminary EEG findings showed that ELAUT+ toddlers exhibited lower EEG power in the theta band (frontal regions) in response to social stimuli compared to ELAUT- toddlers ($F=2.483$; $p=.036$; see Figure 2a,b).

Conclusions: These results underscore the importance of integrating sensory and social processing measures in early assessments, as they may provide valuable insights into the developmental trajectories of children at EL of autism. Further research is needed to confirm these findings and explore their potential for early diagnosis and individualized supports.

403.192 Early Motor Indications for ASD Diagnosis during Infancy

L. Kalich¹, S. Lev-on¹, C. Yoffe¹, A. Yohanan², D. Yaffe² and O. Bar Yosef¹, (1)Weinberg Child Development Center, Sheba Medical Center, Tel HaShomer, Israel, Ramat Gan, Israel, (2)Weinberg Child Development Center, Sheba Medical Center, Ramat Gan, Israel, (3)MDClone, Beer Sheva, Israel, (4)Weinberg Child Development Center, Pediatric Neurology, Safra Children Hospital, Sheba Medical Center, Tel Hashomer, Ramat Gan, Israel

Background: Autism Spectrum Disorder (ASD) is marked by challenges in communication, social interaction, and repetitive behaviors. Many children with ASD also experience additional difficulties, including sensory processing and sleep issues. Prior research has linked ASD to fine motor (FM) deficits, predominantly in children over three years of age. Early assessment of FM skills, starting at one year, may reveal developmental delays associated with ASD.

Objectives: This study examines the relationship between FM difficulties prior to three years of age and the subsequent development of ASD. It aims to characterize FM deficits in children with ASD and compare these to those in children diagnosed with Global Developmental Delay (GDD), with the intention of identifying FM characteristics that may serve as early indicators of ASD.

Methods: We conducted a retrospective analysis of FM function using the Peabody Developmental Motor Scales, 2nd Edition (PDMS-2), which includes assessments for Grasping and Visual-Motor Integration (VMI). Data were gathered from the Sheba Medical Center from 2012 to 2023, employing MDCLONE software for data extraction and Python for statistical analysis.

Results: Over the study period, 9,700 children under 18 years visited the Child Development Center, with 3,590 diagnosed with ASD and 622 with GDD. Among these, 383 ASD and 345 GDD children were evaluated using the PDMS-2 before age three. Fine motor delays (≤ 16 th percentile on PDMS-2) were identified in 60% of the ASD group and 52% of the GDD group. Notably, children with ASD were assessed at an older age than those with GDD (21 months vs. 14 months, $p<0.05$). The average percentile for both groups was 7%. A significant difference was observed in VMI scores: children with ASD averaged 7.2% compared to 12% in the GDD group ($p<0.05$). In the Grasping test, ASD children averaged 19%, while GDD children averaged 14% ($p<0.05$). Similar FM deficit patterns were noted with an 18-month age cut-off.

Conclusions: Our findings highlight a robust association between FM deficits and ASD, with children with ASD exhibiting significantly lower VMI scores compared to those with GDD, even before 18 months of age. Impaired VMI may serve as a critical early indicator for later ASD diagnosis, underscoring the need for early screening and intervention.

403.193 Effectiveness of Jasper Interventions in Community-Based Child Development Support Centers in Japan

M. Kuroda^{1,2}, M. Hamada¹ and M. Tsujii¹, (1)Denen-chofu University, Department of Psychology, Kawasaki, Kanagawaken, Japan, (2)Department of Psychology, Denen-chofu University, Kawasaki, Japan, (3)Department of Psychology, Chukyo University, Toyota, Aichiken, Japan, (4)Department of Contemporary Sociology, Chukyo University, Toyota, Aichiken, JAPAN

Background: JASPER (Joint Attention Symbolic Play Engagement and Regulation) is an intervention designed to improve "social communication," one of the core symptoms of Autism Spectrum Disorder (ASD). In Japan, government policies have led to the establishment of child development support centers within local communities for toddlers with developmental disorders. However, it is uncertain whether validated early intervention methods are being consistently implemented.

Objectives: This study aims to examine the effects of interventions based on the JASPER concept, implemented by multidisciplinary teams in child development support centers within local communities in Japan.

Methods:

[Participants] The study involved toddlers attending child development support centers that incorporated the JASPER concept in both Tokyo and other regional cities. There was one facility in Tokyo and two in other regions.

[Procedure] The intervention methods varied depending on the facility and the specific needs of the toddlers. Sessions typically consisted of one hour of individual instruction.

[Evaluation Measures] The Japanese version of the Vineland Adaptive Behavior Scales, Second Edition (Vineland-II), the New Edition of the K-Developmental Scale (which assesses developmental levels in three areas: postural-motor, cognitive-adaptive, and language-social, as well as overall development), and SPACE (Short Play and Communication Evaluation), a brief assessment used when setting short-term goals in JASPER, were used.

Results:

[Participants] The study included 27 toddlers (22 boys, 5 girls) attending community-based child development support centers. The average age of the children at the start of the intervention was 41 months (range: 19-72 months), and the average duration of attendance was 8 months (range: 4-19 months).

[Changes in Evaluation Measures] Paired t-tests were conducted on the scores of each domain and item in the Vineland-II, SPACE, and the K-Developmental Scale before and after the intervention, and Cohen's d was calculated for effect size. Significant improvements were observed in the following key indicators: In the Vineland-II Adaptive Behavior Scales, significant differences were found in the Socialization ($t(25)=3.59, p<.01, d=.69$) and Communication ($t(25)=2.85, p<.01, d=.55$) domains. Additionally, there were significant improvements in language and play levels. Furthermore, correlations between pre- and post-intervention differences in significant evaluation measures and the age at the start of the intervention were examined. A significant correlation was found between age at the start of intervention and the Communication domain of the Vineland-II ($r=-.48, p<.05$), responding to joint attention in SPACE ($r=-.70, p<.01$), 1-to-1 matching in SPACE ($r=-.51, p<.05$), and pre-symbolic play in SPACE ($r=-.47, p<.05$).

Conclusions: The results confirmed improvements in social interaction and language development, even when the intervention was carried out by staff other than psychologists. In fact, interventions based on the JASPER concept in community-based child development support centers showed improvements across a wide range of developmental areas in Japan. This suggests that frequent interventions within local communities, even by non-psychologists, may yield greater effects. Additionally, it was shown that the earlier the intervention starts, the greater the positive impact on improvements in communication and play levels.

403.194 Effects of Sleep on Motor Abilities of Infants with Higher and Lower Familial Likelihood of Autism in the First Year of Life

M. Leff¹, J. Munson², S. R. Dager³, T. St. John⁴, J. Piven⁵, H. Hazlett⁶, R. T. Schultz⁷, N. Marrus⁷, L. Zwaigenbaum⁸, J. Pandey⁹, M. D. Shen⁵ and A. M. Estes¹⁰. (1)Pediatrics, University of Washington, Seattle, WA, (2)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (3)Radiology, University of Washington, Seattle, WA, (4)University of Washington, Seattle, WA, (5)University of North Carolina, Chapel Hill, NC, (6)The Center for Autism Research/CHOP, Philadelphia, PA, (7)Washington University in St. Louis, St. Louis, MO, (8)University of Alberta, Edmonton, AB, Canada, (9)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (10)Speech and Hearing Sciences, UW Autism Center, Seattle, WA

Background: Sleep alterations can be evident as early as 6 to 12 months of age in infants who later develop autism spectrum disorder (ASD). Infants with a higher familial likelihood of developing ASD (HL) demonstrate longer sleep onset latency and increased nighttime awakenings. HL infants who are diagnosed with ASD also tend to show less advanced gross motor skills compared to typical infants between 6 and 24 months. Research suggests that daytime sleep (i.e., naps) influences motor learning in typically developing infants. Motor abilities represent an accrual of previous learning experiences (i.e., motor learning) and maturation. However, the effect of sleep alterations on motor abilities in HL infants is not well understood. Given the role of sleep in motor learning in the first year of life, understanding how sleep relates to motor abilities has the potential to identify mechanisms in the early development of autism and guide the timing and implementation of effective interventions. **Objectives:** We aim to examine the relationships between sleep and motor abilities in infants with higher familial likelihood (HL) and lower familial likelihood (LL) of developing ASD.

Methods: Participants were part of the ongoing, multi-site, Infant Brain Imaging Study (IBIS) replication cohort and Sleep Study. Sleep characteristics in 192 infants (HL 144; LL 48) at 6 months, 134 (HL 107; LL 27) at 12 months, and 104 (HL 81; LL 23) longitudinally at 6 and 12 months were evaluated using the parent-reported Brief Infant Sleep Questionnaire (BISQ; hours of night sleep, day sleep, sleep onset latency, night wakefulness). Motor abilities were assessed using two examiner-delivered, standardized measures: the Bayley Scales of Infant and Toddler Development (Bayley; Gross Motor/GM, Fine Motor/FM), and the Alberta Infant Motor Scale (AIMS; Total Score). Multiple regression analysis was used to assess if sleep is associated with motor abilities and whether this association differs between groups.

Results: At 6 months, there was a positive association between daytime sleep (hrs) and higher GM scores in LL (Total Score $r=0.39$; $p=.033$; GM $r=0.37$; $p=.008$) but not HL infants (Total Score $r=-0.03$; ns; GM $r=-0.02$; ns). AIMS Total Score was related to sleep at 6 months but the interaction term fell short of significance (see Table 1). We found no significant relationships between sleep and FM at any age, sleep and GM at 12 months, or sleep at 6 months and motor at 12 months.

Conclusions: We found partial, preliminary support for an association between daytime sleep and gross motor ability consistent with a previously established relationship between naps and motor learning in typically developing infants in the first year of life. As this is an ongoing longitudinal study, future research will include outcome diagnosis at 24 months of age which may shed further light on group differences. The sample size will continue to increase, and the trend-level Group by Daytime sleep associations observed here will be clarified. Future research is needed to provide insights into the influence of sleep on the developmental trajectories of motor abilities in infants.

403.196 Examining Early Language Development Among Infant Twin Pairs: Comparing Expressive and Receptive Language and Implications for Autism Diagnosis

M. Hohl¹, N. Islam¹, J. D. Douglas-Brown², R. Young³, M. Pileggi⁴, S. Shultz⁵, A. Klin⁵ and W. Jones³, (1)Marcus Autism Center, Children's Healthcare of Atlanta, Atlanta, GA, (2)Psychology, Marcus Autism Center, Children's Healthcare of Atlanta and Emory University School of Medicine, Atlanta, GA, (3)Marcus Autism Center, Atlanta, GA, (4)Pediatrics, Marcus Autism Center, Atlanta, GA, (5)Marcus Autism Center, Emory University School of Medicine and Children's Healthcare of Atlanta, Atlanta, GA

Background:

Early identification of communication delays can facilitate implementation of early intervention services, thereby significantly impacting a child's developmental trajectory while building foundational language and social-communication skills (Morgan, et al., 2020). Research on multiples has historically reported higher rates of language and speech delays when compared with singleton children, suggesting twins would benefit from early intervention when delays are noted (Thorpe, 2006, Rutter, et. al, 2003, McMahon & Dodd, 1997). There is a gap in research assessing longitudinal language development among infant twin pairs, inclusive of early gestational ages. This prospective study aims to address this gap by comparing direct assessment of early language development at 6 months to direct assessment at 18 months.

Objectives:

1. Evaluate the relationship between 6-month standardized expressive and receptive language scores to 18-month standardized expressive and receptive language scores considering gestational age and zygosity.
2. Evaluate 6-month to 18-month standardized language assessment in correlation with a later autism diagnosis.

Methods:

This study was conducted as part of an ongoing prospective longitudinal study on infant twins of all medical backgrounds. Preliminary data was collected from 15 twin sets (n=30 infants) who completed the Mullen Scales of Early Learning (MSEL; Mullen, 1995) at 6-month and 18-month time points and the parent-reported Goldsmith Child Zygosity Questionnaire (Goldsmith, 1991). Additionally twin pairs may receive further developmental testing, using the Autism Diagnostic Observation Schedule (ADOS-Toddler) and Vineland Adaptive Behavior Scales-3 to determine an autism diagnosis. Participants are reported as identical (n=10) and fraternal (n=20), with gestational age ranging between 27-38 weeks. Eight participants have received a confirmed diagnosis of ASD. Seven participants have received a diagnosis of language delay. ANOVA was used to analyze 6-month and 18-month standard scores for both MSEL expressive and receptive scales. Further examination was done in consideration of zygosity, gestational age, and diagnosis of ASD or language delay.

Results:

Linear regression models indicated that 6-month expressive language scores significantly predicted 18-month expressive language scores ($p=0.025$). However, models showed 6-month receptive did not significantly predict 18-month receptive language scores ($p=0.723$). Logistic regression models show ASD diagnoses were associated with lower 18m receptive scores ($p<0.001$) and lower 18m expressive scores ($p=0.003$). When included in our models, additional demographic predictors such as zygosity and gestational age, did not explain variance.

Conclusions:

Preliminary results indicate 6-month expressive scores predict 18-month expressive scores in twin sets assessed, while 6-month receptive scores do not predict 18-month receptive scores. Additionally, twins with ASD had lower expressive and receptive scores at 18-months than twins with language delay. Findings suggest that 6-month language assessment may provide clinical insight to the child's later language outcomes, and monitoring twins with language assessment as early as 6 months can improve later social-communication outcomes before 2 years. This aligns with language development research that shows expressive language as a strong predictor of later language outcomes. Based on current recruitment data, we expect 24 twin sets (n=48 infants) with complete assessment data by April 2025. Future analysis of these twin sets will continue to examine clinical implications of early assessment.

403.197 The Importance of a Multifaceted Longitudinal Examination of Anthropometric Measures in Studying the Association between Head Growth during Infancy and Risk of Autism Spectrum Disorder

L. Elbedour^a, R. Balaum^b, E. Alhozyel^b, G. Meiri^b, A. Michaelovski^c, I. Dinstein^d, O. Kerub^e and I. Menashe^f, (1)Department of Epidemiology, Biostatistics and Community Health Sciences, Faculty of Health Sciences, Ben-Gurion University of the Negev, Beer-Sheva, Israel, (2)Ben-Gurion University of the Negev, Beer-Sheva, Israel, (3)26 YA'ARA ST., Beer-Sheva, Israel, (4)Child Development Center, Soroka University Medical Center, Beer-Sheva, Israel, (5)Cognitive and Brain Sciences Department, Ben Gurion University, Beer-Sheva, Israel, (6)Ben-Gurion University of the Negev, Ministry of health, Beer-Sheva, Israel, (7)Department of Epidemiology, Biostatistics, and Community Health Sciences, Ben-Gurion University of the Negev, Beer-Sheva, Israel

Background: Some studies have reported that abnormal head size during infancy is associated with autism spectrum disorder (ASD) including reports that children with ASD are born with a relatively small head circumference that normalizes within the first year of life. In addition, higher proportions of both macrocephaly and microcephaly have been consistently reported among children with ASD. However, the specific head growth trajectories during infancy associated with ASD and their relationship with the overall weight gain of these children remain inadequately explored.

Objectives: To investigate the associations of head growth trajectories during infancy and the subsequent likelihood of ASD.

Methods: We conducted a retrospective case-control study including 262 children diagnosed with ASD and 560 controls without ASD or any other developmental disorders that were matched by age, sex, and ethnicity. Growth measures at the ages of 1, 2, 4, 6, 9, and 12 months were obtained from government-funded mother-child health clinics in southern Israel that regularly monitor the growth and development of all children in this region. We divided the sample into seven clusters based on their head growth trajectories (**Figure 1**) and used conditional logistic regression models to assess the independent association of these clusters with ASD.

Results: The study sample comprised 78.2% males and 76.8% Jewish children. HC and weight were significantly correlated throughout the study period (Pearson Correlation $r = 0.45-0.59$, $p < 0.001$), and notably stronger in autism ($r = 0.55-0.69$) than in controls ($r = 0.36-0.55$). Children with small and large heads throughout infancy (**Figures 1 B&C**) had the highest likelihood of developing ASD compared to children with normal head size (**Figure 1A**) (adjusted odds ratio [aOR] = 3.761, 95%CI = 2.288-5.732; and aOR = 3.335, 95%CI = 2.001-6.255, respectively). Further stratification of these lower and upper quartiles revealed that the strongest associations with ASD were seen among children in the most extreme (0-5th and 95-100th) percentiles (aOR = 4.568, 95%CI = 1.991-8.877; aOR = 11.871, 95%CI = 2.765-55.467, respectively). Interestingly, the associations between head growth trajectories depicted in **Figures 1 B&C** and ASD, were mainly driven by children showing similar body weight trajectories (aOR = 6.232, 95%CI = 3.001-11.388; and aOR = 10.564, 95%CI = 3.878-28.543, respectively).

Conclusions: Our findings suggest that the reported associations between atypical head growth during infancy and ASD may be attributed to broader physical growth anomalies. This conclusion highlights the importance of a multifaceted longitudinal examination of such anthropometric measures in studies of child development.

403.198 Eye Tracking Prognosis

E. Lunkova¹, E. Bacon², C. Andreason³, C. Carter⁴, S. Arias⁵, E. Courchesne⁶ and K. Pierce³, (1)Neurosciences, UC San Diego, La Jolla, CA, (2)Neurosciences, University of California, San Diego, La Jolla, CA, (3)Autism Center of Excellence, Department of Neurosciences, University of California San Diego, San Diego, CA, (4)UCSD Autism Center of Excellence, La Jolla, CA, (5)Neurosciences, Autism Center of Excellence, UCSD, La Jolla, CA, (6)Neuroscience, Eric Courchesne, San Diego, CA

Background:

Challenges in social attention are central to ASD diagnosis and can significantly affect a child's ability to form friendships, succeed in school, and excel in future employment. However, parents of newly diagnosed children often receive limited information about the severity of these challenges and future prospects. While the DSM-5 includes severity levels, they focus on support needs rather than social attention impairment. There is a need for tools that provide objective, quantitative information about social attention severity and its potential to predict short- and long-term outcomes.

Eye tracking (ET) offers an objective measure of social attention. Our previous research using various ET tests has shown that toddlers with extremely low social attention can be accurately diagnostically classified. Additionally, we identified an ASD subgroup with markedly low social attention, linked to more severe clinical symptoms at the time of testing. However, ET's ability to predict symptom severity over time remains less understood.

Objectives:

The goals of the present study are to:

- (1) Examine the power of ET collected during the toddler period (ages 12-48 months), to predict language, cognitive, adaptive and symptom severity across short term (i.e., 6-12 months), intermediate term (i.e., 12-24 months following eye tracking) and long term (i.e., > 2 years following eye tracking periods).
- (2) To compare the predictive power of eye tracking from a single test to the predictive power associated with multiple tests.

Methods:

Subjects: Toddlers participated in 1-5 different eye tracking tests. To examine Goal #1, we leveraged ET data from 640 toddlers with ASD who had at least 1 eye tracking test during the toddler period and follow up clinical testing during the short (181), intermediate (346) or long-term testing periods (113). To address Goal #2, we examined the predictive power of 579 toddlers with ASD who had either 2, 3, 4 or 5 eye tracking tests and compared predictive performance to just 1 test. For this analysis, the most extreme eye tracking value was used.

ET: Tobii T120 or Tobii Spectrum Pro 600Hz .

Statistical Analyses: The relationships between variables were examined using Pearson correlation for preliminary analysis, and multiple multivariate regression for the follow up analysis, wherein factors such as level of treatment engagement were included, and subtype stratifiers.

Results:

Preliminary analysis revealed significant correlations between the percentage of fixation on non-social stimuli and clinical outcomes across all follow-up periods (short, intermediate, and long-term). Specifically, higher fixation on non-social stimuli was associated with poorer scores on the ADOS, Mullen, and Vineland assessments ($p < 0.05$, $r > 0.3$). Additionally, a higher number of failed eye-tracking tests was linked to worse clinical outcomes ($p < 0.05$, $r > 0.3$).

Conclusions:

The consistent association between increased fixation on non-social stimuli and poorer clinical outcomes suggests that social attention deficits, as measured through ET, could be used to identify children at higher risk for cognitive, behavioral, and adaptive functioning in toddlers with ASD.

403.199 From Genes to Gaze: Examining Multisensory Attention and Genetic Risk for Autism in Infancy

A. Marin¹, C. D'Amato¹, Y. Hu², N. Pini², L. Shuffrey³, W. P. Fifer⁴, J. Veenstra-VanderWeele⁵ and D. Amso¹, (1)Department of Psychology, Columbia University, New York, NY, (2)Department of Psychiatry, Columbia University Irving Medical Center, New York, NY, (3)Department of Child and Adolescent Psychiatry, New York University Grossman School of Medicine, New York, NY, (4)Division of Developmental Neuroscience, Columbia University Medical Center, New York, NY, (5)Columbia University, New York, NY

Background:

Recent research highlights *de novo* mutations in autism spectrum disorder (ASD), with individually rare single nucleotide variants or copy number variants collectively identified in 15-20% of individuals. In infancy, genetic risk for autism is associated with alterations in brain networks (Girault et al., 2022; Hazlett et al., 2017) that may impact audio-visual attention.

Objectives:

We examined eye gaze behaviors to determine whether audio-visual attention differs between infants at increased genetic risk (IGR) and not at genetic risk (NGR) for ASD.

Methods:

We extended a behavioral measure of audio-visual attention (Bahrick et al., 2018), where infants watched a series of social and non-social trials presented in high- and low-attention competition contexts while measuring eye movements (Fig.1). We examined three behaviors: 1) sustained attention to lateral events, 2) intersensory matching toward audio-visual synchrony, and 3) attentional disengagement from central to lateral stimuli. We analyzed a cohort of IGR ($n=7$ unique infants; $n=19$ cross-sectional datasets; $n=9$ female) and matched NGR infants ($n=5$ unique infants; $n=11$ cross-sectional datasets; $n=7$ female) assessed at 4, 6, 9, 12, and 15 months.

Results:

We conducted three linear mixed-effects models in R, controlling for age, sex, and number of usable trials, for each behavior across trials. In each model, within-subject fixed factors included trial type (social vs. non-social) and competition-type (high vs. low), and a between-subjects fixed factor of group (IGR vs. NGR). We then derived estimated marginal means and conducted pairwise comparisons, using package 'emmeans'. We plotted three-way interactions for each behavior (Fig.2). For sustained attention, there was no main effect of group ($p=.31$), nor any group-level interactions (all $p's > .69$). All infants had greater attention to social than non-social stimuli ($p=.002$), and to low- compared to high-competition trials ($p<.001$).

Regarding intersensory matching toward audio-visual synchrony, there was no effect of group ($p=.96$), nor any group-level interactions (all $p's > .62$). All infants had more accurate intersensory matching for non-social high-competition trials compared to social high-competition ($p=.02$) and non-social low-competition ($p=.02$).

For attentional disengagement, infants were more likely to disengage from low-competition compared to high-competition presentations ($p=.001$). We observed a non-significant three-way interaction between group, trial, and competition types ($p=.33$), and trending two-way interactions between trial-type and group ($p=.18$), and competition-type and group ($p=.18$). To examine these interactions, we conducted pairwise comparisons for each level of social and non-social trial types, accounting for the levels of competition-type and group. For non-social trial types, we found that IGR infants tend to disengage more slowly from central stimuli in high-competition contexts ($p=.14$), which was not observed during social trials ($p=1.0$).

Conclusions:

These results suggest differences between IGR and NGR infants, such that IGR infants showed slower disengagement rates from a central stimulus in non-social contexts compared to NGR infants. These preliminary results underscore the importance of examining attentional behaviors within social and non-social contexts, highlighting that distinctions arise in non-social contexts. Ongoing work will investigate whether differences in attention moderate emerging autistic symptomatology and will focus on increasing the sample size to strengthen these findings and draw more definitive conclusions.

403.201 Assessment of Synchrony in Parent-Child Interaction in Autism: A Systematic Review of Observational Tools.

L. Orsili¹, G. Farabolini², M. Carloni³, S. Aiello⁴, M. Mastrogiuseppe⁵, L. Ruta⁴ and M. G. Ceravolo³, (1)Department of Experimental and Clinical Medicine, "Politecnica delle Marche" University, Ancona, Italy., Ancona, Ancona, Italy, (2)Department of Experimental and Clinical Medicine, "Politecnica delle Marche" University, Ancona, Ancona, Italy, (3)"Politecnica delle Marche" University, Ancona, Ancona, Italy, (4)Institute for Biomedical Research and Innovation (IRIB), National Research Council of Italy (CNR), Messina, Italy, (5)Institute for Biomedical Research and Innovation (IRIB), National Research Council of Italy (CNR), Messina, sicily, Italy

Background:

Synchrony, often described as a 'conversational dance' between parent and child (Stern, 1985), involves a dynamic process where both partners mutually influence each other's behaviours. This mutual responsiveness has been shown to play a crucial role in child development, impacting areas such as early socio-communicative skills, language acquisition, and emotional bonding in both neurotypical and autistic children (Northrup, 2015). Research on synchrony spans multiple domains, including neural (Cui, 2012), physiological (Meyer, 2020; Flory, 2023), and behavioural dimensions (Carnevali, 2024; Koul, 2023), highlighting its importance for understanding early developmental processes. The growing interest in this field underscores the importance of parent-child interactions, particularly in naturalistic settings, as key contexts for observing and identifying early socio-communicative trajectories associated with autism (Kallerman, 2020). Despite systematic reviews on parental behaviours in interactions with neurotypical and autistic children (Ku et al., 2019; Madarevic et al., 2020), there has been a lack of focus on the specific tools and methodologies used to measure synchrony in these interactions.

Objectives:

We aim to conduct a systematic review of the literature, comparing different observational methodologies used to analyse the construct of synchrony in parent-child interaction within the context of autism.

Methods:

A systematic literature review was conducted following PRISMA guidelines (PROSPERO registration code CRD42012002435), consulting the databases PubMed, Eric, PsycNet, and Web of Science. The initial search identified 898 articles, which were reduced to 139 after a blind screening of titles and abstracts by two researchers, and finally to 35 articles after full-text analysis. A quality appraisal was performed for these studies using tools developed by the Joanna Briggs Institute (Barker TH., 2023).

Results:

Data analysis highlighted significant variability in the methods used to observe synchrony, particularly in terms of setting, duration, and coding procedures. The majority of studies favoured naturalistic contexts, with a preference for microcoding methodologies. The children's mean age of the included studies was 24 months and the caregivers involved were almost exclusively mothers. Few studies considered the socio-demographic characteristics of the sample, and only a limited number examined the influence of other factors, such as the parent's psychological profile or the time parents spent with the child during daily routines as possible mediators.

Conclusions:

This systematic review underscores the important role of dyadic synchrony in parent-child interactions in autism. The variability in observational methodologies highlights a significant gap in the literature, suggesting the need for standardised approaches to better understand the dynamics of this 'conversational dance.' While the emphasis on naturalistic settings and microcoding reflects an effort to capture authentic interactions, the limited exploration of socio-demographic factors and parental influences points to an area that needs further investigation. By addressing these gaps, future research is warranted to enhance our understanding of how synchrony contributes to developmental outcomes in both neurotypical and autistic children, ultimately informing interventions and support strategies for families.

403.202 Exploring Dyadic Synchrony in Naturalistic Mother-Child Interactions: Differences between Autistic and Neurotypical Young Children

L. Orsili¹, S. Aiello², C. Carrozza², F. I. Famà², A. Campisi³, E. Leonardi³, T. NEST Team², S. Campisi⁴, R. Bruschetta⁵, G. Tartarisco⁵, G. Pioggia⁵, M. Mastrogiuseppe⁶, M. G. Ceravolo⁷ and L. Ruta², (1)Department of Experimental and Clinical Medicine, "Politecnica delle Marche" University, Ancona, Italy., Ancona, Ancona, Italy, (2)Institute for Biomedical Research and Innovation (IRIB), National Research Council of Italy (CNR), Messina, Italy, (3)University of Trieste, Messina, Italy, (4)Institute for Biomedical Research and Innovation (IRIB), National Research Council of Italy (CNR), Messina, Sicily, Italy, (5)Institute for Biomedical Research and Innovation (IRIB), National Research Council of Italy, Messina, Italy, (6)Institute for Biomedical Research and Innovation (IRIB), National Research Council of Italy (CNR), Messina, sicily, Italy, (7)Department of Experimental and Clinical Medicine, "Politecnica delle Marche" University, Ancona, Ancona, Italy

Background:

Mother-child social interaction and dyadic synchrony are critical components of early development, influencing social, emotional, and communicative skills. Investigating the dynamics of interpersonal synchrony during naturalistic mother-child interactions in neurodivergent autistic children is essential for identifying specific patterns of reciprocal communication that may differ from those of neurotypical (NT) peers. Previous evidence indicates that children with autism spectrum conditions (ASC) exhibit reduced interpersonal synchrony across various domains, such as motor, conversational, physiological, and neural synchrony, compared to their NT counterparts (McNaughton KA, 2020). Atypical synchrony has also been proposed as a potential biomarker for early detection, stratification, and intervention response in ASC (Ward JA, 2018; Siller and Sigman, 2002; Zampella CJ, 2020).

Objectives:

Based on previous evidence, this study aims to investigate mother-child social and communicative synchrony during naturalistic play interactions in NT children and young ASC children.

Methods:

This preliminary sample includes 9 ASC children (4 males; mean age: 19.37 months, SD: 3.41) and 7 NT children (4 males; mean age: 27.24 months, SD: 3.31). The two groups were paired matched by the chronological age of the NT group with the developmental performance age of the ASC group. Videos of naturalistic mother-child play interactions were micro-analytically coded using the Revised Relational Coding System (Fogel, 1993, 2000, 2007) to analyse synchronous communicative exchanges. The non-parametric Mann-Whitney U test was applied to compare total duration of synchrony exchanges between the ASC and NT groups.

Results:

Preliminary analyses revealed significant differences in dyadic synchrony between the two groups. ASC dyads spent significantly less time engaged in synchronous sequential communicative exchanges compared to NT dyads ($z = 11$, $p = 0.03$).

Conclusions:

Our findings indicate that mother-child dyads involving ASC children engage in synchronous and sequential communicative exchanges for a shorter duration compared to NT dyads, showing specific difficulties in maintaining reciprocal social interactions during play. By gaining a deeper understanding of these dynamics, we can develop strategies to support parents in fostering effective communication, enhancing ASC children's engagement in synchronous activities, and ultimately promoting their social and emotional development.

Poster Session**404 - Epidemiology I**

May 1st, 2025, 12:30 PM - 1:30 PM - Hall 4A

404.204 An Investigation of Sexuality in Autistic and Non-Autistic Individuals across the Gender Spectrum

S. A. Parwani¹, G. L. Wallace², J. J. Michaelson³, A. Jack⁴, G. A. McQuaid⁴, A. L. Fischbach⁵, A. D. Todd⁶, J. F. Strang⁶ and C. S. Parkin⁷, (1)Gender and Autism Program, Children's National Hospital, Washington DC, DC, (2)The George Washington University, Washington, DC, (3)Psychiatry, University of Iowa, Iowa City, IA, (4)George Mason University, Fairfax, VA, (5)Department of Psychology, University of Cincinnati, Cincinnati, OH, (6)Gender and Autism Program, Children's National Health System, Washington, DC, (7)Gender and Autism Program, Children's National Hospital, Washington, DC

Background: Evidence suggests that both gender diversity and sexuality diversity are particularly common in autistic populations (Bungert et al., 2024; Dewinter et al., 2024). Emerging evidence suggests that autism is proportionally overrepresented among LGBTQ individuals. For example, according to the Trevor Project (2022), 5% of LGBTQ youth surveyed reported an autism diagnosis, and 35% suspected they may be autistic. In general populations, gender diversity and sexuality diversity are often intersectional, and the intersection may be associated with different patterns of resilience (e.g., Walls et al., 2019). However, little is known about how gender diversity and sexuality diversity intersect among autistic individuals.

Objectives: This study aims to understand how patterns of sexuality may differ among autistic people across the gender spectrum. Specifically, we hypothesize that autistic individuals will demonstrate greater overall sexuality diversity compared to non-autistic individuals, and that this difference will be amplified among autistic gender-diverse individuals.

Methods: This study employs the standardization sample for the Gender Self-Report (n=1654; Strang et al., 2023), the first multi-dimensional gender characterization method validated in autistic and non-autistic youth and adults. The sample was carefully recruited across 7 separate national recruitments to equitably include gender-diverse people (n=725; n=320 autistic) and those with diverse sexualities (n=912; n=484 autistic), oversampling for autistic individuals. To be most inclusive, this study employs reports of sexual attraction for analyses, as some terms for sexual orientation identities are not universally understood. Participants were asked four questions regarding their sexual attraction (i.e., attraction to women, men, and/or nonbinary people, no attraction) and their answer(s) were grouped into four sexual attraction categories: multi-gender attraction, same-gender attraction, no sexual attraction, and attraction to nonbinary individuals. Four logistic regression analyses were conducted, one for each of the sexual attraction categories. Predictors in each model included gender diversity, autism diagnostic status, age, sex assigned at birth, and the interaction between gender diversity and autism status.

Results: The False Discovery Rate was employed for multiple comparisons. Omnibus tests were significant for all types of sexual attraction. The interaction term was significant in all models, save for attraction to nonbinary individuals ($p<.092$). Post hoc tests indicated that autism was associated with greater sexuality diversity among both cisgender and gender-diverse individuals. Cisgender autistic versus cisgender non-autistic individuals, and separately, gender-diverse autistic versus gender-diverse non-autistic individuals, were more likely to report attraction to multiple genders and attraction to nonbinary people ($p<.001$). However, same-gender attraction was less common in autistic versus non-autistic gender-diverse people ($p<.001$) and in gender-diverse autistic versus cisgender autistic participants ($p<.001$). Rates of no sexual attraction differed only between cisgender autistic and cisgender non-autistic participants ($p<.001$), with a higher proportion in the autistic group.

Conclusions: In partial support of our hypotheses, complex patterns of intersectional gender and sexuality diversity were identified. While autistic individuals reported greater multi-gender attraction and attraction to nonbinary individuals, same-gender attraction was less common among gender-diverse autistic individuals than gender-diverse non-autistic and cisgender autistic individuals. Future research should investigate profiles of resilience across intersectional genders and sexualities in autistic communities.

404.205 Association of Autism Spectrum Disorder and Common Co-Occurring Conditions with Suffocation

A. Blanchard¹, C. DiGiuseppi², **G. Li³**, Z. Yang³ and C. Ing³, (1)Department of Emergency Medicine, Columbia University Irving Medical Center, New York, NY, (2)Colorado School of Public Health, University of Colorado Anschutz Medical Campus, Aurora, CO, (3)Department of Anesthesiology, Columbia University Vagelos College of Physicians and Surgeons, New York, NY

Background: People with autism spectrum disorder (ASD) are at heightened risk of injury-related death and specific injuries, such as drowning and self-injury. As ASD prevalence rises, epidemiologic data describing specific injuries, such as suffocation, are essential for prevention efforts.

Objectives: Describe the excess risk of suffocation associated with ASD and common co-occurring diagnoses among people treated in United States (US) emergency departments (EDs).

Methods: Using a repeated cross-sectional study design, we analyzed data from the 2016-2020 Nationwide Emergency Department Sample (NEDS), the largest US all-payer ED visit claims database. Children ≥ 1 years and adults diagnosed with ASD and treated in EDs were identified using ICD-10-CM code F84.0. Intellectual disability (ID), attention-deficit/hyperactivity disorder (ADHD), and Alzheimer's disease and related dementia (ADRD) were similarly identified using relevant ICD-10-CM codes. ED visits for suffocation were identified using the ICD-10-CM external cause-of-injury matrix. Weighted multivariable logistic regression models were used to estimate the adjusted odds ratios (aOR) and 95% confidence intervals (CI) of suffocation-related ED visits in persons with and without ASD, ID, ADHD, and ADRD. Each model was adjusted for the other conditions, age, sex, urbanicity, and payor.

Results: The 2016-2021 NEDS recorded a weighted total of 803,777,608 ED visits, of which 1,012,210 (0.13%) were related to suffocation. Suffocation accounted for 0.35% of ED visits in patients with ASD, 0.67% of ED visits in patients with a diagnosis of ID, 0.07% of ED visits in patients with a diagnosis of ADHD, and 0.34% of ED visits in patients with a diagnosis of ADRD. Patients with ASD had a 75% increased odds of suffocation (aOR = 1.75; 95% CI: 1.65, 1.86), patients with ID a more than six-fold increased odds of suffocation (aOR = 6.56; 95% CI: 6.2, 6.94), patients with ADHD a 44% increased odds of suffocation (aOR = 1.44; 95% CI: 1.35, 1.53), and patients with ADRD a 106% increased odds of suffocation (aOR = 2.06; 95% CI: 2.01, 2.12). Across the lifespan suffocation accounted for a larger proportion of ED visits among patients with ASD than those without ASD.

Conclusions: Children and adults with ASD have an increased odds of ED-treated suffocation. ID, ADHD, and ADRD common co-occurring diagnoses with ASD across the lifespan, are also associated with increased odds of ED-treated suffocation. Further understanding of environmental circumstances and unique factors that may increase risk of suffocation in people with ASD is needed.

404.206 Associations between Exposure to per- and Polyfluoroalkyl Substances and the Risk of Autism Spectrum Disorder in Children

J. Ao¹, Q. Zhang¹ and F. Li², (1)Ministry of Education-Shanghai Key Laboratory of Children's Environmental Health, Xinhua Hospital, Shanghai Jiao Tong University School of Medicine, Shanghai, Shanghai, China, (2)Department of Developmental and Behavioral Pediatric and Child Primary Care & Ministry of Education-Shanghai Key Laboratory for Children's Environmental Health, Xinhua Hospital, Shanghai Jiao Tong University School of Medicine, Shanghai, 200092, China., Shanghai, Shanghai, China

Background: Autism spectrum disorder (ASD) is a neurodevelopmental disorder that occurs in early childhood. The etiology of ASD is unclear, with environmental factors contributing up to 50%. Per- and polyfluoroalkyl substances (PFAS) are a family of artificially synthesized chemicals that persist in the environment and are difficult to biodegrade, causing adverse effects on human health. With the global ban on legacy PFAS, emerging alternatives have been widely developed and applied. Limited attention has been paid to the effects of emerging PFAS alternatives on ASD risk.

Objectives: To investigate the associations of exposure to legacy and emerging PFAS with the risk of ASD in children based on a case-control study.

Methods: We included 201 ASD cases and 96 control children (average age: 5.4 years) from the Shanghai Autism Early Development (SAED) Cohort. Baseline information and plasma samples were collected at the enrollment. Levels of 33 legacy and emerging PFAS in plasma samples were measured using ultra-performance liquid chromatography-tandem mass spectrometry. A binary logistic regression model was used to calculate the adjusted odds ratio (aOR) and 95% confidence interval (95% CI) between PFAS levels and ASD risk. The joint effects of PFAS mixture on ASD risk were assessed by principal component analysis (PCA) and Bayesian kernel regression model (BKMR) models.

Results: 23 PFAS were identified in 50% of the children, with the highest level being PFOA (median 7.84 ng/mL), followed by PFOS (median 2.66 ng/mL). In single-chemical model, significant positive associations of four legacy PFAS [PFOA (aOR=1.52, 95% CI: 1.04-2.25), PFDA (aOR=1.29, 95% CI: 1.01-1.65), PFNA (aOR=1.49, 95% CI: 1.07-2.07), PFOS (aOR=2.23, 95% CI: 1.02-4.86)] and an emerging short-chain alternative [PFHxS (aOR=1.38, 95% CI: 1.08-1.78)] with increased ASD risk were observed. Mixture models showed that the joint effect of PFAS mixture on ASD was mainly driven by PFOA, PFNA, PFOS, and PFHxS.

Conclusions: Exposure to legacy and emerging PFAS during childhood may increase the risk of ASD.

404.207 Associations between Maternal Thyroid Dysfunction during Pregnancy and Autism Outcomes in the Marbles Prospective Cohort

Z. B. Kaplan¹, H. M. Shin², E. N. Pearce³, M. Miller⁴ and R. J. Schmidt⁵, (1)Public Health Sciences, University of California, Davis, Davis, CA, (2)Department of environmental science, Baylor University, Waco, TX, (3)Boston University Chobanian & Avedisian School of Medicine, Department of Medicine, Section of Endocrinology, Diabetes, Nutrition, and Weight Management, Boston, MA, (4)Psychiatry and Behavioral Sciences, UC Davis Health, MIND Institute, Sacramento, CA, (5)University of California, Davis, Davis, CA

Background: Women of reproductive age are at risk for multiple types of thyroid dysfunction, including hypothyroidism (affecting 4% of pregnancies), hyperthyroidism (2.4% of pregnancies), and hypothyroxinemia (2% of pregnancies). The fetus receives maternal thyroid hormones throughout pregnancy, but is reliant on maternal thyroid hormones until around 18 weeks when the fetal thyroid starts to secrete hormones. Severe maternal hypothyroidism is a well-documented predictor of neurodevelopmental disability in children, but less is known about the relationship between maternal thyroid function and autism. Multiple population-based studies found a positive association between maternal hypothyroidism and child autism, but the relationship between hyperthyroidism and autism is less consistent. More studies are needed that use laboratory measures to assess thyroid dysfunction in all participating mothers and assess autism in all participating children to reduce misclassification bias.

Objectives: The objective is to examine associations between maternal thyroid dysfunction during pregnancy and child autism. We hypothesize that maternal thyroid dysfunction (in particular, hypothyroidism) will be associated with increased likelihood of autism.

Methods: Participants were from the Markers of Autism in Babies: Learning Early Signs (MARBLES) study, a prospective cohort that enrolls mothers in the Davis/Sacramento area who already have a biological child with autism spectrum disorder (ASD) and are planning another pregnancy. For this study, MARBLES mothers needed at least one pregnancy blood sample for the enrolled child and the child must have had an ASD assessment. Thyroid function (thyroid stimulating hormone, TSH, and free thyroxine, FT4) and thyroid autoantibodies (thyroid peroxidase, TPO and thyroglobulin, Tg) were measured in up to one blood sample per trimester per pregnancy. Normal thyroid function was defined using a TPO and TG negative subsample of mothers who reported no thyroid conditions in a study questionnaire. For most children, ASD was assessed by study clinicians using the autism diagnostic observation schedule. A small number of children were assessed using other assessments because of COVID-19 pandemic precautions. Multinomial regression was used to examine the associations between maternal thyroid dysfunction during pregnancy and developmental outcomes (ASD or non-typical development that was not ASD [non-TD] compared to typically developing).

Results: 281 pregnancies from 269 mothers met inclusion criteria. 28.11% of children were diagnosed with ASD (25 females, 54 males) and 14.59% were non-TD (18 females, 23 males). The proportion of children with ASD varied depending on maternal thyroid status (Table 1). Maternal hypothyroidism during pregnancy was associated with an increased likelihood of ASD (AOR 3.802, 95% CI 1.431-10.102) and non-TD (AOR 5.604, 95% CI 1.773-17.718) compared to typical development after controlling for thyroid antibodies, number of blood draws, maternal age, and child birth year. There was no association between hyperthyroidism and either outcome (Table 2).

Conclusions: Minimally-adjusted models supported a positive association between maternal hypothyroidism, though not hyperthyroidism, for ASD and non-TD. Maternal hypothyroidism may have a shared effect on autism and other developmental conditions. Additional planned analyses include examining TSH and FT4 as continuous predictors, examining autistic traits as an outcome, sex stratified analysis, trimester stratified analysis, and further adjustment for demographic characteristics.

404.208 Autism Spectrum Disorder (ASD) Prevalence in Somali Children in Minnesota: Data from the MN-ADDM Study

A. N. Esler¹, L. Hallas², R. Nguyen³ and J. A. Hall-Lande¹, (1)Department of Pediatrics/Masonic Institute for the Developing Brain, University of Minnesota Medical School, Minneapolis, MN, (2)University of Minnesota - Twin Cities, Minneapolis, MN, (3)University of Minnesota, Minneapolis, MN, (4)UCEDD, University of MN, Minneapolis, MN

Background: Minnesota has the largest population of Somali immigrants in the U.S with an estimated 57,000 people. We have been tracking prevalence of autism in Somali children in Minnesota since 2010 in response to community concerns that Somali children had higher rates of autism and a form of autism with greater support needs than other children. Previous prevalence estimates have not yet detected higher prevalence of autism for Somali 8-year-old children, but higher prevalence among Somali 4-year-olds began to emerge in 2018. Rates of co-occurring intellectual disability (ID) varied, with some study years showing higher rates of autism with ID in Somali children and some showing no differences. Small sample sizes have limited interpretability of these results.

Objectives: We will compare autism prevalence in 4- and 8-year-olds across racial/ethnic groups using data from the Minnesota site of the CDC's Autism and Developmental Disabilities Monitoring Network (MNADDM), surveillance year 2020, with a focus on Somali children.

Methods: Prevalence calculations utilize standardized ADDM methods involving systematic review of health and special education records of 4- and 8-year-old children within our defined surveillance area, which includes three large urban counties that house four of the five largest school districts in Minnesota. Population denominators are from the National Center for Health Statistics' bridged-race postcensal population estimates using the most recent vintage available at the conclusion of each study year and adjusted to include only children living in the surveillance area. A child is classified as Somali based on reported home language in education and/or health records. Prevalence estimates from surveillance year 2020 were compared across racial/ethnic groups assuming a Poisson distribution. Chi squared and Fisher's exact tests were used to identify differences between populations.

Results: For 2020, overall prevalence rates in 8-year-old children in MN revealed one in 34 children were estimated to have ASD. ASD prevalence for Somali 8-year-olds was one in 25 children and not statistically different from that of children in other race categories. Somali 4-year-old children had a significantly *higher* prevalence of ASD compared to 4-year-olds in other races. When compared to 4-year-old White children, Somali 4-year-olds had 3.43x the prevalence of autism. For both 4- and 8-year-olds, Somali autistic children had higher rates of co-occurring ID than White children. Sample sizes were small, and 95% CIs were broad but did not overlap in these comparisons.

Conclusions: The data reveals higher ASD prevalence rates in our 4-year-old Somali population compared to other racial groups, but this pattern was not found among 8-year-old children. It is possible that early detection of autism among Somali children has increased in the past few years resulting in increased identification by age 4, and subsequent years may show increased prevalence at age 8 as well. Somali children at both ages had higher rates of ID than other groups. Differences in rates of ID by racial/ethnic group may suggest barriers to early intervention or underidentification of autism without ID. Additional research is needed to understand these disparities and inform public health efforts and culturally appropriate practices.

404.209 Autism and Gender Variance Co-Occurrence Rates: A Preliminary Survey Analysis

R. Osband¹, A. J. Schwartz² and M. J. Morrier³, (1)Emory Autism Center, Atlanta, GA, (2)Department of Psychiatry & Behavioral Sciences, Emory University School of Medicine, Decatur, GA, (3)Department of Psychiatry & Behavioral Sciences, Morrier Consulting LLC, Decatur, GA

Background: Recent research has shown an overrepresentation of gender variance (GV) among autistic individuals when studies were conducted at autism clinics, gender clinics, and through broad data collections. However, no papers at the time of this study have been published that investigated the number of GV individuals seeking an autism diagnosis or directly surveyed diagnosticians to gather estimates of how many GV individuals they are assessing and diagnosing with autism.

Objectives: To investigate the number of GV individuals seeking and/or receiving an autism diagnosis by surveying autism diagnosticians.

Methods: 34 participants were recruited through the International Collaboration for Diagnostic Evaluation of Autism (IDEA) Listserv from May 2023 to August 2023 to answer the primary question of the study. Data were collected via an online survey consisting of 20 questions. Due to the recent COVID-19 pandemic, and its impact on direct services, the data were collected across two time periods: January 1, 2019 to December 31, 2021, and January 1, 2022 to present (the time the participant completed the survey). The survey was divided into four sections: (a) Section 1 – participant biographical information; (b) Section 2 – the total number of individuals and the total number of GV individuals seeking an autism assessment from January 1, 2022, to present (Section 2a), and the total number of all individuals and total number of GV individuals who were diagnosed with autism by the participant for January 1, 2022 to present (Section 2b); (c) Sections 3a and 3b – same questions as Section 2 but for the time period of January 1, 2019 to December 31, 2021, and (d) Section 4 – an open-ended comment section. Primary data was analyzed for the frequency of selections within the ranges. A qualitative analysis determined common themes among participants' reports and barriers to assessments.

Results: Compared to the 2019 to 2021 data, the 2022 to present data had an equal or greater number of respondents who reported assessing GV clients in each of the time periods. Similarly, the 2022 to present data had more individuals who reported diagnosing GV clients in each of the provided ranges than 2019 to 2021. Both assessment and diagnosis rates of GV individuals increased or remained stagnant in all ranges for the 2022 to present period relative to the 2019 to 2021 period. This qualitative analysis indicates that assessment and diagnosis rates of GV individuals appear to be increasing over time. Analysis of open participant comments revealed that the age of the clients assessed and the provider location were significant variables in the number of assessments and diagnoses done by each participant.

Conclusions: Clinicians reported an increase in GV individuals seeking autism assessments in their clinics but further research is definitively needed into the co-occurrence of autism and GV in clinics. The study's limitations provide insight into specific recommendations for the field and clinicians moving forward. For future research to be successful, it is imperative that clinicians implement a more comprehensive record-keeping system that includes gender identity.

404.210 Being Aware: Engaging the Community in Development of a Web-Based Tool for Autism Research

A. Singh¹, C. P. Lawler², A. E. Garton³, V. R. Walker⁴, J. Rochester⁵, R. Blain⁶, K. Pelch⁶, A. Hannani², J. Frye³, T. Wren³ and A. Rooney¹, (1)Division of Translational Toxicology, National Institute of Environmental Health Sciences, Durham, NC, (2)Division of Extramural Research and Training, National Institute of Environmental Health Sciences, Research Triangle Park, NC, (3)National Institute of Mental Health (NIMH), Durham, NC, (4)National Institute of Environmental Health Sciences, Durham, NC, (5)ICF, Reston, VA, (6)Natural Resources Defense Council, San Francisco, CA

Background: Over the last two decades, the goal of understanding the role of nongenetic factors in autism spectrum disorder (ASD) has resulted in a large and heterogeneous body of research on potential associations with environmental chemical exposures, diet, nutrition, lifestyle, social factors, and maternal medical conditions. The range and diversity of these studies presents a challenge to researchers and the public to understanding the state of the science or effectively using available research to inform decisions. Hence, the goal of turning data on ASD into knowledge motivated the development of a **Web-based tool for Autism Research and the Environment (aWARE)** using a systematic evidence map (SEM) approach.

Objectives: To identify and characterize published literature relevant to environmental chemical exposures associated with ASD, mapping the research gaps and knowledge clusters to enable better understanding of these associations.

Methods: SEMs use the rigor and transparency of systematic review methodology to identify, categorize, and display data in an interactive visual format to aid synthesis and support evidence-based decisions. Our workflow leverages Artificial Intelligence (AI) methods in two steps: 1) to prioritize references for screening, which reduces the screening burden, and 2) for data extraction to capture relevant details from each study (e.g., exposure, model, and measure of ASD-related outcomes). Equally, or perhaps more important than the technical approach, we have engaged the broad autism community, including autistic individuals and families, advocacy groups, clinicians, and researchers throughout the project. Before tool development, we engaged the autism community through four listening sessions conducted between 2022-2023. These listening sessions were small, targeted meetings to identify features that would enhance the tool's use and utility. In the next phase, we developed a beta version of aWARE (limited to studies from the last five years) to obtain input from the autism community before developing the full tool. We conducted a workshop on September 5-6, 2024, to capture user experiences, invite questions, gather feedback, and to listen. Participants were engaged through hands-on testing of the tool, use case presentations, and theme-based breakout sessions.

Results: To develop the beta-version of aWARE, we systematically searched PubMed, Scopus and Web of Science for studies published between 2018-2024. The search yielded 12,218 studies; after removal of 5838 duplicates, 6380 studies were screened using DistillerSR software, and 589 studies included after full-text screening. We used Dextr to extract data from the included studies for display in evidence maps (figure 1). These interactive evidence maps are hosted using Tableau Public at: <http://bit.ly/4ggyl1aA>. At the workshop, we gathered valuable feedback about customizing the aWARE tool to different users, improving search and display, and increasing the scope of chemical exposure. Additionally, participants highly appreciated the plain language summaries and requested adding these accessible summaries for all studies.

Conclusions: The aWARE tool will facilitate better understanding of the associations between environmental chemical exposures and ASD. This tool is one of a kind in merging community engagement with evidence synthesis approaches, thus ensuring the creation of a valuable resource that resonates with diverse perspectives within the community.

404.211 Breastfeeding Duration and Autism Spectrum Disorder: The Role of Sociodemographic and Birth Factors in a Population-Based Study

A. Ben-Sasson¹, A. Mimouni Bloch², S. Samhat-Darawshi³, K. Ilan^{4,5} and L. V. Gabis⁶, (1)University of Haifa, Haifa, ISRAEL, (2)Child Development Center, Loewenstein, Ra'anana, Israel, (3)Clalit health services, Haifa, Israel, (4)University of Haifa, Haifa, Israel, (5)Schneider children's medical center of israel, Petah Tikva, Israel, (6)Pediatrics, Maccabi Healthcare Services, Rehovot, Israel

Background:

Evidence for a relationship between breastfeeding patterns and Autism Spectrum Disorder (ASD) is inconsistent. Some studies suggest that children with ASD are half as likely to have ever been breastfed, while in contrast others show no significant difference in breastfeeding duration. Breastfeeding challenges may reflect sensory-motor and social-emotional regulation difficulties as well as disruptions in infant-maternal synchrony. Previous studies have identified demographic and birth factors such as maternal education, mode of delivery and prematurity, which may influence both breastfeeding duration and ASD outcomes.

Objectives:

This study aimed to examine the relationship between breastfeeding duration and ASD while accounting for sociodemographic and birth-related factors in an Israeli population, which is a demographically diverse population.

Methods:

This study used a population-based cohort extracted from Electronic Health Records (EHR) through TIMNA, Israel's national health database. The cohort included children born between January 2014 and December 2019. ASD diagnosis was verified through Israel's National Social Security system. Infants with health conditions that impair breastfeeding (e.g., cleft palate, congenital heart disease) and those born prematurely, with very low birth weight, or from multiple births were excluded to minimize confounding factors. Data on breastfeeding duration were collected from routine well-baby visits. Four SES classes were defined based on the SES classification of geographical data from the Central Bureau of Statistics.

Results:

The sample included 780,610 children. After exclusions, the final sample comprised 589,629 (98.1%) with typical development and 11,766 (1.9%) with ASD. A random subsample of 12,000 (2.03%) typically developing (TD) children was selected.

On average, children with ASD were breastfed for a shorter duration (mean = 5 months, SD = 6.10) compared to TD children (mean = 6.61 months, SD = 6.30). Independent samples t-tests showed a significant difference between groups ($t(23764) = 19.13, p < .001, d = .25$). Non-Jewish nationality, lower maternal age, cesarean section and higher SES class were significantly related with shorter breastfeeding duration. Nonetheless, only the two-way ANOVA for SES, showed a significant interaction with ASD ($F(3, 17,536) = 11.46, p < .001$). Post-hoc comparisons showed that both Low SES ASD and Low SES TD groups showed similar significantly longer duration than all other groups ($p < .001$). For all other SES classes, breastfeeding duration was shorter for infants with ASD versus TD.

Conclusions:

Children with ASD tend to have shorter breastfeeding durations compared to TD children, regardless of birth-related factors. SES is significant, with children from lower SES backgrounds demonstrating longer breastfeeding durations, irrespective of ASD status. These findings emphasize the importance of early monitoring for breastfeeding challenges in infants at risk for ASD even when birth-related risk factors are not present.

404.212 Bullying Victimization and Engagement in Bullying Among Autistic Adolescents

C. DiGuseppi¹, K. Bartholomay¹, B. Holst¹, S. Schmiede¹, P. Powell¹, N. Reyes³ and L. Wiggins², (1)Colorado School of Public Health, University of Colorado Anschutz Medical Campus, Aurora, CO, (2)Centers for Disease Control and Prevention, Atlanta, GA, (3)University of Colorado, Anschutz Medical Campus, Aurora, CO

Background: Evidence is growing that autistic individuals are at greater risk of bullying victimization than typically developing peers, which may result from specific challenges in social communication and interaction. Evidence is more limited about risks of different types of bullying victimization, which might vary in autistic individuals. Further, the few investigations of engagement in bullying behavior by autistic youth report conflicting results.

Objectives: We aimed to describe and compare bullying victimization (overall and by type) and engagement in bullying among autistic adolescents and adolescents from the general population.

Methods: The Study to Explore Early Development (SEED) is a multi-site case-control study that identified autistic children using standardized instruments and population comparison children from birth certificate samples in Phase 1 (2006-2011, children 2-5 years old). Caregivers completed a follow-up survey about their child's health and development at 12-16 years old (SEED Teen, 2018-2021). In SEED Teen, caregivers were asked if their adolescent had experienced bullying ever (lifetime experiences) and in the past year (current experiences), and types of bullying currently experienced, including verbal (e.g., teased), physical (e.g., pushed), social (e.g., purposely excluded) or cyber (e.g., hurtful post) bullying. Caregivers were also asked if their child had "ever bullied another child." We compared bullying risks in adolescence between SEED autism and population comparison groups using log binomial regression models to calculate risk ratios adjusted for child sex at birth and maternal education.

Results: Among 165 autistic and 277 comparison adolescents, mean age was 14.7 years (IQR, 14.4, 15.1), 59.7% were male, and 66.1% were Non-Hispanic White. Autistic adolescents were more likely than their peers to have experienced bullying victimization in their lifetime (56.4% vs.

38.6%; adjusted Risk Ratio (aRR)=1.34, 95%CI: 1.08, 1.67) and in the past year (28.5% and 10.1%, aRR=2.58; 95%CI: 1.66, 4.12). The risk of experiencing social bullying in the past year was nearly four times higher in autistic adolescents (19.4% vs 5.4%; aRR=3.75, 95%CI: 2.06, 7.12). Autistic adolescents were also at increased risk for verbal (28.5% vs 9.7%; aRR=2.75, 95%CI: 1.76, 4.41) and physical bullying (10.3% vs. 4.0%; aRR=2.23, 95%CI: 1.04, 5.04) compared to peers. Cyberbullying did not differ between groups (3.6% vs. 4.3%; aRR=0.72, 95%CI: 0.25, 1.94).

Autistic adolescents were more likely than their peers to have ever engaged in bullying (13.3% vs. 5.1%; aRR=2.37, 95%CI: 1.21, 4.81) and to have both ever engaged in and ever been victimized by bullying (versus either alone or neither) (11.5% vs. 3.6%; aRR=2.99, 95%CI: 1.39, 6.83).

Conclusions: Based on caregiver report, autistic teens are at higher risk for experiencing social, verbal, and physical bullying, and for engaging in bullying, compared to peers from the general population. Some autistic youth may have difficulty establishing friendships, and bullying may exacerbate this challenge, leading to further isolation. Social, verbal, and physical bullying can have significant long-term impacts, including aggressive behavior, school problems, and depression. School-wide programs promoting prosocial behavior and social skills potentially could both help autistic teens with social interaction challenges and reduce peer antisocial behaviors that disproportionately impact autistic adolescents.

404.213 Early Life Exposure to Severe Adverse Life Events in the Family and Diagnosed Autism and Autistic-like Traits at Age 3 in Children in the Norwegian Mother, Father and Child Cohort Study (MoBa): Genetically Informative Study.

A. Kanina¹, A. Sjölander¹, M. I. Martini¹, A. Butwicki¹, H. Larsson², M. Rosenqvist¹, H. Ask³ and M. Taylor¹, (1)Department of Medical Epidemiology and Biostatistics, Karolinska Institutet, Stockholm, Sweden, (2)School of Medical Sciences, Örebro University, Örebro, Sweden, (3)Norwegian Institute of Public Health, Oslo, Oslo, Norway

Background: Mothers' experience of adverse life events (ALEs, e.g., divorce, bereavement, injury) early in life has been linked with neurodevelopmental conditions like autism, and related traits in children, including social communication differences and difficulties, behavioral inflexibility and sensory processing differences. However, the impact of severe, repeated exposure to ALE during early childhood and the underlying mechanisms are unclear. These associations may also be confounded by unmeasured genetic or early environmental factors shared within families.

Objectives: This study aims to investigate the relationship between severe, repeated early-life exposure to adverse events within the family and the diagnosis of autism, as well as the presence of autistic-like traits in children by age 3.

Methods: This study included 113,496 individuals born in Norway between 1999 and 2009 who participated in the Norwegian Mother, Father and Child cohort study (MoBa), a longitudinal population-based cohort. A total of 47,166 mothers assessed their child's development using Social Communication Questionnaire (SCQ) and reported whether they had experienced severe adverse life events (ALE) when their child was 6 and 18 months old. We examined the association between severe, repeated maternal exposure to ALE and a clinical diagnosis of autism, as well as maternal reports from the SCQ, both in the full sample and sibling comparison (N=11,328).

Results: In the full analytical sample, children of mothers exposed to severe ALEs at one time point had a 40% higher likelihood of being diagnosed with autism (HR: 1.40, 95% CI: 1.19-1.69), and an 87% higher likelihood (HR: 1.87, 95% CI: 1.47-2.35) if exposed at two time points in adjusted models. When accounting for unmeasured familial confounding in sibling comparisons, children whose mothers experienced severe ALE exposure at one time point had HR=2.36 (95% CI: 0.81-4.16) of being diagnosed with autism, and HR=3.89 (95% CI: 1.07-14.22) if exposed at two time points, based on a crude model. After adjustment for birth year HR decreased (HR: 2.01, 95% CI: 0.65 – 6.25; HR: 3.43, 95% CI: 0.91-12.95 for exposure at 1 and 2 time points respectively). In the full sample, maternal exposure to severe repeated ALE was associated with maternal reports of autistic-like traits in children at age 3, with a mean increase in standardized SCQ scores of 0.14 (95% CI: 0.09-0.19) for exposure at one time point, and 0.20 (95% CI: 0.09-0.19) for exposure at two time points in adjusted models. In sibling comparisons, the mean increase in SCQ scores was 0.01 (95% CI: -0.05-0.06) for exposure at one time point, and 0.08 (95% CI: -0.01-0.17) for exposure at two time points in adjusted models.

Conclusions: The association between maternal exposure to severe, repeated adverse life events in early life and the diagnosis of autism or autistic-like traits seem to be explained by unmeasured familial confounding. We recommend using family-based study designs when investigating risk factors for autism to avoid inaccurate conclusions and misinterpretations about the nature of autism.

**404.214** Five-Year Trend in the Incidence of Physical Health Conditions Following Autism Diagnosis: A Nationwide Cohort Study in Taiwan

Y. C. Chuang¹, Y. J. Huang^{2,3}, M. C. Lai⁴ and C. J. Kuo^{1,2,3}, (1)Taipei City Psychiatric Center, Taipei City Hospital, Taipei, Taiwan, Taipei, Taiwan, (2)Department of Psychiatry, School of Medicine, College of Medicine, Taipei Medical University, Taipei, Taiwan, Taipei, Taiwan, (3)Psychiatric Research Center, Taipei Medical University Hospital, Taipei, Taiwan, Taipei, Taiwan, (4)Campbell Family Mental Health Research Institute, Centre for Addiction and Mental Health, Toronto, ON, Canada

Background:

In recent years, the prevalence of autism has increased significantly across the globe. Informed by autistic lived experiences, there is growing concern about the physical wellbeing and co-occurring illnesses in autistic people.

Objectives:

This study aims to assess the incidence rate ratios (IRRs) of co-occurring physical health conditions following a formal Autism Spectrum Disorder (ASD) diagnosis, using a nationwide, population-based claims database from Taiwan, with a particular focus on autistic children diagnosed between 0 to 5 years of age.

Methods:

We analyzed data from the Taiwan National Health Insurance Research Database to assess the incidence of physical illnesses in preschoolers diagnosed with ASD, in the observation window of 2000 and 2019. A total of 45,680 autistic children were matched in age and sex (assigned at birth) in an ratio of 1:20 with 913,600 general population-based comparison group who have not been diagnosed with ASD. IRRs for various physical illnesses within the five years following the ASD diagnosis were calculated using Poisson regression models, adjusted for person-time, with significance level set at $p < 0.01$.

Results:

Taiwanese children newly diagnosed with ASD before 5 years of age experienced elevated risks within the first year after their autism diagnosis for a range of physical illnesses, particularly cerebrovascular disorders, endocrine disorders, and epilepsy. They were also more likely to be diagnosed with intellectual disabilities and congenital abnormalities. The adjusted incidence rate ratios (aIRRs) ranged from 2.30 to 71.42. Although these risks declined over the next four years, they remained significantly higher than those in the non-autistic comparison group, with most aIRRs for physical illnesses exceeding 2 by the fifth year after autism diagnosis.

Conclusions:

This population-based study in Taiwan confirms that autistic children experience the highest risks for co-occurring physical health conditions within the first year following autism diagnosis, with these risks gradually declining but still remaining substantial over the next 4 years. Further research is needed to understand the underlying mechanisms connecting autism to physical illnesses.

404.215 Gender Diversity and Creativity in Communicating Gender Among Autistic and Not-Autistic Four- to Eight-Year-Old Children

S. Schillinger¹, C. S. Parkin², A. S. Russell³, A. L. Lee⁴, M. Lyons⁴, K. Liles⁴, O. C. Putnam⁵, M. Karpinsky⁶, A. Neal⁷, A. L. Fischbach⁸, M. L. Covello⁹, J. Parish-Morris⁴, C. Harrop² and J. F. Strang¹⁰, (1)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (2)Gender and Autism Program, Children's National Hospital, Washington, DC, (3)University of North Carolina at Chapel Hill- Carolina Institute for Developmental Disabilities, Chapel Hill, NC, (4)Department of Health Sciences, University of North Carolina at Chapel Hill, Chapel Hill, NC, (5)Department of Allied Health Sciences, University of North Carolina - Chapel Hill, Chapel Hill, NC, (6)University of North Carolina at Chapel Hill, Chapel Hill, NC, (7)University of South Alabama, Mobile, AL, (8)Department of Psychology, University of Cincinnati, Cincinnati, OH, (9)The Center for Autism Research/CHOP, Philadelphia, PA, (10)Gender and Autism Program, Children's National Health System, Washington, DC

Background: Gender diversity refers to the absence of exclusive congruence between a person's gender identity and their assigned sex. A series of studies have identified a proportional overrepresentation of gender diversity among autistic individuals ranging from school-aged (e.g. Corbett et al., 2022) through adulthood (e.g. Bungert et al., 2024). The Sex and Gender in Autism study investigates children's gender self-concept in the earliest possible period at which young children may be able to communicate their gender-related experiences.

Objectives: (1) We investigated whether 4- to 8-year-old autistic children, as compared to not-autistic children, are more likely to endorse gender diversity. (2) Given findings that autistic people show highly individualized patterns of creativity that emphasize originality and detail (Pennisi et al., 2019), we examined whether expansion beyond common gender conceptualizations differed between autistic and not-autistic youth, and how youth gender conceptualizations related to parent report of gender. Finally, (3), we present case studies highlighting the range and characteristics of personalized systems of gender expression that children designed.

Methods: This study included 173 children ages 4-8 (M age=6.55, SD=1.48; 76 autistic, 97 not-autistic; 73 girls, 94 boys, 6 nonbinary youth). Youth completed the Gender Development Scale (GDS; Strang et al., 2016), a self-report line-based gender assessment method (Gülgöz et al., 2022) of children's gender self-concepts. Parents also reported what they understood their child's gender to be. GDS assessments were hand-coded. Researchers measured the distance from the midpoint of the child's mark(s) to one side of the "girl/boy" line and also recorded whether a response was in the "not a girl or boy" box. Gender-diverse responses were coded as marks more distant from the child's assigned sex, and/or marks in the "not a girl or a boy" box. Scores were averaged across seven items. Some children created their own system for communicating their gender, moving away from the line and box system. T-tests and logistic regressions were conducted in R.

Results: A two-sample t-test revealed significant differences in gender diversity between diagnostic groups, with autistic youth endorsing higher overall gender diversity than not-autistic youth $t(171)=2.33, p=0.02$ (Figure 1). There was no difference between diagnostic groups in likelihood to create a new system to express gender ($\beta_{\text{not-autistic}}=-0.54, SE=0.78, p=0.48$). Logistic regression showed a positive association between parent-reported gender diversity and the child creating a new system on the GDS ($\beta_{\text{gender-diverse}}=1.83, SE=0.90, p=0.042$). Figure 2 presents examples from children who created their own systems, reflecting three overall themes: expressing gender *differently* than the GDS outlines (A & B), expressing *more* about gender than the GDS includes (C), and rejection of classifying gender (D).

Conclusions: This is the first study demonstrating that the proportional overrepresentation of gender diversity in autistic people is observable in early years of child development. Autistic youth were not more likely to move beyond the GDS system for expressing gender. However, given that youth who moved beyond the GDS were more likely gender-diverse by parent report, future studies should investigate more flexible gender report systems to accurately capture gender diversity in young children.

**404.216 Intersectionality of Race/Ethnicity and Sex in Autism: Prevalence, Age of Diagnosis, and Diagnostic Patterns**

K. K. A. Acheampong, C. J. Zampella, R. Abdullah, S. Craig, L. Iglio, K. E. Wallis and W. Guthrie, Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA

Background: Disparities for autistic people assigned female sex at birth (hereafter “girls”) and children of color (COC) are well documented and include lower and later rates of diagnosis than their White and/or male peers. However, there remain important gaps in our understanding of the diagnostic experiences of marginalized groups, including how having multiple marginalizing identities may have specific or compounded impacts on diagnosis. Our team previously examined diagnostic disparities related to race (Wallis et al., 2023), but that work did not address intersectionality between race, ethnicity, and sex, or the “diagnostic odysseys” (long, complex diagnostic journeys) experienced by many autistic children.

Objectives: Using the same sample as Wallis and colleagues (2023), we aimed to 1) Examine the interactive effects of race/ethnicity and sex on (a) autism prevalence, and (b) age at first documentation of autism diagnosis, and (2) Compare rates and timing of other diagnoses received before autism.

Methods: Participants ($N=23,015$) included all children within the Children’s Hospital of Philadelphia (CHOP) primary care network who (1) presented for a well child visit between ages 16 and 26 months from 2011-2015, (2) were screened for autism at least once, and (3) continued to receive primary care at CHOP through at least 4 years of age. Autism diagnoses and age at first diagnostic documentation were extracted from electronic health records (EHR).

Results: Regarding autism prevalence, we found higher diagnostic rates for Asian, Non-Hispanic children compared to White, non-Hispanic children ($p<0.001$), and for boys compared to girls ($p<0.001$), after controlling for median household income ($p=0.007$). There was no significant interaction between sex and race/ethnicity ($p=0.61$). Regarding age of diagnosis, a Cox regression (accounts for censored time to diagnosis data) revealed significant main effects of sex ($p<0.001$) and race/ethnicity ($p<0.001$). Girls and Asian, non-Hispanic and Black, non-Hispanic children were diagnosed significantly later than male and White, non-Hispanic children; however, the difference between Black, non-Hispanic and White, non-Hispanic children was no longer significant ($p=0.31$) after controlling for median household income ($p=0.01$). Again, the interaction between sex and race/ethnicity was not significant ($p=0.50$).

Conclusions: Results add to previous research demonstrating disparate diagnostic experiences for some marginalized groups. The effect of sex on rates or timing of diagnosis did not differ by race/ethnicity. This may reflect a true lack of a difference (after accounting for income), such that differences between boys and girls are similar across race/ethnicity groups. Alternatively, broad metrics like prevalence and age of diagnosis may not capture subtle differences in the diagnostic experiences of intersectional groups. Given this possibility, we will analyze group differences in “diagnostic odysseys” by examining children’s diagnostic journeys in terms of non-autism diagnoses received prior to an autism diagnosis. Our study may have limited statistical power to detect an interaction with a small effect size, due to relatively small sample sizes in some groups of non-White and non-Black autistic girls (see Table II). Future analyses will include updated data extracted from the EHR to expand our sample to children with more recent diagnoses.

404.217 Investigating the Role of Social Identity Threat in Healthcare Environments Among Autistic Adults

O. Abubakare, *Psychology and Neuroscience, Boston College, Chestnut Hill, MA*

Background: Social Identity Threat (SIT) describes how fear of being stigmatized or discriminated against because of membership to a marginalized identity or group can impact one’s psychological well-being (Branscombe et al., 1999). SIT is associated with health inequities among other marginalized identities (e.g., racial and ethnic minorities) (Aronson et al., 2013). Patients that experience SIT have reported increased anxiety, lower treatment seeking behavior, and poorer healthcare quality (Abdou & Fingerhut, 2017). Given autism is a marginalized identity, SIT may be a contributing factor in autistic health care inequities. In this study, we measured SIT for autistic individuals’ healthcare environments and the ways in which cues (linguistic, visual, etc.) might trigger or alleviate social identity threat.

Objectives:

We investigate whether autistic individuals experience social identity threat in the context of interactions with a mock health care system using three variables of interest: anxiety, treatment seeking behavior, and impressions of clinic.

Methods:

699 participants were recruited from Prolific. Inclusion criteria stated participants had to be adults (ages 18-45) with native English backgrounds and identify as autistic and/or have an autism diagnosis (professional or self-diagnosis). A between-subjects design, participants randomly viewed mock websites of a mental health clinic that were designed to reflect either the medical model (threat condition) or neurodiversity model (safety condition) of autism/disability. Each website included three webpages: a *Homepage*, welcoming participants, a *What Is* page, describing autism, and a *Meet Therapists* page, showcasing three therapists from the mock mental health clinic. Figure 1 displays the *What Is* page for these two conditions, which differed in both lexical choices (e.g., “deficit” and “characteristics”) and visual display (e.g., puzzle piece and infinity symbol). Each participant viewed the webpages for at least 30 seconds; then, threat was measured through the Spielberger’s State-Trait Anxiety Inventory. Afterwards, participants provided qualitative and quantitative responses about their overall impressions and treatment seeking behavior at either clinic. Independent t-tests were used to analyze mean differences in variables by condition. Qualitative responses were analyzed using VADER, a natural language processing algorithm for sentiment analysis. Data collection is completed.

Results:

We compared differences in treatment seeking behavior, impressions, and state anxiety following each condition. We found that participants who experienced the threat condition were less likely to seek treatment ($d = -0.55$, 95%CI: -0.70, -0.40, $p < 0.001$) and had overall more negative impressions (e.g., “[The clinic] didn’t look like a good place for autistic people”) compared to participants who experienced the safety condition ($d = -0.45$, 95%CI: -0.60, -0.30, $p < 0.001$). Table 1 presents differences by condition for treatment seeking behavior, overall impressions, and anxiety.

Conclusions:

Autistic individuals who viewed mock websites of mental health clinics that promoted the medical model had lower treatment seeking behavior and more negative impressions, on average, than autistic individuals who saw the same type of website, but from a neurodiversity affirming perspective. Future analyses could explore how identification with an autistic identity impacts the perception of social identity threat, possibly building resilience to social identity threat in autistic populations.

404.218 Maternal Health in Pregnancy and Autism Risk – Genetic and Non-Genetic Mechanisms

M. Janecka¹, V. Khachadourian², E. Arildskov³, J. Grove³, P. F. O'Reilly⁴, J. D. Buxbaum⁵, A. Reichenberg⁶, S. Sandin⁷, L. A. Croen⁸, D. Schendel⁹ and S. Hansen³, (1)NYU Grossman School of Medicine, New York, NY, (2)Icahn School of Medicine at Mount Sinai, New York, NY, (3)Aarhus University, Aarhus, Denmark, (4)Icahn School of Medicine at Mount Sinai, New York, NY, (5)Mount Sinai School of Medicine, New York, NY, (6)Seaver Autism Center, Department of Psychiatry, Icahn School of Medicine at Mount Sinai, New York, NY, (7)Department of Medical Epidemiology and Biostatistics, Karolinska Institute, Stockholm, Stockholm, Sweden, (8)Division of Research, Kaiser Permanente Northern California, Oakland, CA, (9)Drexel University, Philadelphia, PA

Background: Efforts to identify modifiable risk factors for autism have revealed multiple associations between maternal health in pregnancy and autism risk offspring. However, the mechanisms underlying these associations remain unknown, including the role of transmitted and non-transmitted genetic variation.

Objectives: Identify associations between maternal health in pregnancy and autism in offspring, and establish the evidence for familial confounding in those associations.

Methods: We used the Danish registry data (N=1.13M), with 3 generation family linkage, and genotype data (N~130k, iPSYCH) to test the associations between all maternal diagnoses and autism. To triangulate evidence for genetic confounding, we implemented (1) family-based (paternal negative control; sibling comparison; risk in maternal cross and parallel cousins), and (2) polygenic risk score (PRS) analyses.

Results: We identified 30 maternal diagnoses associated with autism risk, after accounting for their comorbidity and chronicity, familial correlations and potential confounders, and controlling for multiple testing. We observed evidence for genetic confounding for most of those associations, including through both direct (psychiatric and neurological disorders) and indirect (obstetric complications) genetic effects. For example, for epilepsy: (i) autism risk was the same irrespective of which parent was affected; (ii) children born to affected mothers had higher autism PRS, compared to children of unaffected women; and (iii) autism risk was the same in offspring of sisters and brothers of women with epilepsy, and for both higher than in the general population.

Conclusions: In summary, associations between maternal health in pregnancy and autism risk are largely attributable to genetic factors, both direct and indirect.

Poster Session**405 - Sensory, Motor, and Repetitive Behaviors and Interests I**

May 1st, 2025, 12:30 PM - 1:30 PM - Hall 4A

405.219 Analyzing Correlations between Oculomotor Behavior and Cognitive Ability in Minimally Verbal Autism

S. C. Yuditskaya¹, C. Jafari¹, P. Hickey Townsend^{2,3}, L. Nowinski², J. Williamson¹, N. Kosmyna¹, M. Pecukonis², N. Protyasha⁴, L. Sarnie², C. J. McDougle², P. Maes⁴, M. Mody^{2,3} and T. Quatieri², (1)Lincoln Laboratory, Massachusetts Institute of Technology, Lexington, MA, (2)Lurie Center for Autism, Massachusetts General Hospital, Lexington, MA, (3)Athinaoula A. Martinos Center for Biomedical Imaging, Charlestown, MA, (4)Media Lab, Massachusetts Institute of Technology, Cambridge, MA, (5)Lincoln Laboratory, MIT Lincoln Laboratory, Lexington, MA

Background: Because eye movements are tightly coupled to many aspects of neurological processing, analysis of oculomotor behavior during target-based eye tracking tasks may provide insight into specific neurological deficits in minimally verbal autism spectrum disorder (mv-ASD). Due to severe attention challenges and chinrest intolerance within the mv-ASD population, our analysis focuses on target-agnostic oculomotor behavior. We explore oculomotor relationships with standard neuropsychological measures in mv-ASD compared with neurotypical adults.

Objectives: Identify salient correlations of oculomotor behavior with cognitive ability in mv-ASD adults.

Methods: Visually-Guided Saccade (VGS), Fast Smooth Pursuit (FSP), and Slow Smooth Pursuit (SSP) tasks were completed without chinrest by 24 mv-ASD and 19 neurotypical subjects, 18-40 years of age, with Tobii screen-mounted eye tracking. We computed target-agnostic features from the recorded gaze trajectories: gaze entropy (GE) and dispersion, fixation duration and density, saccade amplitudes, peak velocities, durations, main sequence [Gibaldi2021], and Q-ratio [Garbutt2003]. We also measured pupil diameter (PD) as an indicator of cognitive load [vanDerWel2018]. All features except PD were computed with distance-to-target threshold of T=150 pixels to exclude artifacts related to attention loss and task disengagement. We computed within- and between-group Pearson correlations between oculomotor features and raw scores on the Stanford Binet Abbreviated Battery (SB-5), Expressive Vocabulary Test (EVT-3), and Beery Visual-Motor Integration Task (VMI), measuring verbal and nonverbal skills, expressive language, and visual-motor integration, respectively.

Results: Within-group results for mv-ASD (Table 1) show an association between greater PD and lower EVT-3 scores across all three tasks.

Greater horizontal GE in the VGS task, where the target moves only horizontally, correlated with lower VMI, while in the circular trajectory of the FSP task, both horizontal and vertical GE correlated with lower Verbal IQ (VIQ). Also, lower fixation density in FSP correlated with lower VIQ. Top significant between-group correlations include: horizontal GE in each task vs. VMI (VGS: $\rho=-0.60$, FSP: $\rho=-0.71$, SSP: $\rho=-0.63$); horizontal GE vs. EVT in FSP ($\rho=-0.77$); fixation density vs. EVT in FSP ($\rho=0.65$); fixation density vs. VMI in SSP ($\rho=-0.53$). Within the neurotypical group, we observe that saccade dynamics (amplitudes, durations, Q-ratio, main sequence) and fixation durations in Smooth Pursuit, and fixation dispersion in VGS, correlate significantly with various neuropsychological test scores, verbal and nonverbal. PD, fixation density, and GE, all prominent among correlations within the mv-ASD group, are absent within neurotypical group results.

Conclusions: Results indicate relationships between gaze behavior and language ability in mv-ASD. Also, PD correlations with EVT suggest an association between higher cognitive load in oculomotor control tasks and lower expressive language ability that is not observed in the neurotypical group. Absence of saccade feature correlations in mv-ASD suggests greater variability in saccade control compared to neurotypicals, consistently with prior findings in verbal [Schmitt2014] and high functioning [Johnson2012] ASD populations. Correlations between gaze entropy in the oculomotor control tasks and VMI task performance may indicate a common neurological basis underlying fine motor demands of each task.

Future work should investigate these relationships and multivariate interactions using predictive analysis.

405.220 Altered Oculomotor Entrainment in Children with Autism Spectrum Disorder (ASD)

Y. S. Bonneht¹, O. Kadosh², S. Molholm³ and S. Beker⁴, (1)School of Optometry and Vision Science, Bar-Ilan University, Ramat Gan, Israel, (2)School of Optometry and Vision Science, Bar-Ilan University, Ramat Gan, center, Israel, (3)Albert Einstein College of Medicine, Bronx, NY, (4)Department of Pediatrics, Albert Einstein College of Medicine, Icahn School of Medicine at Mount Sinai, Bronx, NY

Background:

Neural activity and behavior of individuals with Autism Spectrum Disorder (ASD) indicate altered synchronization with external events, which could be linked to the rigid routines and restricted interests that define this disorder. Recently, we have shown that children with ASD are impaired in phase locking to, and anticipation of predictable, periodic visual stimuli, as shown by encephalography (EEG).

Objectives:

Test whether oculomotor activity, as indicated by microsaccades and pupil dilation dynamics recorded from children with ASD has intact entrainment to periodic sensory stimuli, when compared with typically developed (TD) controls

Methods:

In this study, 31 children aged 6-9 with an ASD diagnosis and 21 age- and IQ-matched controls engaged in a computerized task, where sequences of four visual stimuli (cues) appeared at equal intervals, followed by an auditory stimulus (target). Oculomotor activity was recorded using Eyelink100© eye-tracking system (sampling rate: 1000Hz), and a video camera. The analysis tracked the entrainment of the pupil and the microsaccades to the rhythm of the cues, in terms of the variability of the pupillary light response latency (Pupil-RT), and the microsaccade inhibition release latency (msRT) in response to each of the cues, as well as to the auditory target.

Results:

Both pupil dynamics and microsaccades showed a periodic pattern of response to the cues in both groups, with the expected repeated constriction events of the pupil, and repeated phasic inhibition of microsaccades, with a final more variable response to the auditory target due to its non-visual modality. Importantly, the variability of both the msRT and the Pupil-RT decreased with the repeated cues in both groups, reflecting increasing temporal entrainment, but this entrainment effect was significantly smaller for the ASD group for both parameters, with a maximal group effect found in the response to the target. Moreover, oculomotor activity was correlated with EEG: significant correlations between oculomotor entrainment measures and inter-trial phase coherence (ITPC) were found across groups.

Conclusions:

Results show overall larger variability of oculomotor activity in children with ASD, with reduced entrainment to the visual sequence. This is in line with the results from EEG done on the same task with the same participants, and, together with finding of oculomotor-EEG correlations indicate analogy between oculomotor activity and EEG in children with ASD.

405.221 The Relationship between Motor Abilities and Cultural Factors in Autistic Children

L. Anderson¹, A. Gladfelter², M. Buac³, C. Cheung³, Z. Wang⁴ and S. Onal⁵, (1)Northern Illinois University, DeKalb, IL, (2)Speech-Language Pathology, Northern Illinois University, DeKalb, IL, (3)Physical Therapy, Northern Illinois University, DeKalb, IL, (4)Industrial and Systems Engineering, Northern Illinois University, DeKalb, IL, (5)Industrial Engineering, Southern Illinois University, Edwardsville, IL

Background: Gross motor delays and poor postural control may be an early indicator for autism (May et al., 2016). Poor postural control leads to delays in crawling and walking because postural stability is essential to maintain an upright balance (Koos, 2018). Motor and balance differences continue as autistic children reach school-age (Gladfelter et al., 2020; McPhillips et al., 2014). Cultural factors are known to shape aspects of motor development (Karasik et al., 2010), yet previous studies have not considered cultural factors when analyzing autistic walking gait (Buac et al., 2023). A better understanding of how cultural factors influence balance in autistic children is needed to ensure motor assessments and interventions aimed at autistic children are culturally responsive and therapeutically effective.

Objectives: The purpose of this study was to explore the relationship between balance skills, autism, and cultural factors (i.e., age, gender, socioeconomic status (SES), number of languages spoken, race/ethnicity) in school-aged children. Consistent with previous literature, we predicted that autistic characteristics influenced balance performance. We also predicted that cultural factors would influence balance skills in autistic and non-autistic children.

Methods: To determine which, if any, cultural factors mediate the relationship between balance and autism, 44 children (16 autistic and 28 non-autistic) aged 5-12 years with various cultural backgrounds and autistic traits participated in this study. To assess balance skills, all children completed the Balance subscale tasks on the Movement Assessment Battery for Children- 2nd edition (MABC-2), a standardized assessment of motor skills for children. The balance subscale was chosen because it relates most closely to autism status (Gladfelter et al., 2020; McPhillips et al., 2014). Cultural factors were collected via a parent survey to gather information regarding gender, age, number of languages spoken, racial/ethnic identity, SES, etc. To capture each child's level of autistic characteristics, parents also completed the Social Responsiveness Scale-2nd Edition (SRS-2). Data was then analyzed using a multiple linear regression model to determine which cultural factors mediate the relationship between balance abilities and autistic characteristics.

Results: The linear regression model was a good fit for the data ($F(11, 32) = 5.72, p < 0.001$), and the independent variables taken together accounted for 66% of the variability in MABC-2 Balance standard scores. Degree of autistic traits was the most significant contributing factor (SRS-2 scores $p < 0.001$), along with the cultural factors of gender ($p < 0.01$) and SES (estimated by Caregiver 1 ($p = 0.02$) and Caregiver 2 ($p = 0.03$) years of education).

Conclusions: Consistent with previous research, autism status relates to balance abilities. Also, cultural factors, such as gender and SES, influence balance performance, yet are rarely taken into consideration in autism assessment, intervention, or research. The consideration of cultural factors, especially gender and SES, when conducting future motor research with autistic individuals, is essential to develop effective, responsive assessments and interventions.

405.222 Association between Emotion Regulation and Core Features of Autism Spectrum Disorder

S. Herguner¹, S. Fırat² and S. Yılmaz³, (1)Sarıkonak Apt Çukurambar, Sabri Hergüner, Ankara, Turkey, (2)Private Practice, Samsun, Turkey, (3)Private Practice, Yalova, Turkey

Background: Autism spectrum disorder (ASD) is characterized by a persistent deficit in social communication and interaction skills, and repetitive and restricted patterns of behavior. The relationships between emotion regulation and core features of ASD are poorly investigated.

Objectives: The aim of this study was to examine the associations between social communication deficits, sensory processing patterns, emotion dysregulation, and repetitive behaviors using structural equation modeling (SEM).

Methods: One hundred and five children with a diagnosis of ASD (between the ages of 3-6 years) and their parents participated in the study. Social communication and interaction skills were measured by Social Communication Checklist-Revised (SCC-R), repetitive and restricted behaviours were measured by Repetitive Behavior Scale-Revised (RBS-R), emotion regulation was measured by Child Behavior Checklist-Dysregulation Profile (CBCL-DP), and sensory processing was measured by Sensory Dunn Sensory Profile (DSP).

Results: According to the SEM, social communication skills predicted sensory processing (0.31), sensory processing predicted emotion regulation (-0.29), and emotion regulation predicted all subtypes of repetitive behavior (repetitive behaviours: 0.24; insistence on sameness: 0.71). We also found that repetitive behaviors were directly predicted by social communication and sensory processing (0.05, -0.03, respectively).

Conclusions: These findings implies that social communication skills are related with sensory features and repetitive behaviours. Interventions targeting social communication may improve emotion regulation, repetitive behaviours and sensory difficulties in young autistic children.

405.223 Attention to Food Stimuli in Autistic Youth: An Eye Tracking Study

C. Harrop¹, K. Gowan², K. Liles³, S. W. Nowell⁴ and A. Wallisch⁵, (1)Department of Allied Health Sciences, University of North Carolina - Chapel Hill, Chapel Hill, NC, (2)Department of Public Health, University of Chapel Hill at Chapel Hill, Chapel Hill, NC, (3)Department of Health Sciences, University of North Carolina at Chapel Hill, Chapel Hill, NC, (4)University of North Carolina at Chapel Hill, Carrboro, NC, (5)Juniper Gardens Children's Project, Juniper Gardens Children's Project, University of Kansas, Kansas City, KS

Background: Eye tracking research has revealed attention differences and biases in autism that may contribute to observed phenotypic profiles.

Most eye tracking studies in autism have focused on social stimuli, however, outside of autism, eye tracking has been utilized to characterize attention to food and eating-related stimuli, with attentional mechanisms implicated in the development and maintenance of several eating behaviors and disorders (e.g., Jiang & Vartanian, 2018). Non-autistic children (3-6 years) are distracted more by food stimuli relative to other stimuli and children with quicker fixations to food stimuli had higher BMI scores (Brand et al., 2020). In clinical samples, eye tracking has provided insight into the attention biases of individuals with anorexia nervosa (Giel et al., 2011), binge eating disorder (Sperling et al., 2017), and obesity (Doolan et al., 2017). Given that challenging eating behaviors, and later diagnoses of eating disorders and obesity, are common in autism (Healy et al., 2019; Sharp et al., 2013), eye tracking may elucidate attentional biases that underlie developmental risk for later adverse health outcomes.

Objectives: Characterize attentional biases to food stimuli by diagnosis (autistic, non-autistic) and appeal (high appetizing, neutral, low appetizing) using a novel paired preference eye tracking paradigm.

Methods: 49 children (4 to 10; 14 autistic) completed a paired-preference eye tracking paradigm, where they viewed a series of paired food images drawn from the International Affective Picture System (IAPS; Lang et al., 2005). Food stimuli is categorized as high appetizing, neutral, or low appetizing (Figure 1). A total of 78 pairs (each shown twice), equally split by high-neutral, high-low, neutral-low pairings and counterbalanced across participants, were shown for 5 seconds while the child passively attended to the screen. Gaze data was collected via Tobii Pro.

Results: Autistic children attended less overall to the paradigm (all p 's $< .005$) therefore proportional data is used for the following analyses. There were no significant differences in the proportion of attention autistic and non-autistic youth directed towards high, neutral or low appetizing foods (Figure 2a). Non-autistic youth directed more discrete fixations to foods categorized as neutral, $t(47)=2.02, p=.02$ (Figure 2b) and their fixations were longer to high appetizing stimuli, $t(47)=1.96, p=.03$ (Figure 2c). Autistic youth were slower to orient to food categorized as neutral, $t(47)=-2.36, p=.01$ (Figure 2d) than non-autistic youth.

Conclusions: Attentional patterns to food stimuli were strikingly similar between autistic and non-autistic youth (Figure 2), however some nuanced differences were found: autistic youth directed fewer fixations and were slower to attend to *neutral* foods. These foods include several fruits (e.g., watermelon, cherries, pears) as well as common snacks or meals (e.g., grilled cheese, tacos, granola bar). While preliminary, our data suggests high and low appetizing foods may have unique attentional components (e.g., approach or avoidance) when compared to neutral foods. Future directions include expanding this data to a larger sample of autistic youth oversampled for assigned females (anticipated N by April 2025 = 100), the impact of stimuli pairing (high-neutral, high-low, neutral-low) on attention profiles, and associating attentional patterns with parent-rated eating behaviors.

**405.224 Auditory Imbalance between Spectral and Temporal Processing in Autism**

L. Yu¹, L. Mottron, M.D.², L. Wang³ and S. Xie⁴, (1)Center for Autism Research, School of Education, Guangzhou University, Guangzhou, Guangdong, China, (2)CIUSSS NIM, Montréal, QC, Canada, (3)Guangzhou Nansha Qihui Special School, Guangzhou, Guangdong, China, (4)Guangzhou University, Guangzhou, Guangdong, China

Background: Altered perception of fine acoustic details may exert deleterious or beneficial effects on the development of higher-order language skills in children with autism. Multiple research groups (e.g., Haesen et al., 2011; Yu & Wang, 2021) have suggested an imbalanced auditory profile in autism, characterized by enhanced spectral (frequency) processing but diminished temporal (timing) processing. However, direct empirical evidence for this hypothesis remains scarce.

Objectives: This study aimed to examine the auditory processing abilities of children with prototypical autism, focusing on their capacity to process both temporal and spectral information—two key, complementary aspects of human auditory perception. The data will help 1) determine whether there is an imbalance in autistic auditory system between spectral and temporal processing; 2) explore sensory correlates of atypical hemisphere specialization in terms of spectral (right hemisphere) vs. temporal (left hemisphere) processing; 3) understand the potential role of low-level auditory functions in language development in prototypical autism.

Methods: Participants included 21 children with autism aged 8-12 years and 23 age-and-sex matched typically developing (TD) children. The autistic children were screened for a prototypical presentation of autism according to criteria in Rabot et al. (2023). Temporal gap detection (TGD) and frequency modulation detection (FMD) tasks were employed to assess auditory temporal and spectral resolution, respectively. An imbalance index (IBI) was introduced to estimate each individual's temporal-spectral processing imbalance (IBI > 1 indicates spectral dominance; IBI < 1 indicates temporal dominance).

Results: Children with autism exhibited significantly higher TGD thresholds and lower FMD thresholds compared to TD children, reflecting impaired temporal precision and enhanced spectral precision. The IBI further demonstrated a significant group difference (autism = 1.69, TD = 0.58; $p < .001$), indicating spectral dominance in autism and temporal dominance in the TD group. In the autism group, lower TGD and FMD thresholds were associated with higher overall language proficiency, a pattern not observed in the TD group.

Conclusions: Children with autism exhibit an imbalanced auditory profile, characterized by relative deficiencies in the temporal domain and enhancements in the spectral domain. This study provides the first empirical evidence of such auditory imbalance in prototypical autism. The results also support the hypothesis of enhanced right but decreased left hemisphere functions in autism. These alterations in the low-level auditory functions may shape language development in this group. The findings emphasize the importance of considering sensory factors and their specific pathways of influence on speech and language development in autistic individuals.

405.225 Autism Stakeholders' Perceptions of Restricted and Repetitive Behaviors and Interests in Autistic Children Systematic Review

C. L. Hilton¹, K. Foskey², A. Hassell², L. Jones², A. Kindla², E. Lass² and L. Ponce de Leon², (1)Occupational Therapy, University of Texas Medical Branch, Galveston, TX, (2)University of Texas Medical Branch at Galveston, Galveston, TX

Background: Attitudes differ about the nature of the specific repetitive behaviors and interests (RRBIs) in autistic children across behaviors. Historically, RRBIs have been considered purposeless, but recent research has contradicted prior assumptions and shown that RRBIs may sometimes be advantageous.

Objectives: To examine stakeholders' attitudes about RRBIs.

Methods: Three databases (Ovid-PsychINFO, Ovid-MEDLINE, and CINAHL) were searched in July, 2024 and produced 1,558 articles. Of the 1,558 articles, 1,111 were screened and 129 were retrieved for full-text review. 15 articles met inclusion criteria, and two more were added later on, resulting in 17 total articles. This systematic review and protocol were registered and approved with Prospero (CRD42024575580). No funding supported this review. Included studies focused on children ages 3-18 with a confirmed autism spectrum disorder (ASD) diagnosis, were published in the past ten years, and explored repetitive behaviors as an outcome measure. Excluded studies were published more than ten years ago or consisted of the wrong population. The first six authors screened these studies, reached a consensus on the articles included, and then synthesized the themes that emerged.

Results: This review examined 17 articles with 3,258 total participants. Data gathered from various stakeholders presents mixed findings on attitudes about some RRBIs including ritualistic, sameness, compulsive, restricted, and stereotyped behaviors. Results are divided into categories pertaining to impact on a child's occupational performance, impact on a child's emotional regulation, and impact on a child's family, teachers and clinicians. Limitations included high frequencies of parent responses, unequal gender distribution of participants, and small sample sizes. Some studies found that RRBIs such as ritualistic behaviors may have negative consequences, however, other studies recognized that stereotyped behaviors may be of benefit to autistic children. Restricted, compulsive, and sameness behaviors depend upon many factors and should be studied further. Stakeholders should recognize the invaluable information discovered on the impact of RRBIs and ensure autistic voices are represented.

Conclusions: Findings suggest that not all RRBIs are considered problematic and should not be targets for intervention. Evidence indicates that stereotyped behaviors may be advantageous, but ritualistic, restricted, compulsive, and sameness behaviors should be studied further to understand contextual factors and assess potential benefits. This review provides insight for understanding stakeholder attitudes about the impacts of RRBIs on autistic children's occupational participation, emotional regulation, and influence on family, teacher, and clinician dynamics.

405.226 Autistic Individuals Show Increased Variability of Spatiotemporal Dimensions of Gait from Childhood through Adulthood

R. L. Shafer¹, J. Wang², J. Simpson³, M. Terza⁴, D. J. Shirley⁵, W. S. McKinney⁶, S. P. Pulver⁷, A. M. Orlando⁸, R. A. A. Romero⁹, B. Karmakar¹⁰, M. W. Mosconi¹¹ and Z. Wang⁵, (1)Life Span Institute, University of Kansas Life Span Institute, Lawrence, KS, (2)Neurocognitive and Behavioral Development Laboratory, University of Florida, Gainesville, FL, (3)University of Florida, Gainesville, FL, (4)Department of Applied Physiology and Kinesiology, University of Florida, Gainesville, FL, (5)Applied Physiology and Kinesiology, University of Florida, Gainesville, FL, (6)Cincinnati Children's Hospital Medicine Center, Cincinnati, OH, (7)Marcus Autism Center, Atlanta, GA, (8)Center for Autism and Related Disabilities (CARD), University of Florida, Gainesville, FL, (9)UF Health Center for Autism and Neurodevelopment (UF Health CAN), University of Florida, Gainesville, FL, (10)The University of Florida, Gainesville, FL, (11)Clinical Child Psychology Program, Schiefelbusch Institute for Life Span Studies, University of Kansas, Lawrence, KS

Background:

Sensorimotor issues, including gait atypicalities, are prevalent in autistic individuals and are associated with poorer social-communication and adaptive skills, highlighting their clinical significance. While gait issues are commonly reported in autism, findings are inconsistent across studies. These inconsistencies likely reflect, at least in part, differences in sample ages – walking undergoes complex maturational changes from the first year of life into adulthood – and in the spatiotemporal gait variables that are selected for analysis, as separate component gait processes may be variably affected across individuals.

Objectives:

To define autism-associated differences in gait function across a broad range of ages and parameters.

Methods:

Sixty autistic individuals (ages 4-35 years) and 53 age-, sex-, and IQ-matched neurotypical controls completed trials of unconstrained walking (3-5 meters depending on site) at a self-selected pace. Motion capture cameras tracked 16 reflective markers attached to participants' major joints. Common spatiotemporal metrics of gait were derived from the motion capture data and analyzed with multivariate analysis of covariance. Gait variables that were significantly different across groups were included in a canonical correlation analysis with demographic variables (group, age, sex, IQ) to derive a composite gait score that accounted for multicollinearity across discrete gait and demographic variables. Composite gait scores were examined in relation to age and autistic traits.

Results:

Seven variables relating to variability (standard deviation; SD) of gait component processes differentiated autistic and neurotypical individuals: cadences_{SD} ($F=5.63$, $p_{FDR}=.03$), step widths_{SD} ($F=8.02$, $p_{FDR}=.01$), step velocity_{SD} ($F=10.24$, $p=.01$), hip angle_{SD} at heel-strike ($F=8.55$, $p_{FDR}=.01$), hip angle_{SD} at toe-off ($F=13.21$, $p_{FDR}=.004$), and knee angle_{SD} ($F=8.48$, $p_{FDR}=.01$) and ankle angle_{SD} ($F=5.07$, $p_{FDR}=.04$) at heel strike. These seven variables were subsequently included in the canonical correlation analysis. One canonical variate, referred to as “composite gait variability”, explained significant variance in the data ($F=2.82$, $p<.001$). Autistic individuals showed higher composite gait variability than neurotypical individuals ($t=3.76$, $p<.001$, $d=.727$), and the composite gait variability dimension showed a larger effect size than group comparisons of each discrete gait variable ($d_s \leq .628$). Composite gait variability was inversely associated with age across both groups ($\rho=-0.38$, $p=.005$) and positively correlated with more severe ritualistic behaviors in autism ($\rho=0.37$, $p=.01$).

Conclusions:

Findings that gait variability selectively differentiated autistic from neurotypical individuals are consistent with prior studies reporting increased variability of spatiotemporal dimensions of gait in autism. Importantly, our composite gait variability dimension was more robust to autistic gait differences than any discrete gait variable suggesting that gait in autism is characterized by elevated spatiotemporal variability across multiple parameters. While gait variability was elevated in autism, it showed similar age-related reductions in autism and neurotypical development suggesting that differences are persistent across childhood and adulthood. The relation of composite gait score to repetitive behavior in autistic individuals suggests that gait issues may share important neurodevelopmental mechanisms with core autistic traits.

405.227 Autistic Persons with Auditory Difficulties: The Use of Audio Technology. a Scoping Review

M. Herrebrøden¹, A. Dechsling², G. Marentakis¹ and A. Nordahl-Hansen³, (1)Østfold University College, Halden, Østfold, Norway, (2)Faculty of Teacher Education and Languages, Østfold University College, Fredrikstad, Norway, (3)Østfold University College, Halden, Norway

Background:

Given the high prevalence of auditory sensory difficulties in the autistic population (e.g. Williams et al., 2021), it is likely that autistic persons face challenges as a result of the sounds they are exposed to in their daily lives. This can lead to avoidance of certain environments and interactions, reduced participation or engagement in important life activities and performance-impairing distractibility, all of which have been reported to affect overall quality of life (e.g. Pfeiffer et al., 2019).

Audio technologies can enhance the auditory environment for autistic people who are sensitive to sound (e.g. Ikuta et al., 2016). While the use can be beneficial in several ways, there are also concerns about the potential disadvantages that its use may cause (e.g. Neave- DiToro et al., 2020). Despite the widespread use of audio technology in everyday life for many autistic persons, there is little empirical research to justify proper use, and the current body of research does not fulfil the standards of evidence-based practice (Kulawiak, 2021).

Objectives:

Map the extent and type of evidence that exists on the use of audio technology for autistic persons with auditory difficulties and identify potential research gaps in the existing research field.

Methods:

This scoping review is conducted in accordance with the JBI guidelines for scoping reviews (Peters et al., 2020) and the PRISMA ScR (Tricco et al., 2018).

It includes peer-reviewed empirical research studies with no restrictions on study design or year of publication. Participants are autistic persons and there are no age or gender restrictions. The concept is use of audio technology as an aid for autistic people to modify their experience of sound.

Sources of evidence from any contextual setting would be eligible for inclusion. The databases searched include PubMed, ERIC, Web of Science Core Collection, Apa PsycInfo, Cinahl, IEEE Xplore, ACM Digital Library.

Results:

The initial search resulted in 5417 publications and the screening resulted in 17 publications meeting the inclusion criteria. See Flow chart (Fig. 1) for the details. The total number of autistic participants in the included publications was 325, 16% whom were female. The reported mean age ranged from 8.2 to 14.5 years. Quantitative methodological approaches with experimental research design were used in the majority of studies (16). The audio technologies addressed in the studies were remote microphone systems (10), noise-attenuating headphones (5), headphones (1) and earbuds (1). Listening in noise was the most frequently reported target area.

Conclusions:

The studies report potential positive outcomes of different types of audio technologies that may be useful for autistic people who are sensitive to sound in different contexts. However, there is a paucity of research in this area and there are several research gaps that need to be explored. For example, studies that include a wider variety of methodological approaches, focus on a wider range of participant demographics (age, gender, ID), and take place in a wider variety of contextual settings and different types of technology used. Increased focus is also needed on the potential disadvantages of using audio technology.

405.228 Autistic Traits and Auditory Rate Discrimination in Autistic Children

N. J. Dodgson¹, Y. Li², J. Cohen³, J. Shannon³, M. M. Luszczowski⁴, S. Larmer⁵, R. Guerville², K. Schaaf⁶, M. S. Rajab², Y. L. E. Chan⁶, T. W. W. Ho⁶, K. Scott⁷, S. Schmid⁸ and R. A. Stevenson³, (1)Psychology, Sensory and Perception Research Lab at Western University, London, ON, Canada, (2)University of Western Ontario, London, ON, Canada, (3)Sensory and Perception Research Lab at Western University, London, ON, Canada, (4)Western University, London, ON, Canada, (5)Western University of Ontario, London, ON, Canada, (6)Sensory and Perception Lab at Western University, London, ON, Canada, (7)Anatomy and Cell Biology, Western University, London, ON, Canada, (8)Anatomy and Cell Biology, University of Western Ontario, London, ON, Canada

Background:

Sensory features are extremely common in Autistic people, with the majority of Autistic people exhibiting differences in sensory processing compared to Allistic controls. Recent research suggests differences in sensory processing, even low-level sensory processing, can have cascading, downstream effects on social features and repetitive behaviors/interests present in Autistic people. Research has found that many Autistic people have difficulty with the temporal component to auditory processing, with some Autistic people displaying difficulty discerning the speed and length of auditory stimuli. Importantly, these sensory differences have been specifically associated with processing speech sounds and language.

Objectives:

The present study examined differences in auditory rate discrimination between Autistic and Allistic people and index of auditory temporal processing, and the relationship between temporal processing and traits associated with Autism.

Methods:

The project consisted of two sequential studies using the same auditory rate discrimination paradigm. For the first study, a non-clinical sample of university-aged adults were recruited (N=48). For the second study, children with Autism (N=23) and typically developing children (N=33) were recruited.

For both studies, participants completed three Autism-related questionnaires: the Autism Spectrum Quotient (AQ), the Broad Autism Phenotype Questionnaire (BAPQ), and the Repetitive Behaviors Questionnaire. Participants were then presented with a slideshow explaining the rate discrimination task (See Figure 1 a–c). A series of auditory stimuli with varying frequency (3-20Hz) were presented, with the instructions to categorize them as “fast” or “slow”, and participants were trained on the extreme examples (3 & 20Hz). The rates were spaced such that the intervals between different rates were *perceptually* equivalent. In total, participants completed 200 ratings, with the fast (20Hz) and slow (3Hz) stimuli presented more frequently than the other stimuli. Each participant’s data were fitted with a sigmoid function, and perceptual reliability measures were calculated representing the consistency of an individual’s temporal precision (Figure 1d).

Results:

In experiment 1, correlational analyses were conducted between reliability scores and the three Autism-trait questionnaires. As predicted, in the non-clinical adult sample, significant correlations were observed such that people with more Autistic traits had less reliable auditory temporal perception). In experiment 2, comparing Autistic and Allistic samples, we were surprised to find no statistical difference between diagnostic groups. Future analyses will be presented examining the relationship between Autistic traits and temporal perception in our Autistic sample.

Conclusions:

The correlation between Autistic traits and auditory temporal perception in the general population supports the premise that a temporal perception is related to traits associated with Autism, but the lack of differences by diagnostic group suggests that this relationship may not be specifically related to Autism per se, but may be associated with Autism-related traits more broadly. Further study involving different audio processing paradigms may further explain auditory processing differences in Autistic people.

405.229 Automated Detection of Play Behavior in the ADOS-2 Make-Believe Play Task Using Composite AI

K. Karaköse¹, P. G. Molnar¹, B. C. Dos Santos Melicio¹, A. Sarkany², L. V. Valluripalli Soorya³, K. Fenech¹, A. Lorincz¹ and K. Kamal¹,

(1)Department of Artificial Intelligence, Eotvos Lorand University, Budapest, Budapest, Hungary, (2)Argus Cognitive Inc., Budapest, Hungary,

(3)Department of Psychiatry, Rush University Medical Center, Chicago, IL

Background: Accurate assessment of play behavior is key in evaluating Autism Spectrum Disorder (ASD), particularly during the 'Make-Believe Play' task of the Autism Diagnostic Observation Schedule-Second Edition (ADOS-2). Current methods rely on subjective human observation, which can be time-consuming and inconsistent. Automated detection of play behaviors could improve the efficiency and objectivity of ASD assessments, but remains challenging due to the complexity of hand-object interactions.

Objectives: This study aims to 1) develop an automated system for detecting the first instance of play interaction during the ADOS-2 Make-Believe Play task, potentially serving as a diagnostic cue given that ASD and Typically Developing (TD) individuals play behavior may differ significantly; and 2) evaluate how the system can augment traditional clinical observations by enhancing the detection of subtle or complex play behaviors that may be difficult to detect through human observation alone.

Methods: Our work involves ADOS-2 Module 3 session recordings from a US based university clinic dataset, featuring 32 children (22 male, 10 female; total mean age: 9.38±1.74 years). The participants included 27 children with ASD and 5 TD children. Three annotators established the ground truth by recording the first play interaction time in each video. We developed a novel Composite AI framework that integrates several deep learning models, including object detection and segmentation, tracking, depth, age, gender, hand and body pose, and optical flow estimation. A rule-based system combining the outputs of all models was implemented to detect the initiation of hand-object interactions indicative of play behavior.

Results: The system detected the first play interaction in 21 out of 32 videos, achieving a detection rate of 65.63%. The mean time difference between the correctly predicted and annotated first play interactions was 0.69 seconds. Of the 11 unsuccessful cases, 7 (63.6%) were attributed to model limitations: 4 cases of hand keypoint detection failure and 3 cases of incorrect toy detection. The remaining 4 cases (36.4%) were associated with environmental constraints in the clinical setting: 2 cases involved toys with dimensions below the threshold for reliable detection, 1 case where occlusion made the object undetectable and 1 case with blurring due to fast movement distorted the video quality.

Conclusions: This study demonstrates the potential of integrating multiple AI techniques to automate the analysis of child play behavior, achieving promising results without task-specific training. Model limitations, especially in object and hand detection, represent a key area for improvement, which should change as individual models advance. Furthermore, the findings underscore the importance of standardized recording settings as high-resolution and fast multi-camera detection in clinical settings can further enhance performance. Future work should involve larger and more diverse samples and assess the system across different age groups and play scenarios. As technological advancements continue and clinical conditions are optimized, we anticipate significant improvements in the accuracy and reliability of automated play behavior analysis in ASD assessments.

405.230 CAMI-2DNet: Computerized Assessment of Motor Imitation for Distinguishing Children with Autism in Video

A. Sperry¹, K. Kinfu², C. Pacheco³, D. Crocetti⁴, B. Tuncgenç⁵, S. H. Mostofsky⁴ and R. Vidal^{1,3}, (1)Center for Neurodevelopmental Imaging and Research, Kennedy Krieger Institute, Baltimore, MD, (2)University of Pennsylvania, Philadelphia, PA, (3)Johns Hopkins University, Baltimore, MD, (4)Center for Neurodevelopmental and Imaging Research, Kennedy Krieger Institute, Baltimore, MD, (5)Psychology, University of Nottingham, Nottingham, Nottinghamshire, United Kingdom

Background:

Motor impairments, including motor imitation, are common in individuals with Autism Spectrum Disorder (ASD), such that quantifying motor imitation could prove useful for phenotyping autism. Traditional methods assessing motor imitation required Human Observation Coding (HOC), a subjective, labor-intensive process. Addressing this, we developed semi-automated Computerized Assessment of Motor Imitation (CAMI) methods to quantify imitative performance, first using 3D (CAMI-3D) and then using 2D (CAMI-2D) videos. In published studies, we showed that both CAMI-3D and CAMI-2D reliably distinguished children with ASD from typically developing (TD) children. However, these methods still require somewhat labor-intensive and subjective manual correction and HOC annotations for training.

Objectives:

To address the limitations of previous methods, we developed CAMI-2DNet, a deep learning-based approach that eliminates the need for HOC annotations and manual joint correction. We then validated CAMI-2DNET, comparing performance to prior methods (CAMI-3D, CAMI-2D).

Methods:

CAMI-2DNet utilizes a pose estimation network to extract a sequence of 2D joint positions from videos, learning to map it to robust motion representations that are disentangled from nuisance factors. To effectively learn these disentangled representations, we employ synthetic data, generated by motion retargeting of virtual characters through reshuffling motion, body, and camera views, in addition to child experimental data. The synthetic dataset consisted of 18 different 3D categories with 4,428 base motions with 103,143 variations. The child experimental dataset included 194 children, 6-12 years (88 ASD, 106 TD) who participated in an imitation task consisting of two brief (one-minute) independent movement sequences (Seq1 and Seq2). CAMI-2DNet automatically generates a score for these sequences by computing a similarity score between motion representations. Scores were also generated using CAMI-3D, CAMI-2D and HOC. Each method's ability to classify children into diagnostic (ASD vs. TD) groups was evaluated by calculating the receiver-operating characteristic (ROC) curves across both sequences from 47 participants (27 ASD, 20 TD) with HOC scores, with larger areas under the curve (AUC) indicating better discriminative ability. We also examined the validity of the CAMI methods by analyzing their correlation with "gold standard" HOC scoring.

Results:

Assessment of correspondence with manual HOC scoring was strongest for CAMI-2DNet ($r=0.71$) (Fig.1c) as compared to CAMI-3D ($r=0.69$) (Fig.1a) and CAMI-2D ($r=0.66$) (Fig.1b).

Assessment of diagnostic (ASD vs. TD) discriminative ability across both sequences revealed CAMI-2DNet had $AUC=0.843$, which neared that of CAMI-3D ($AUC=0.859$) and outperformed CAMI-2D ($AUC=0.789$) and HOC ($AUC=0.792$) (Fig.1d). On Seq1, CAMI-2DNet ($AUC=0.885$) outperformed both CAMI-3D ($AUC=0.794$) and CAMI-2D ($AUC=0.785$) (Fig.1e). For Seq2, CAMI-2DNet ($AUC=0.825$) outperformed CAMI-2D ($AUC=0.802$) and neared CAMI-3D ($AUC=0.906$) (Fig.1f).

Conclusions:

These results demonstrate that the newly developed CAMI-2DNet method provides a reliable, automated alternative to previous, labor-intensive CAMI methods (CAMI-3D, CAMI-2D) for quantifying motor imitation. CAMI-2DNet, which does not require manual correction or HOC annotation during training, showed a strong correlation with "gold standard" HOC scores and performed similarly, if not better, at classifying children as ASD or TD when compared with previous methods. CAMI-2DNet offers a highly scalable method for assessing motor imitation that could prove valuable for autism phenotyping in accessible (clinic, home) settings.

**405.231 Characterizing Neural Tactile Processing Differences to Spatial Context in Autism**

L. Jones¹, G. Parra², Y. Braverman³, K. E. Takach⁴, C. MacKay⁵, M. Shao², K. A. McNair², C. Serianni² and A. R. Levin¹, (1)Boston Children's Hospital/Harvard University, Boston, MA, (2)Boston Children's Hospital, Boston, MA, (3)Neurology, Boston Children's Hospital, Brookline, MA, (4)Laboratories of Cognitive Neuroscience, Boston Children's Hospital, Boston, MA, (5)Neurology, Boston Children's Hospital / Harvard Medical School, Brookline, MA

Background: Autism Spectrum Disorder (ASD) is characterized by atypical sensory processing that negatively impacts quality of life. Previous work has demonstrated that atypical sensory processing consists of co-occurring hyper- and hypo-reactivity in response to different tactile stimuli. Therefore, investigating reactivity to various levels of tactile stimulation may enhance our understanding of how individuals process sensory information. Previous studies have shown altered encoding of spatial context in ASD sensory responses. However, many existing paradigms studying this phenomenon cannot be readily used with children with ASD. As such, objective measures are needed to investigate differences in sensitivity to spatial context of tactile stimuli in children with ASD.

Objectives: The present study uses electroencephalography (EEG) paired with a novel tactile paradigm to investigate (a) event-related potential (ERP) response differences to the spatial context of tactile stimuli in young children with ASD and typical development (TD) and (b) how these differences relate to response to tactile stimuli duration.

Methods: We developed two versions of a novel tactile paradigm. Version 1 consisted of 32 Hz vibrotactile stimuli, each with a 2000 ms duration, which were delivered to either the right index finger, right middle finger, or both of the right index and middle fingers simultaneously. Each of the three conditions was presented 20 times. In Version 2 of the paradigm, each stimuli had a 500 ms duration with each condition presented 40 times. EEG data were collected during Version 1 from 17 3–4-year-old children (4 ASD, 13 TD) and Version 2 from 15 3–4-year-old children (6 ASD, 9 TD) with data collection ongoing. Data were collected with 128-channel Hydrocel Geodesic Sensor Nets and NetStation software (Magstim EGI, Eugene, OR, USA). The Batch EEG Automated Processing Platform (BEAPP) and the Harvard Automated Processing Pipeline for Electroencephalography (HAPPE) v3 were used for pre-processing. The peak amplitude of the P1 component (50–125ms) at electrode C3 was extracted for each participant in each condition. The average differences in the P1 component between dual-finger (both) and single-finger (index; middle) stimulations were computed for each participant to capture sensitivity to spatial context using the following formula:

$$P1 \text{ Amplitude Difference} = (((|SEP(Both) - SEP(Index)|) + (|SEP(Both) - SEP(Middle)|))) / 2$$

Results: Preliminary results suggest that, on average, children with ASD who experience tactile stimuli of 2000 ms durations have a greater sensitivity to spatial context, as measured by P1 average amplitude difference, between dual-finger and single-finger stimulations ($M=4.03$, $SD=1.15$) relative to TD children ($M=2.46$, $SD=1.37$), with a trend towards significance (Figure 1A), $t(15) = 2.06$, $p = .057$. This relationship is insignificant for tactile stimuli of 500 ms durations (Figure 1B), $p = .963$.

Conclusions: These findings demonstrate that following a longer stimulus duration, children with ASD respond with more neural sensitivity to tactile stimuli of various spatial contexts than TD children. Further, these findings suggest that children with ASD may experience atypical processing of tactile information based on spatial and temporal characteristics of the stimuli. This work will enhance our understanding of atypical sensory processing in ASD and potentially inform clinical advancements in the field.

405.232 Characterizing Sleep in Children with Autism Spectrum Disorder and Sensory Processing Concerns

S. R. Rogers¹, K. A. McNair¹, R. M. Mankaryous¹, C. Serianni¹, D. S. Manoach² and A. R. Levin¹, (1)Boston Children's Hospital, Boston, MA, (2)Lurie Center for Autism, Lexington, MA, (3)Neurology, Boston Children's Hospital / Harvard Medical School, Brookline, MA

Background: Sleep is vital to emotional and physical health and overall life enjoyment. Children with autism spectrum disorder (ASD) often have trouble sleeping and sensory processing challenges. Thalamocortical circuits modulate both sleep and sensory processing, and indeed previous studies report that children with more severe sleep disturbances have a higher prevalence of atypical sensory processing. However, the relationship between sleep and sensory processing challenges have not been extensively studied in children with atypical sensory processing who do not meet criteria for ASD. Parent surveys and clinical sensory observations can serve as a springboard to objectively understand how sleep and sensory processing impact each other in children with and without ASD.

Objectives: This study assesses children with ASD, children with sensory processing concerns (SPC) who do not meet criteria for ASD, and children with typical development (TD) to determine: (a) group differences in sleep challenges (b) the correlation between sleep and sensory processing, where sensory processing is measured by parent report and clinician observation.

Methods: 59 3- to 4-year-old children (20 ASD, 20 TD, 19 SPC) have participated in the current study, with data collection ongoing (target N = 120). Sleep quality was assessed using the Child Sleep Habits Questionnaire (CSHQ). Higher CSHQ total sleep disturbance scores indicate lower sleep quality. The Sensory Assessment for Neurodevelopmental Disorders (SAND) was used to measure sensory behavior through a clinician assessment and parent interview. Higher SAND scores indicate an increase in sensory sensitivity. Group differences were assessed by ANOVA and correlations were assessed using linear regression.

Results: ANOVA results reveal significant differences between all groups in total SAND sensitivity scores, $F(1,43) = 29.51$, $p < 0.001$, $\eta^2=0.58$ (Figure 1a). Total SAND hyperreactivity scores were found to be significantly different between ASD and TD groups only ($p = 0.05$) where individuals with ASD had higher scores. Preliminary ANOVA results reveal significant differences between groups in total sleep disturbance scores measured by the CSHQ, $F(1,59) = 7.19$, $p = 0.002$, $\eta^2=0.20$ (Figure 1b). Post-hoc analyses of total sleep disturbance scores revealed significantly larger scores in ASD compared to TD. There is no significant difference in SPC compared to ASD or TD. Furthermore, linear regression analysis reveal positive correlations between total sleep disturbance scores and both total sensory sensitivity scores, $F(1,44)=6.29$, $p=0.02$, $R^2=0.11$ (Figure 1c) and total sensory hyperreactivity scores, $F(1,44)=6.39$, $p=0.02$, $R^2=0.11$. No significant differences were found between total sleep disturbance scores and total sensory hyporeactivity ($p = 0.10$) or seeking scores ($p = 0.097$).

Conclusions: These findings align with prior research that shows sleep quality and sensory processing are both significantly different between individuals with ASD and TD. The results also suggest that sensory processing and sleep quality interact. Future studies that objectively measure sleep quality and neurophysiology (e.g., sleep EEG) would provide opportunities to better understand how shared thalamocortical circuitry function impacts sleep and sensory processing.

405.233 Clinical Correlates of Motor Function in Autistic Adults

J. Y. Yan¹, W. L. Hsu² and Y. L. Chien³, (1)School of Medicine, National Taiwan University School of Medicine, Taipei, Taiwan, (2)School and Graduate Institute of Physical Therapy, National Taiwan University, Taipei, Taiwan, (3)National Taiwan University Hospital, Taipei, Taiwan

Background: Challenges in motor coordination are a prominent feature of autism spectrum disorder (ASD) across the lifespan, with a co-occurrence rate of 50-80%. Recent studies have demonstrated a bi-directional relationship between motor skills and core autism symptoms. However, evidence regarding the impact of motor skills on other areas of function remains limited, and most research focuses on children and adolescents. The role of motor skills in autistic adults and their relationship to various functional domains are largely underexplored.

Objectives: This study aims to explore the association between motor difficulties and autistic traits, sensory features, and executive function in autistic adults.

Methods: We recruited 60 adults on the autism spectrum (15 females), aged 19 to 43 (mean age 29.2 ± 6.3), from the Department of Psychiatry at National Taiwan University Hospital. Motor coordination was assessed using the Timed Up and Go (TUG) test, which measures the time it takes to rise from a standard chair, walk three meters, turn around, walk back to the chair, turn before sitting, and sit down again. It has been shown to be reliable in teenagers with ASD. Longer test times indicate poorer motor control. The duration of each TUG phase was recorded using a G-WALK® sensor on a waist belt at the L2 level. Meanwhile, the Social Responsiveness Scale (SRS), Sensory Profile (SP), Behavior Rating Inventory of Executive Function (BRIEF), and Autism-Spectrum Quotient (AQ) were used to evaluate social behavior, sensory features, executive function, and overall autistic traits, respectively. Higher scores suggest greater challenges in the given area. Pearson correlation analysis was used to examine the association between TUG phase durations and each clinical scale, controlling for weight, height, and gender.

Results: All participants were able to complete the measurement without stopping during the tasks. **Fig. 1** presents the partial correlations and p-values between TUG phase durations and each clinical scale. Overall, longer test times were associated with greater difficulties in corresponding functional domains. Specifically, difficulties in Social Emotion, Sensory Registration, BRIEF-Initiate, Global Executive Composite, and Metacognitive Index were correlated with longer end-turning phase and total test durations. Additionally, Attention Switching was linked to increased time spent during total test duration, as well as the forward and return gait phases. Extended times in both the sit-to-stand and stand-to-sit phases were associated with difficulties in Social Awareness, while being inversely related to Sensory Seeking. Of the six phases, the end-turning phase duration and total test duration showed the strongest correlations with clinical variables. Notably, Total SRS, Sensory Sensitivity, and BRIEF-Shift were positively correlated with the end-turning phase duration, while BRIEF-Inhibit, Working Memory, Plan/Organize and Organization of Materials were associated exclusively with total test duration.

Conclusions: The findings suggested that slower motor coordination was correlated with sensory features, executive function, and social behavior, emphasizing the need for greater clinical attention to motor difficulties in autistic adults. It is also important to note that the absence of intelligence quotient as a controlling variable may introduce confounding factors. Future investigation is needed to validate our findings.

405.234 Altered Auditory Modulation in Children with Autism Spectrum Disorder

M. Shao¹, Y. Braverman², L. Jones³, R. M. Mankaryous⁴, K. A. McNair¹, S. R. Rogers¹, C. Serianni¹ and A. R. Levin¹, (1)Boston Children's Hospital, Boston, MA, (2)Neurology, Boston Children's Hospital, Brookline, MA, (3)Boston Children's Hospital/Harvard University, Boston, MA, (4)Neurology, Boston Children's Hospital / Harvard Medical School, Brookline, MA

Background: In our everyday experience, important sound stimuli (e.g. conversation) typically co-occur with noise (e.g. wind, traffic). The ability to discriminate target sound stimuli from noise is imperative for young children's development of speaking ability and their awareness of the environment, two skills that children with autism spectrum disorder (ASD) often struggle with. Electroencephalography (EEG) recording offers opportunities to explore the association between stimuli salience and auditory middle latency responses (MLR), responses to auditory stimuli that occur 10-75 milliseconds after stimulation. Past research has shown the distance between the amplitude of two consecutive MLR components, Na and Pa, to be positively correlated with listener's loudness judgment. However, to date, no EEG study has investigated how TD children and children with ASD differ in their responses to auditory stimuli of varying salience, as influenced by the introduction of background noise.

Objectives: This study aims to evaluate: (1) how varying levels of background noise play a role in affecting young children's brain response to target tone stimuli, and (2) how the effect of background noise on Na and Pa amplitudes differs for TD and ASD children.

Methods: We created a novel paradigm to test MLR to target tones in background noise. Participants are presented with 3600 randomized tones (1200 tones at each volume level: low, medium, high) that are each 0.1ms in duration. Among the 1200 tones of the same volume level, an equal number of tones are presented concurrently with a low, medium, and high background white noise. EEG data were collected with Geodesic Sensor Nets through NetStation software (Magstim EGI, Eugene, OR, USA). Data was preprocessed by using the Batch EEG Automated Processing Platform (BEAPP) and the Harvard Automated Processing Pipeline for Electroencephalography (HAPPE) v3. The amplitude of the Na-Pa peak-to-peak distance measured at electrode C5, as previously described for MLR analyses, was extracted from the average ERP of each participant. Data collection is ongoing, with a current usable sample size of seven 3-4 years old children (4 TD, 3 ASD). Target sample sizes for this study are 25 TD and 25 ASD.

Results: Results suggest that, at high background noise level, as tone volume increases, children from both the TD and the ASD group show increased Na-Pa peak-to-peak distance at electrode C5 (Figure 1a). In addition, children with ASD show such an increase at a steeper slope than TD children (Figure 1b), $t(5) = -4.89$, $p < .001$, $d = -3.73$, suggesting between-groups differences in brain activity in response to auditory stimuli delivered concurrently with noise. Currently, there are no significant group differences at lower levels of background noise.

Conclusions: These results indicate that children with ASD exhibit a greater rate of increase in brain activity in response to the amplification of target tone amidst high background noise, suggesting that children with ASD may have atypical auditory processing or attentional difficulty when presented with competing sounds. Continuing to monitor this finding will advance our understanding of the atypical sensory processing observed in many children with ASD.

405.235 Differences in Sensory-Motor Profiles between Low Risk and High-Risk Infants: Preliminary Results from ERI-Sibs Project (Early Recognition and Intervention in SIBlings at High Risk for Neurodevelopment Disorders)

G. Purpura^{1,2}, S. Annunziata¹, G. Mantegazza¹, E. Piazza¹, S. Biancardi¹, M. Brivio¹, A. Restelli¹, C. Caporali¹ and A. Cavallini¹, (1)IRCCS Fondazione Don Carlo Gnocchi ONLUS, Milan, Milan, Italy, (2)School of Medicine and Surgery, University of Milano Bicocca, Monza, Monza e Brianza, Italy, (3)IRCCS Don Carlo Gnocchi Foundation, Milan, Milan, Italy

Background: Recent research underscored the importance of early diagnosis and intervention in children at risk of neurodevelopmental disorders. For example, siblings of children with autism spectrum disorder (ASD) are at increased risk of abnormal developmental trajectories, even in the absence of a specific diagnosis (McDonald et al., 2020). Several authors suggest that, before the 18 months of life, atypia in sensory-motor profiles may precede social communication symptoms in these infants (Costanzo et al., 2022; Esposito et al., 2009; Purpura et al., 2017; Srinivasan & Bhat, 2016; Van Etten et al., 2017). Bhat et al. (Bhat et al., 2012) reported a correlation between early visual-motor integration skills and late social-communication abilities. Bradshaw and colleagues (Bradshaw et al., 2021) highlighted that observable social-communication differences for infants with ASD seem to unfold at nine months of life. Therefore, the second semester of the first year of life may be a critical window for targeted intervention. In this context, ERI-SIBS was developed as an innovative and ecological early recognition and intervention program designed for siblings of ASD children (Clinicaltrials.gov identifier NCT06512649).

Objectives: This study aims to analyse sensory-motor profiles during the second semester of the first year of life to detect potential early differences between high-risk (HR) and low-risk (LR) infants.

Methods: We aim to recruit 48 siblings at LR and HR for neurodevelopmental disorders. To this day, we have recruited 21 infants (age range: 6-12 months), 8 of whom are siblings of typical developing children (LR) and 13 of whom are siblings of ASD children (HR). Scores at Griffiths Scales of Child Development-3, Communication and Symbolic Behaviour Scales-Infant-Toddler Checklist (CSBS-IT-C) and Questionnaire Sensory Profile-2 (SP-2) are reported and analysed. Since the limited sample, statistical analyses were performed through a non-parametric approach.

Results: Preliminary results showed different developmental profiles in the two groups. In particular, the Mann-Whitney Test highlighted lower quotients in language and communication ($p=0.015$) and eye-hand coordination ($p=0.042$) subscales of Griffiths-3 in HR infants than in LR infants (see Figure 1). General Developmental Quotients showed different distributions and variances (HR: mean 97, SD 15.5; LR: mean 108.2, SD: 7.9), and in the HR group, 5/13 infants showed at least a sub-quotient lower than 85.

As regards CSBS-IT-C scores, the two groups also showed differences with a tendency to statistical significance in social engagement, with lower scores in HR infants in comparison to LR infants (HR: mean 8.1, SD 2.9; LR: mean 10.2, SD 1.7; HR vs LR p -value: 0.057). Finally, wider sensory dysfunctions were revealed at SP-2 in the HR group, particularly in the auditory processing.

Conclusions: Preliminary results from the ERI-SIBS project indicated different sensory-motor profiles between LR and HR infants. In particular, preverbal communication abilities and visual-motor coordination appear to be the most critical aspects at this age. This suggests that an early global assessment, including sensory-motor skills, is necessary to tailor and address early intervention for HR infants. According to these insights, ERI-SIBS provides a naturalistic early intervention that can positively impact the neurodevelopment of this population.

405.236 Distinguishing between Normal Gait and Toe-Walking Using Kinematic Data Gathered Via Openpose and Machine Learning Classifiers: A Pilot Study.

L. E. Molteni¹, G. Valagussa^{2,3,4}, M. Boccotti⁵, G. Purpura¹, C. Perin¹, A. Crippa¹, G. Andreoni^{1,6} and E. Grossi¹, (1)Scientific Institute IRCCS "E.Medea", Bosisio Parini, Lecco, Italy, (2)Autism Research Unit, Villa Santa Maria Institute, Tavernerio, Como, Italy, (3)School of Medicine and Surgery, University of Milano-Bicocca, Milano, Milano, Italy, (4)PhD Program in Neuroscience, University of Milano-Bicocca, Milano, Milano, Italy, (5)Autism Research Unit, Villa Santa Maria SCS, Tavernerio, Como, Italy, (6)Department of Design, Politecnico di Milano, Milan, Italy

Background: Altered gait patterns, such as toe walking (TW), are common in various clinical conditions, including Autism Spectrum Disorder (ASD), where TW affects about 20-30% of individuals. Quantification of TW can provide valuable insights into gait abnormalities and guide interventions. A recently proposed video-based coding protocol allows TW quantification in natural settings but requires manual video review by an operator. However, a markerless gait analysis system (MGAS) could address the challenges of non-acceptance in individuals with ASD or intellectual disabilities, enabling automated kinematic analysis and detection of uncommon gait patterns like toe walking with minimal operator involvement during data processing. This approach could improve the efficiency and accuracy of gait assessments in such populations.

Objectives: This study aimed to develop a novel method for detecting toe-walking using the OpenPose module.

Methods: The present study involved 10 subjects with neurotypical development (aged 4-18 years; 7 males) who simulated toe-walking and 2 individuals with ASD (age: 5 and 8,1 years; 2 males), diagnosed according to DSM-5 criteria and presenting toe-walking. All participants were administered a validated video-based coding protocol based on standardized video recordings to quantify toe-walking. The test consisted of transporting an object (e.g., puzzle, Lego®) from a therapist to a playing table located 3 meters away and back again 10 times. All tests were conducted without shoes, albeit with socks. The subjects with neurotypical development were tested once, while the individuals with ASD were tested three times on three different days (6 acquisitions), resulting in 16 tests. Sagittal-plane video recordings of the walking trials were collected based on a setup described in the literature. Using the OpenPose module, the skeletons were extracted in the sagittal plane, and gait kinematics were computed. A two-tailed T-test was applied to identify the most relevant features: we selected features at p -value test <0.05 as inputs for the classifiers. Then, these selected features were then used to train supervised neural networks (NNs) to evaluate accuracy, sensitivity, specificity, and the area under the curve (AUC).

Results: Finally, 1140 normal and 648 tip-toe gait samples were used to train three neural network classifiers. We identified 12 relevant features, summarized in Table 1. The classifiers were trained using these selected features and a leave-one-out cross-validation process, repeated 19 times. Classifier performance metrics (mean and standard deviation for accuracy, sensitivity, and specificity) were evaluated using Support Vector Machine (SVM), K-Nearest Neighbors (KNN), and Bayesian classifier, with z-score normalization. The results, summarized in Table 2, showed that the SVM classifier obtained the best results.

Conclusions: The proposed method offers the potential for automated detection and quantification of toe walking in standardized protocols and settings. This approach provides detailed kinematic data with a fully non-intrusive method, not requiring the patient's instrumentation. The following research steps will be dedicated to the study of a larger court of subjects to further validate the findings of this preliminary study.

405.237 Distinguishing between Restricted and Unusual Interests: Investigating the Role of Social Functioning and Inflexibility
K. Paszek¹, L. Chetcuti², E. Spackman³, R. E. Nevill⁴, J. M. Phillips¹, T. N. Takahashi⁵, A. M. Gunn⁶, E. Fuhrmann⁴, J. Gong⁴, R. Libove¹, K. P. Nowell¹, M. Mazurek⁴, S. M. Kanne⁸ and A. Y. Hardan¹, (1)Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA, (2)Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA, Australia, (3)Psychiatry and Behavioral Sciences, Department of Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA, (4)University of Virginia, Charlottesville, VA, (5)Thompson Center for Autism & Neurodevelopmental Disorders, Thompson Center for Autism & Neurodevelopmental Disorders, Columbia, MO, (6)University of Missouri Thompson Center for Autism & Neurodevelopment, Columbia, MO, (7)Health Psychology, Thompson Center for Autism & Neurodevelopmental Disorders, Columbia, MO, (8)Center for Autism and the Developing Brain, Weill Cornell Medicine, White Plains, NY

Background: Recent findings have suggested that rather than being a unidimensional construct, special interests are complex and multidimensional subdomains of restricted and repetitive behaviors (RRB). More specifically, across both factor analytic studies and qualitative studies, unusual interests (UI), or interests that are unusual in terms of their content, and restricted interests (RI), or interests distinguished by their atypical intensity or focus rather than topic or content, have emerged. Developmental accounts of special interests suggest that early emerging differences in social reward processing may lead to increased seeking out of rewarding non-social activities and interests. Although previous studies have suggested that RI and UI show distinct patterns of associations with age and cognitive functioning, potential differences in their associations with social functioning requires further investigation.

Objectives: This study focused on characterizing associations between RI and UI with distinct facets of social functioning and inflexibility. Given that UI are primarily characterized by topics/content that is specific to autism and RI primarily by difficulties regarding the ability to disengage and shift focus, we hypothesized that UI would show the strongest associations with social functioning and RI with insistence on sameness (IS).

Methods: Secondary data were utilized from a sample of 59 parents of autistic youth (mean age [SD] = 92.11 [33.51] months; 78% male), as part of a larger study conducted across three U.S. sites: Stanford University, University of Missouri, and University of Virginia. The Dimensional Assessment of Repetitive Behaviors (DARB) was employed to assess RI, UI, and IS. Social functioning was measured using the Stanford Social Dimensions Scale-2 (SSDS-2), which evaluates social motivation (SM), social affiliation (SA), expressive social-communication (ESC), and social recognition (SR). Spearman's correlational analyses explored relationships among DARB and SSDS-2 subscales, while Fisher's z-test determined the statistical significance of differences in correlation strengths. A significance level of .05 was used.

Results: Results of correlational analysis are depicted in **Figure 1**. Positive correlations were observed between IS and both RI and UI. The correlation between IS and UI was significantly stronger ($z = -2.10$, $p < .05$) than the correlation between IS and RI. IS and UI each showed negative correlations with SA, ESC, and SR, with no significant differences in the magnitudes of these correlations (all contrasts $p > .05$). Neither IS nor UI showed significant correlations with SM, while RI exhibited non-significant correlations with all SSDS-2 subscales.

Conclusions: Distinct patterns of association found for RI and UI further demonstrates the need to independently assess and characterize these constructs. IS displaying a stronger association with UI than RI may suggest that UI have a more ritualized component than RI or may reflect a stronger general association between UI (a phenomena not commonly seen outside of autism) and autistic features. Finally, SM showing no association with either RI and UI is somewhat inconsistent with the social reward processing hypothesis of special interests and indicated that further work is needed elucidate the role of specific aspects of social functioning in the development of intense interests, in particular UI.

Additional analyses will be completed as the study is ongoing and more data is being collected.

405.238 Early Gait Features Predict Later Autism Diagnosis

L. A. Wang¹, B. Tunc², E. Sariyanidi³, J. M. Iverson⁴, C. J. Zampella³, W. Guthrie⁵, L. S. Cubit⁶, M. Drye⁶, M. Fecher⁷, S. Craig⁸, G. Megginson⁸, L. D. Yankowitz⁹ and R. T. Schultz¹⁰, (1)Center for Autism Research, Yale Child Study Center, Yale School of Medicine, Philadelphia, PA, (2)Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, (3)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (4)Boston University, Boston, MA, (5)Clinical and Social Sciences in Psychology, Center for Autism Research, Rochester, NY, (6)University of Miami, Miami, FL, (7)Center for Autism Research, Center for Autism Research (CHOP), Philadelphia, PA, (8)Center for Autism Research, CHOP Center for Autism Research, Philadelphia, PA, (9)Laboratories of Cognitive Neuroscience, Boston Children's Hospital/Harvard Medical School, Boston, MA, (10)The Center for Autism Research/CHOP, Philadelphia, PA

Background: Motor delays are among the earliest-emerging developmental differences in children who are diagnosed with autism spectrum disorder (ASD) (West, 2019). A growing literature has demonstrated that quantitative gait measures, such as higher variability of spatiotemporal gait metrics, hold promise as novel biomarkers of ASD (Lum et al., 2021). However, no studies have prospectively assessed early gait in infants who develop ASD.

Objectives: Prospectively investigate whether objective measures of toddlers' early gait predict later ASD diagnoses and language outcomes.

Methods: The study sample consisted of 77 children (28 with an older sibling with a diagnosis of ASD and 49 with no first-degree autistic relatives). Children participated in a gait task approximately one month after they began to walk independently, during which their movements were recorded via a pressure-sensitive gait mat and a three-dimensional (3D) depth camera. Means and standard deviations of spatiotemporal gait features were extracted from gait mat data; computer vision methods were used to compute kinematic and postural features from 3D camera data (Fig. 1). Children underwent a comprehensive autism evaluation at 24 months. Hypothesis-driven logistic and linear regression models examined whether a measure of gait variability (the enhanced gait variability index; Gouelle et al., 2013) predicted later ASD diagnosis, symptom severity (CARS-2 raw score), and language ability (Bayley-4 Communication Standard Score), after statistically controlling for Bayley-4 cognitive scores at 12 months. We hypothesized that greater gait variability would be significantly associated with a higher degree of ASD symptoms and poorer language skills at 24 months. Exploratory analyses used cross-validated machine learning classifiers to predict ASD diagnostic outcomes.

Classifiers were run with four different feature sets to compare predictive utility across possible screening tools: 1) an established parent-report measure (the Autism Parent Screen for Infants; APSI), 2) gait mat features, 3) computer vision features, 4) combined gait mat & computer vision features.

Results: A total of 18 children were diagnosed with ASD. Regression models demonstrated that greater gait variability was associated with more ASD symptoms ($\beta = 0.02, p = 0.04$) and marginally significantly associated with a higher likelihood of receiving an ASD diagnosis ($\beta = 0.09, p = 0.06$). Gait variability was not associated with later language outcomes ($\beta = -0.22, p = 0.45$). Exploratory findings demonstrated that classifiers trained on computer vision features alone achieved the highest prediction accuracy (77%), compared to classification based on gait mat features (65%), combined motor features (72%), and the APSI (62%). See Table 1 for additional performance metrics for all feature sets.

Conclusions: This study is the first to prospectively investigate whether early gait features are associated with later clinical outcomes in autistic children. Findings indicate that gait variability is significantly and specifically associated with ASD symptom severity but not language outcomes. Classifiers trained on motor features not only predicted later ASD diagnoses with high accuracy, but outperformed prediction based on an established screening tool designed to assess for early signs of ASD. Results support the conclusion that motor differences hold potential to enhance screening and early detection of ASD.

405.239 Ecological Momentary Assessment: A Novel Tool for Assessing Rrbs and Their Relationship with Adaptive Functioning
S. Rozenblat¹, T. Mentch Lifshits^{2,3}, M. Nahum³, E. R. Lebowitz⁴ and J. Koller¹, (1)*Seymour Fox School of Education, The Hebrew University of Jerusalem, Jerusalem, Israel,* (2)*Seymour Fox School of Education, The Hebrew University of Jerusalem, Jerusalem, Jerusalem, Israel,* (3)*School of Occupational Therapy, The Hebrew University of Jerusalem, Jerusalem, Jerusalem, Israel,* (4)*Yale Child Study Center, Yale School of Medicine, New Haven, CT*

Background:

Restricted and repetitive behaviors (RRBs) represent a heterogeneous group of behaviors, ranging from repetitive motor movements and speech to persistent rituals and preoccupation with intense and fixed interests. These vary from person to person and their presentation can change within individuals across time and contexts (Lombardo et al., 2019). The literature shows inconsistent findings regarding the relationship between RRBs and adaptive functioning, partially due to our inability to accurately assess these traits.

Researchers and autistic self-advocates have long expressed concerns regarding the state of assessment of autistic traits, including challenges related to content and ecological validity (e.g., Sturm et al., 2017). RRBs have proven particularly difficult to reliably and validly measure (e.g., Uljarević, 2021). Most studies rely on observational measures of autism symptomatology, which largely skew toward criterion A of the DSM, impairment in social communication and interaction. Such measures (e.g., ADOS) produce a single score intended to capture all RRBs, ignoring the variable nature of this symptom class (Ozonoff et al., 2005). An ecological momentary assessment (EMA) of RRBs could serve to capture the multidimensionality of RRBs and more accurately characterize the way in which they manifest in different contexts in the child's daily life. This framework would allow to examine how specific RRBs associate with functional outcomes in the context of a specific child and his/her environment, allowing for the differentiation of adaptive from maladaptive RRBs in a subjective fashion.

Objectives:

(1) To establish the feasibility of the EMA of RRBs. (2) To examine the association between RRB subtypes, as measured through EMA, and adaptive functioning in a subjective manner.

Methods:

Participants are parents of autistic children aged 3-6. Through a novel mobile EMA platform developed by the Computerized Neuroscience Laboratory at the Hebrew University (Yitzhak et al., 2023; Nahum et al., 2023), participants will report on the frequency of six subtypes of RRBs twice daily for a period of two weeks. Participants will also report on child adaptive functioning (ABAS-3; Harrison & Oakland, 2015). Hierarchical linear modeling will be used to examine patterns of association between RRB subtypes and adaptive functioning.

Results:

Preliminary analyses from 8 participants (2 females; mean age = 50±9.7 months) show feasibility for the EMA tool, pointing to high completion rates (mean = 86.5% ± 24.3, range = 50-100%) and time efficiency (mean time to complete per EMA entry = 3.8 min). The EMA data reveals a unique RRB profile for each child, and comparison of EMA data to retrospective parent-report measure (i.e., RBS-R; Bodfish et al., 1999) shows that EMA provides a distinct perspective on RRB expression (see Figures below). Data collection is ongoing and future analyses with a larger sample will examine associations of RRB subtypes and adaptive functioning.

Conclusions:

EMA is a feasible framework for measuring RRBs, which may more accurately depict naturalistic RRB phenotypes than single timepoint retrospective reporting. Through this framework, we can examine how specific RRBs associate with functional outcomes in the context of a specific child, operationalizing a way to distinguish adaptive from maladaptive RRBs.

405.240 Elevated Heart Rate Reactivity during Unanticipated Acoustic Startle in Autistic Children

E. R. Palser^{1,2}, J. Han², V. H. Bal³, M. Knudtson², G. Gocheva², Z. A. Miller², C. Pereira⁴, M. L. Gorno Tempini⁵ and V. E. Sturm¹, (1)Department of Psychology, Palo Alto University, Palo Alto, CA, (2)Department of Neurology, University of California, San Francisco, San Francisco, CA, (3)Graduate School of Applied and Professional Psychology, Rutgers University - New Brunswick, Piscataway, NJ, (4)University of California, San Francisco, San Francisco, CA, (5)Department of Neurology; Department of Psychiatry and Behavioral Sciences, University of California, San Francisco, San Francisco, CA

Background: Autistic children demonstrate both sensory and emotional differences, such as auditory hyper-reactivity and challenges with emotion regulation, which can have a significant impact on everyday functioning and quality of life. Previous studies have mostly examined sensory and emotional differences in autism independently, using diverging methods. Autonomic nervous system differences have also been sporadically reported in autistic people, and may relate to sensory and emotional differences, but have not been comprehensively investigated in either sensory or emotional paradigms.

Objectives: The present study aimed to examine differences in baseline unanticipated acoustic startle, an involuntary reaction that lies at the intersection of emotion and reflex, in autistic and neurotypical children, using heart rate reactivity and self-reported emotional experience.

Methods: We investigated heart rate reactivity and subjective emotional experience in response to a 100 ms, 105 dB unanticipated acoustic startle stimulus in 27 autistic children (4 female, 23 male) and 31 neurotypical children (15 female, 16 male). Participants were aged 7 to 14, and groups were matched on age, body mass index (BMI), nonverbal reasoning, and time of testing (AM/PM). Inter-beat interval (IBI) reactivity was computed as a measure of heart rate reactivity immediately following the stimulus (0-10 seconds) and during a recovery period (11-60 seconds), by subtracting IBI during these periods from resting IBI. After the recovery period, participants were asked to report their experience of 11 discrete emotions on a three-point scale from 0 (not at all) to 2 (a lot), which were summed to obtain a total emotional experience score. All analyses controlled for sex.

Results: All participants demonstrated similar resting IBI and similar changes in IBI immediately following the startle stimulus, $B = 14.42$, $t = 0.44$, $p = .437$, Adjusted $R^2 = -.027$, $f^2 = -.013$. Throughout the recovery period, however, autistic children maintained lower IBI, indicating faster heart rate, than neurotypical children, $B = 38.86$, $t = 2.14$, $p = .038$, $R^2 = -.027$, $f^2 = -.089$. Autistic children also reported greater total emotional experience than neurotypical children, $B = -1.43$, $t = 0.70$, $p = .047$, Adjusted $R^2 = .114$, $f^2 = -.080$.

Conclusions: Findings suggest that autistic children experience prolonged heart rate recovery and greater subjective emotional experience in response to an unanticipated acoustic startle stimulus. Such differences in autonomic nervous system reactivity and subjective experience may underlie the sensory hyper-reactivity and emotion regulation challenges autistic people experience. Moreover, the findings demonstrate the utility of multi-modal approaches for studying the emotional and sensory features of autism.

405.241 Elucidation of the Relationship between Sleep Disturbance and Sensory Characteristics Leading to Behavioral Problems in Children with Autism Spectrum Disorder

H. Shimizu¹, **A. Ohashi²**, **K. Tazoe³**, **K. Terada⁴**, **R. Iwanaga⁵** and **H. Kumazaki⁶**, (1)Department of Neuropsychiatry, Nagasaki University Hospital, Nagasaki, Nagasaki, Japan, (2)neuropsychiatry, Nagasaki University Hospital, Nagasaki, Nagasaki, Japan, (3)Department of Neuropsychiatry, Nagasaki University, School of Medicine, Nagasaki, Nagasaki, Japan, (4)Gifu University, Gifu, Gifu, Japan, (5)Graduate School of Biomedical Sciences, Nagasaki University, Nagasaki, Japan, (6)Department of Neuropsychiatry, Graduate school of Biomedical Sciences, Nagasaki University, Hirokazu Kumazaki, Nagasaki, Japan

Background:

Children with autism spectrum disorder (ASD) (70–95%) have atypical sensory processing. Atypical sensory processing, especially sensory seeking, is strongly associated with maladaptive behaviors related to antisocial behaviors and caregiver strain. ASD is known to complicate sleep disturbances in up to 80% of patients and exacerbate behavioral problems. The identified causative genes for ASD with sensory features, including *CHD8*, *SCN2A*, and *SYNGAP1*, are known to be involved in sleep disturbances, suggesting an innate link between sensory and sleep profiles in children with ASD. Although a proper understanding of the relationship between sleep and sensation may reduce behavioral problems, the results of previous studies have been inconsistent owing to a lack of detailed information on sleep and sensation profiles.

Objectives:

The objective of our study was to clarify the relationship between sleep and sensory characteristics to reduce behavioral problems in children with ASD.

Methods:

Between March 2023 and March 2024, we asked parents of children with ASD aged 3–6 years to complete online questionnaires (the Japanese Sleep Questionnaire for Preschoolers [JSQ-P], the Autism-Spectrum Quotient, the Eyberg Child Behavior Inventory [ECBI], and sensory questionnaires, which provide three categories (hypersensitivity, hyporesponsiveness, and sensory seeking) for each of the seven sensory dimensions: auditory, visual, tactile, proprioceptive, vestibular, gustatory and oral, and olfactory. Parental consent was obtained electronically, and ethical approval for this study was obtained from Gifu University (approval number: 27-230).

Results:

A total of 122 boys (73.5%) and 44 girls participated in the study; 96.4% of the respondents were mothers. The mean age of the participants was 63.0±11 months, and 98 (59%) participants had behavioral problems, as assessed by the ECBI intensity scales. Welch's t-test showed that the group with behavioral problems had a significantly higher JSQ-P total score ($t[157]=8.52, p<.001$) than the group without behavioral problems. Parasomnia ($t[158]=4.27, p<.001*$) and insomnia or circadian rhythm disorders ($t[159]=6.77, p<.001*$) were sleep disturbance-related factors that were significantly higher in the group with behavioral problems. None of the lifestyle factors, such as screen time, starting time of dinner and bath, or bedtime, showed significant differences ($p>.05$). Correlation analysis revealed significant correlations between behavioral problems and sleep problems ($r=0.60, p<.001*$), hypersensitivity ($r=0.43, p<.001*$), hyporesponsiveness ($r=0.33, p<.001*$), and sensory seeking ($r=0.51, p<.001*$). Correlations exist between sensations and sleep disturbances, as well as between sensory factors. Partial correlation analysis using sensory scores as a control variable revealed a significant correlation between sleep disturbances and behavioral problems ($r_p=0.46, <.001*$) (Fig. 1).

Conclusions:

A strong positive correlation exists between sleep disturbance and behavioral problems in children with ASD. The group with behavioral problems had significantly higher scores on all seven sensory dimensions. Nevertheless, assuming spurious correlations due to sleep disturbances, only sensory seeking was significantly correlated with behavioral problems, and hypersensitivity was not directly responsible for the behavioral problems. Focusing on sensory seeking and satisfying their need for sensory seeking may improve sleep status and reduce behavioral problems in children with ASD.

**405.242** Emotion Regulation and Family Accommodation in Autism

T. Graucher¹, **J. Koller²** and **T. Matz Vaisman²**, (1)Education, Hebrew University, Jerusalem, Israel, Israel, (2)Seymour Fox School of Education, The Hebrew University of Jerusalem, Jerusalem, Israel

Background:

Emotion regulation (ER) refers to the processes by which individuals influence which emotions they have, when they have them, and how they experience and express them (Kooze et al., 2011; Gross, 1998). Recent research supports a relationship between RRBs and emotion regulation difficulties in autism, specifically self-injurious RRBs, which were found to be the best predictors of ER (Martínez-González et al., 2022). Parental ER is also associated with the child's ER and externalizing problems (Ting & Weiss., 2017).

Family accommodation (FA) refers to proactive modifications made by family members intended to decrease their child's distress, which stems from the child's psychopathology. FA of RRBs has been preliminarily documented, with elevated FA being associated with elevated RRB severity, reduced adaptive functioning, and increased disruptive behavior and parenting stress (Feldman et al., 2019; Koller et al., 2021).

The association between child and parent ER and FA of RRBs has yet to be examined.

Objectives:

To examine the cross-sectional presence and nature of the association between child and parent ER and FA among families of young autistic children.

Methods:

Participants were 133 children, (mean age 38.9 months; 94 males) with suspected autism and their parents. Based on a gold-standard evaluation including measures of child development (Mullen, 1995) and autism symptomatology (ADOS-2; Lord et al., 2000; RBS-R; Bodfish et al., 2000), three groups were generated: 88 autistic children, 28 characterized as having developmental delays (DD; based on at least one Mullen scale ≥ 2 SD below the mean or at least two scales ≥ 1.5 SD below the mean; Ozonoff et al., 2014), and 23 children who did not receive a diagnosis and did not display any DDs.

Parents completed several questionnaires regarding child ER (CBQ; Rothbart et al., 2001), parental ER (ERQ; Gross et al., 2003), and accommodation (FAS-RRB, Feldman et al., 2019).

Results:

Spearman's correlations between the study variables found that family accommodation (FA) indices positively and significantly associated with child negative affect ($r(82) = .41-.50$), with no significant differences between groups. Additionally, among autistic children, FA positively associated with child surgency ($r(82) = .24-.28$).

Regarding FA and parental ER (ERQ), the lone significant finding points to a positive correlation between maternal accommodation of children's RRBs with maternal expressive suppression ($r(43) = .37, p < .007$) among mothers of autistic children.

Conclusions:

This study is the first to shed light on the relationship between ER and FA of RRBs. Results show a positive correlation between negative affect and FA, meaning that when a child presents more negative emotions, there are likely to be more accommodating behaviors. Within the autistic group, there are further connections between accommodation and ER. When considering factors subsumed by child surgency, impulsiveness and high activity level are associated with increased accommodation. Additionally, mothers who tend to conceal emotion-expressive behavior tend to accommodate more. A longitudinal examination of the interaction between these constructs is necessary in order to gauge their clinical significance.

405.243 Examining Object Play Initiation Delays during ADOS-2 Make-Believe Play Task

B. C. Dos Santos Melicio¹, K. Karaköse¹, P. G. Molnar¹, **K. KamaF**, A. Sarkany², F. Alshaban³, I. Ghazal³, F. Al-Faraj³, L. V. Valluripalli Soorya⁴, K. Fenech¹ and A. Lorincz¹, (1)Department of Artificial Intelligence, Eotvos Lorand University, Budapest, Budapest, Hungary, (2)Argus Cognitive Inc., Budapest, Hungary, (3)Neurological Disorder Research Center, Qatar Biomedical Research Institute, Doha, Doha, Qatar, (4)Department of Psychiatry, Rush University Medical Center, Chicago, IL

Background: Autism Spectrum Disorder (ASD) is often associated with Restrictive and Repetitive Behaviors (RRB), which include restricted interactions with objects. Object play, a crucial aspect of children's development, offers insights into the sensory and motor processes underlying these behaviors. This study explores whether children with ASD exhibit delays in initiating interactions with objects, potentially due to factors such as increased inspection time or sensory processing differences, which shape how children with ASD perceive and respond to their surroundings.

Objectives: This study analyzes the differences in time taken to start interactions with objects between ASD and non-ASD children during the ADOS-2 Module 3 Make-Believe Play task. The objectives are to: (1) compare the time taken to initiate a touch contact with an object between ASD and non-ASD children; (2) compare the time taken to initiate a play behavior with an object between ASD and non-ASD children; (3) assess whether initiating touch is likely to lead to subsequent play; and (4) evaluate differences in the total number of objects interacted with by each group.

Methods: This study included 79 children (49 male, 30 female; mean age: 8.7 ± 1.9 years), with 41 diagnosed with ASD and 38 non-ASD, from ADOS-2 session recordings from a combined dataset from clinics in the US and Qatar. Time intervals between the initial touch and the onset of play were separately annotated for all videos by three annotators.

Results: Children with ASD took longer on average to initiate play behaviors compared to non-ASD children (ASD median = 17 seconds, IQR = 26; non-ASD median = 7 seconds, IQR = 11; $p = 0.0009$), indicating a notable difference in how quickly each group engaged with objects. A similar pattern was observed with touch initiation times (ASD median = 12 seconds, IQR = 20; non-ASD median = 7 seconds, IQR = 10.5; $p = 0.0028$).

In non-ASD children, touch often led to play quickly, with an average transition time of 1.4 seconds, in comparison to the longer ASD average transition time of 4.8 seconds. There was no significant difference between the groups in the total number of objects interacted with (ASD mean = 7.2 objects, SD = 3.5; non-ASD mean = 8.4 objects, SD = 4.5; $p = 0.29$).

Conclusions: This study highlights differences in the timing of object interactions between ASD and non-ASD children during the ADOS-2 Make-Believe Play task. The findings reveal that children with ASD require more time on average to initiate both touch and play interactions with objects, suggesting potential delays in sensory processing or decision-making during object engagement. The longer transition times from touch to play in the ASD group compared to non-ASD children, further support the idea that ASD children may experience additional cognitive or sensory demands before engaging fully in play. Despite these timing differences, both groups interacted with a similar number of objects. These findings offer insights into the ways that children with ASD interact with their surroundings, emphasizing the importance of considering timing and transition patterns in the assessment of play behaviors.

405.244 Experimental Manipulation of Sensory Processing in Electroencephalography and Pupillometry

N. Bast¹, C. M. Freitag², A. K. Müller³ and C. Luckhardt⁴, (1)Autism Research and Intervention Center of Excellence Frankfurt, Goethe University Frankfurt / Department of Child and Adolescent Psychiatry, Frankfurt, Germany, (2)Autism Research and Intervention Center of Excellence Frankfurt, Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, JW Goethe University, Frankfurt, Hessen, Germany, (3)Goethe University Frankfurt / Department of Child and Adolescent Psychiatry, Frankfurt, Hessen, Germany, (4)Autism Research and Intervention Center of Excellence Frankfurt, Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, University Hospital Frankfurt, Goethe University, Frankfurt, Hessen, Germany

Background:

Sensory symptoms are often reported by autistic individuals (ASD). Different cortical processing of sensory information is discussed as an underlying neurophysiological mechanism. The locus coeruleus (LC) has been established to modulate sensory processing via tonic and phasic norepinephrine (NE) release.

Objectives:

We explored the effect of a non-invasive, experimental manipulation of LC-NE activity on sensory processing in autistic and non-autistic adolescents.

Methods:

We combined pupillometry and electroencephalography (EEG) during a passive auditory oddball task to concurrently assess LC-NE activity and sensory processing. Baseline pupil size (BPS) and stimulus-evoked pupillary response (SEPR) indexed tonic and phasic LC-NE activity, respectively. In line with previous studies, mismatch negativity (MMN) and P3a amplitude were used as measures of sensory processing. The oddball task consisted of a sequence of frequent (standard) or infrequent (oddball) pure tones (500 versus 750 Hz). The oddball task included a handgrip exercise as an experimental manipulation of LC-NE activity. The handgrip exercise required participants to repeatedly press a handgrip as hard as possible. This manipulation was applied in a within-subject design between blocks of the oddball tasks. The sample consisted of 46 autistic adolescents (ASD), 52 healthy controls (CON) and 31 adolescents with mental health condition including ADHD, anxiety and depression (mental health conditions = MHC). Manipulation effects and group differences were analyzed using linear mixed-effects models on subject and on single-trial level.

Results:

On a subject and per-trial level, oddball tones evoked an increased amplitude of SEPR, MMN and P3a compared to standard tones. After the manipulation, SEPR, MMN and P3a were increased in response to oddballs ($bs = 0.20-0.28$). These manipulation effects last about 5 min. In addition, ASD and MHC compared to CON showed a higher BPS after manipulation ($bs = 0.10-0.14$). In ASD, the manipulation led to a positive association of BPS and P3a amplitude ($b = 0.06$ [0.01, 0.10]).

Conclusions:

Our findings confirm conceptualizations of LC as a neuromodulator of sensory processing. The handgrip exercise had a temporarily enhancing effect on LC-NE activity and sensory processing measures. A group-specific manipulation effect was found for tonic LC-NE activity in the autistic adolescents and individuals with mental health condition. In these individuals, the manipulation increased LC-NE tonic activity, which could be interpreted as compensatory arousal. In the autistic adolescents, this increased LC-NE tonic activity specifically improved sensory processing of oddballs on a neurophysiological level as indicated by the association of BPS and P3a amplitudes after the manipulation. Together, findings further characterize potential neurophysiological mechanisms of different sensory processing in neurodiversity, which could be manipulated by increased LC-NE tonic activity.

405.245 Exploring Gender Differences in Emotional Outbursts Triggered By Sensory Stimuli in Latino Youths

V. L. Villarreal¹, S. Masso², M. C. V. Teixeira³ and C. Montiel-Nava², (1)Department of Psychological Science, University of Texas Rio Grande Valley, Edinburg, TX, (2)Department of Psychological Science, University of Texas Rio Grande Valley, Edinburg, TX, (3)Human Developmental Sciences Graduate Program, Mackenzie Presbyterian University, sao paulo, SP, Brazil

Background:

Autism Spectrum Disorder (ASD) is a neurodevelopmental condition characterized by challenges in social communication, repetitive behaviors, and sensory processing differences. For autistic individuals, emotional dysregulation (ED) can be prevalent, persistent, and clinically significant, contributing to potential functional impairment (Davico et al., 2022). Intense emotional reactions can lead to emotional outbursts (EO) as individuals struggle to cope with overwhelming emotions in unpredictable or overstimulating environments. EOs in individuals with ASD can stem from various triggers. Research has shown that atypical sensory processing patterns in children with ASD are closely linked to emotional and behavioral challenges (Sakamoto et al., 2024), underscoring the importance of investigating how certain sensory sensitivities may contribute to emotional dysregulation.

Moreover, there may be significant sex differences in how sensory triggers affect emotional regulation in autistic individuals, with autistic females often experiencing more severe sensory processing difficulties than males, particularly in areas such as hearing and balance/motion (Osorio et al., 2021).

Objectives:

This study aimed to examine sex differences in the frequency of emotional outbursts triggered by specific sensory stimuli (i.e., touch, smell, noise, temperature) among autistic Latino children and adolescents (ages 6-18).

Methods:

Caregivers of 120 autistic youths aged 6 to 18 years ($x=10.35$, $SD=2.43$) residents of the Rio Grande Valley region in South Texas completed the Emotional Outbursts Questionnaire. This study is part of a larger multisite study comprising samples from seven countries of the Latin American Network for Autism (REAL): Argentina, Brazil, Chile, the Dominican Republic, Uruguay, USA and Venezuela. Descriptive data analysis included frequencies and central tendency analysis, and chi-square tests were performed to establish sex differences across variables.

Results:

There was a higher number of females (59%, $n=71$) than males (41%, $n=49$). In terms of the different sensory triggers, the most common one was temperature too hot or too cold (81.7%, $n=98$), followed by light and smell (80.8%, $n=97$). Emotional outburst triggered by temperature (64.8 %, $n=46$), light (73.2%, $n=52$), smell (61.9%, $n=44$) and tact (80%, $n=52$) were more frequent in females without reaching statistical significance. Those triggered by loud noises did not show differences between sexes.

Conclusions:

The findings indicate no significant sex differences in the frequency of EOs triggered by sensory inputs such as touch, sound, temperature, and smell. This suggests that sex did not play a substantial role in emotional outbursts in response to sensory stimuli in this autistic population, despite a higher number of female participants than males. These findings are consistent with previous literature. A potential explanation may be the subtlety of sensory processing differences between sexes, with females often exhibiting less overt sensory symptoms (Edwards et al., 2024). Additionally, the discrepancy between behavior and sensory experiences may explain why EOs did not differ by sex, despite some reports of heightened sensitivity. Future research should further investigate how sensory processing manifests across sexes, including potential biomarkers, to develop more personalized interventions (Asaridou et al., 2022). Additionally, exploring other variables, such as cultural or developmental factors, could enhance our understanding of emotional regulation in autistic individuals.

405.246 Exploring Sensory Processing Patterns in Autistic Children with Co-Occurring ADHD and Anxiety: Links to Emotional Reactivity and Neural Measures

K. L. Carpenter^{1,2}, N. O. Davis³, S. Major⁴, C. Stone⁵, A. C. Henley⁶, A. Dea⁷, E. Peters⁸, D. Akinsooto³, H. L. Morgan⁶, M. Spanos¹, R. E. Aiello⁷, J. Schechter⁶, E. Ng-Cordell⁸ and C. M. Kerns⁹, (1)Department of Psychiatry and Behavioral Sciences, Duke University Medical Center, Durham, NC, (2)Department of Psychiatry and Behavioral Sciences, Duke Center for Autism and Brain Development, Durham, NC, (3)Department of Psychiatry and Behavioral Sciences, Duke University Medical Center, Durham, NC, (4)Psychiatry and Behavioral Sciences, Duke Center for Autism and Brain Development, Durham, NC, (5)Psychiatry and Behavioral Sciences, Duke University Medical School, Durham, NC, (6)Department of Psychiatry and Behavioral Sciences, Duke University School of Medicine, Durham, NC, (7)Duke Center for Autism and Brain Development, Duke University, Durham, NC, (8)Psychology, The University of British Columbia, Vancouver, BC, Canada, (9)University of British Columbia, Vancouver, BC, Canada

Background: Heterogeneity among autistic individuals poses challenges to early identification and intervention development. A significant contributor to this heterogeneity is co-occurring conditions, particularly anxiety and ADHD, which affect 40-60% of autistic children. Autism, ADHD, and anxiety share unique and common neural and behavioral features, with sensory processing differences being a key area of overlap. These shared characteristics can delay diagnosis and worsen other challenging behaviors, such as emotional reactivity, necessitating transdiagnostic approaches to better understand shared and distinct behavioral patterns across these conditions.

Objectives: This study aims to (1) examine sensory processing differences in autistic children with and without co-occurring ADHD and/or anxiety, (2) explore the relationship between sensory processing and emotional reactivity, and (3) assess the relationship between sensory processing and visual evoked potentials (VEP), a neurophysiological measure of cortical excitation/inhibition balance.

Methods: Ninety-two autistic children aged 4-8 years [29% female; 24% non-white] were divided into four groups: autistic ($n=22$), autistic with co-occurring ADHD (AuADHD; $n=21$), autistic with co-occurring anxiety (AuAnx; $n=19$), and autistic with co-occurring ADHD and anxiety (AuADHDAnx; $n=30$). Sensory hyperreactivity and hyporeactivity measured using the Sensory Experiences Questionnaire. Emotional reactivity was assessed via the Emotion Dysregulation Index. VEP data were collected from a subset of participants ($n=48$) using black-and-white checkerboard stimuli with phase reversal. The N1 and P1 midline occipital amplitude and latency were analyzed. Group differences and correlations between sensory processing, emotional reactivity, and VEP were examined using general linear models.

Results: Significant group differences were found in both sensory hyperresponsivity ($F(3)=5.7, p<.01$) and hyporesponsivity ($F(3)=5.5, p<.01$). Sensory hyperresponsivity was associated more with co-occurring anxiety; AuAnx children exhibited higher levels of sensory hyperresponsivity compared to autistic children alone ($t=2.3, p<.05$), while AuADHDAnx children had higher hyperresponsivity than both autistic children ($t=4.1, p<.001$) and AuADHD children ($t=2.3, p<.05$). Sensory hyporesponsivity was linked more to ADHD, with AuADHD children showing higher hyporesponsivity than AuAnx children ($t=2.2, p<.05$), and AuADHDAnx children showing higher hyporesponsivity than both autistic children ($t=3.2, p<.01$) and AuAnx children ($t=3.5, p<.001$). Sensory hyperresponsivity also significantly moderated the relationship between diagnostic group and emotional reactivity ($F(4)=4.4, p<.01$), with the strongest effect seen in AuAnx children. No significant effect was found for hyporesponsivity. Although VEP P1 latency or amplitude was not associated with sensory features, there was a correlation between sensory hyperresponsivity and N1 latency ($r(46)=-.34, p<.05$).

Conclusions: This study highlights distinct sensory patterns in autistic individuals with co-occurring anxiety and/or ADHD. Sensory hyperresponsivity appears related more to anxiety, while sensory hyporesponsivity is linked to ADHD. The connection between sensory hyperresponsivity and emotional reactivity was strongest in AuAnx children, suggesting that anxiety may heighten the impact of sensory sensitivities on emotional responses. Preliminary findings also suggest a potential link between VEP and sensory processing patterns. Overall, these findings highlight the need to understand how sensory processing differences affect autistic individuals with various co-occurring conditions, supporting the integration of sensory processing considerations in intervention planning. Furthermore, the VEP may serve as a promising biomarker for evaluating treatment efficacy in studies addressing sensory processing in autistic children.

405.247 Exploring the Multiple Facets of Interoception and Anxiety in Autism

A. Zoltowski^{1,2}, C. A. Convery³, E. E. Eyoh⁴, E. Plump⁵, E. R. Arumalla⁵, M. Sullivan⁵, J. Quinde Zlibut⁶, B. Keceli-Kaysili⁶, B. Lewis⁷ and C. J. Cascio^{2,7,8}, (1)Department of Psychiatry and Behavioral Science, Vanderbilt University, Nashville, TN, (2)Life Span Institute, University of Kansas, Lawrence, KS, (3)Department of Psychiatry and Behavioral Science, VUMC, Nashville, TN, (4)Institute of Child Development, University of Minnesota, Institute of Child Development, Minneapolis, MN, (5)Vanderbilt University, Nashville, TN, (6)Hearing and Speech Sciences, Vanderbilt University Medical Center, Nashville, TN, (7)Department of Psychiatry and Behavioral Science, Vanderbilt University Medical Center, Nashville, TN, (8)Department of Psychology, University of Kansas, Lawrence, KS

Background: Sensory processing differences may impact the prevalence and presentation of anxiety in autistic individuals. This includes the sense of interoception, i.e., how we perceive sensory information from within our bodies. Autistic individuals report various challenges with sensing and interpreting their bodily signals. Interventions that focus on increasing interoceptive accuracy have shown preliminary efficacy in reducing autistic individuals' anxiety. However, most prior work has just focused on one interoceptive sub-modality (cardiac), and on lower-level processing of signals (e.g., heartbeats) rather than higher-level features (e.g., heart rate). Thus, we aimed to expand the understanding of how different aspects of interoceptive perception relate to confusion in interpreting bodily states (interoceptive confusion) as well as trait anxiety.

Objectives: We analyzed how different features of interoception relate to anxiety in autistic and non-autistic individuals, across a wide age range and variety of tasks.

Methods: Our sample included $n=43$ non-autistic (ages 8-55 years, 60% female, 2% non-binary) and $n=83$ autistic individuals (ages 8-51 years, 32% female, 6% non-binary, 5% with $IQ < 70$). Interoceptive discrimination and integration were measured using three tasks with different stimulus modalities and time scales: two cardiac tasks focused on different time scales (heartbeat (HBD) and heart rate discrimination (HRD; Legrand et al., 2022)) and a respiratory integration task (Walsh et al., 2019). Participants completed one survey to characterize interoceptive confusion, the Interoception Sensory Questionnaire (ISQ), and two anxiety scales: the Anxiety Scale for Children (or Adults) with ASD and the Screen for Child (or Adult) Anxiety Related Disorders. We used a principal component decomposition to compare shared versus distinct features captured by questionnaire measures. Then, we used a general linear model to analyze group by task relationships with the resulting component scores, controlling for age.

Results: We found two separable components of interoceptive confusion and anxiety: one anxiety-linked component in which greater interoceptive confusion closely correlates with higher anxiety and one anxiety-independent component, in which individuals may have higher interoceptive confusion without higher anxiety levels. Though results were inconclusive statistically, there were some trends that may point towards task- and group- specific relationships. Imprecise heart rate discrimination was related to higher anxiety in the non-autistic group, whereas precise discrimination related to higher anxiety in the autistic group (Group x HRD interaction, $t=1.54$, $p=0.127$). Of the three tasks, an increased ability to successfully map visual and respiratory information in the respiration task most closely related to anxiety-independent interoceptive confusion ($t=-1.55$, $p=0.125$).

Conclusions: These findings suggest that cardiac versus respiratory interoception may differentially relate to anxiety levels, such that precise cardiac interoception may be a marker of higher anxiety in autistic but not non-autistic individuals. On the other hand, respiratory interoception may be a transdiagnostic marker of anxiety-independent interoceptive difficulties. Further work is needed to clarify these relationships, including relations with broader participant features than examined here. Overall, it may be useful to combine performance across multiple tasks to determine which individuals may benefit from targeting simple detection of their bodily signals versus the broader contextualization and meaning of their interoceptive signals.

405.248 Exploring the Survey of Favorite Interests in Autism (SOFIA) in Autistic Preschoolers

R. J. Luyster^a, L. Adam Ali^b, T. Buonocore^c, M. Cannon^b, R. Turner^d and S. Arunachalam^a, (1)Communication Sciences and Disorders, Emerson College, Boston, MA, (2)Emerson College, Boston, MA, (3)University of Bath, Bath, United Kingdom, (4)Communicative Sciences and Disorders, New York University, New York, NY

Background:

Autistic individuals often have favorite interests across their lifespan. Although these interests are conventionally associated with impairments, some studies and first person-perspectives attest to potential benefits of favorite interests (e.g., Winter-Messiers et al., 2007). Smerbeck (2019) introduced the Survey of Favorite Interests in Autism (SOFIA) to examine parent-reported benefits/difficulties associated with children's favorite interests. The SOFIA was validated on a sample of autistic children ages 6-17 years. Results suggested that a five-scale structure – Social Flexibility, Perseveration, Respondent Discomfort, Adaptive Coping, Atypicality – best fit the data. Scores were meaningfully associated with participant characteristics, including autism features and adaptive skills (Smerbeck, 2019). To our knowledge, the SOFIA has not yet been applied to early development (i.e., preschool years), when favorite interests often emerge in autistic and nonautistic children.

Objectives:

This study employs the SOFIA in a younger sample of autistic children. This will advance our understanding of (1) how suitable this tool is for preschoolers and (2) how parents of young children with autism perceive the strengths and challenges associated with their children's favorite interests.

Methods:

English-speaking autistic children (36-71.9 months) completed an online study about language development. Parents completed the SOFIA, Social Communication Questionnaire (SCQ, Rutter et al., 2003), Vineland Scales of Early Learning (VABS, Sparrow et al., 2016) and the MacArthur-Bates Communicative Development Inventory III (MBCDI, Fenson et al., 2003). Preliminary analyses include 60 autistic children (48 male, 12 female; $M=58\text{mos}$, $SD=7.66\text{mos}$). Expressive vocabulary skills were heterogeneous (MBCDI III: $M=45.7$, $SD=37.8$, range=0-100).

Results:

Analyses followed the structure of Smerbeck (2019). The five-factor scale structure in the current sample yielded similar Cronbach's α coefficients to Smerbeck (2019), except for the Respondent Discomfort scale, which was much lower (.58) than in Smerbeck's report (.87) (Table 1). However, scale intercorrelations were markedly different than in Smerbeck (2019), with the only overlap being a significant correlation between the Atypicality and Respondent Discomfort scales (Table 2). Finally, we replicated a significant correlation between autism symptoms (per the SCQ) and the Social Flexibility scale, as well as significant correlations between adaptive skills (per the Vineland Adaptive Behavior Composite) and the Social Flexibility and Adaptive Coping scales. Some associations found in these preliminary analyses, including higher flexibility scores in children with higher autism symptoms and higher levels of atypicality in children with higher adaptive scores, are unexpected and require further exploration.

Conclusions:

These results attest to the SOFIA's usefulness in autistic preschoolers. The internal consistency of the scales appeared generally robust, although the associations between the SOFIA scales diverged from the original validation sample. Participant characteristics were associated with scale scores: children with more autism features showed lower coping associated with special interests, and children with higher adaptive skills showed greater flexibility and coping associated with special interests. Planned analyses will further examine the role of children's developmental and language level. Overall, parents reported varied perspectives on special interests in autistic preschoolers, and the SOFIA may be a useful tool for this population.

405.249 Factors Related to Self- and Caregiver-Reported Quality of Life in Autistic Children

E. Skaletski¹ and **B. G. Travers²**, (1)University of Wisconsin-Madison, Madison, WI, (2)The University of Wisconsin-Madison, Madison, WI

Background:

Quality of life (QoL) is a key outcome identified by autistic individuals (Benevides et al., 2020) and federal agencies (IACC, 2023). Despite discrepancies between self- and caregiver-reported QoL (Egilson et al., 2017; Stokes et al., 2017), studies regularly focus on caregiver-reported QoL and its predictors, not self-reported QoL. We do not yet have a clear understanding of what factors, such as a child's sensory, autistic, or ADHD features and age, predict self-reported QoL, which is important for understanding possible mechanisms by which to enhance self-perceived quality of life in autistic children.

Objectives:

To determine how age, IQ, autism features, ADHD features, sleep difficulties, and sensory features relate to QoL depending on the reporter.

Methods:

This study consisted of 59 autistic children (5.3-10.9 years-old), 25% female, IQ 47-147, mean= 97.4). Children needed to understand English. Children completed IQ testing and caregivers completed measures regarding their child's autism features, ADHD features, sleep difficulties, and sensory features. Both children and their caregivers completed the Pediatric Quality of Life Inventory, Version 4.0. To evaluate level of agreement, we used intraclass correlation coefficients. To determine how individual variables related to QoL based on reporter, we used linear mixed-effects regression.

Results:

We found poor agreement ($ICC = 0.10$, $p = .22$) between self- and caregiver-reported QoL. Age and IQ did not relate to QoL, regardless of reporter. Autism and ADHD features demonstrated large-sized distinct relations for self- and caregiver-reported QoL, $p < .001$, $d = 1.01$, respectively, and sleep difficulties demonstrated medium-sized distinct relations for self- and caregiver reported QoL, $p = .02$, $d = 0.61$. Follow-up correlations showed that these interaction effects represented stronger relations for caregiver-reported QoL than self-reported. Only sensory features related to both self- and caregiver-reported QoL, $p < .001$, $d = 1.11$. These results were consistent across our full sample and in follow-up sensitivity analyses of participants who used spoken language and participants with IQ scores above 70.

Conclusions:

This study highlights the importance of including both self- and caregiver reports when assessing the QoL of autistic children, as these likely provide distinct and complementary sources of evidence. Like previous research (De Vries & Geurts, 2015; Leader, Dooley, et al., 2021), age and IQ were not predictors of either caregiver- or self-reported QoL. Whereas sleep quality, autistic and ADHD features were found to be only important to caregiver-reported QoL, sensory features were important to QoL for both reporters. Processing sensory information is important for many of the activities included as part of QoL measures, like play or classroom activities. Focusing on supporting the sensory features of autistic children could promote QoL from the perspective of both the child and their caregiver.

405.250 Functional Connectivity Alterations Associated with Restricted, Repetitive Behaviors in Children with Autism: An MVPA Analysis

A. L. Farmer¹, M. D. Prigge², S. Nelson¹, C. Traiser¹, N. Lange³, E. Bigler⁴, A. L. Alexander⁵, J. E. Lainhart⁶ and B. A. Zielinski⁶, (1)Pediatrics, University of Florida, Gainesville, FL, (2)University of Utah, Salt Lake City, UT, (3)McLean Hospital, Cambridge, MA, (4)Brigham Young University, Provo, UT, (5)University of Wisconsin-Madison, Madison, WI, (6)Pediatrics, Neurology, and Neuroscience, University of Florida, Gainesville, FL

Background:

Despite being diagnostic symptoms for autism spectrum disorder, the neurocircuitry underlying restricted, repetitive behaviors (RRB) remains poorly understood. These behaviors have received less study than social symptoms, and treatment development has been limited. Multivariate pattern analysis (MVPA) is a powerful, data-driven analytic approach capable of detecting altered functional connectivity patterns. This approach has rarely been applied to ASD data and holds great promise for uncovering new associations. We examined the functional connectivity differences associated with RRB clinical measures in children with ASD, as well as functional connectivity associated with different RRB subtypes to determine if subtypes reflect unique neurocircuitry alterations.

Objectives:

Determine functional network alterations associated with RRB in ASD.

Determine if different subtypes of RRB exhibit functional connectivity differences.

Methods:

We used an MVPA approach and fMRI data to examine the functional connectivity relationships associated with Repetitive Behavior Score-Revised (RBS-R) total and subtype scores in an existing all-male dataset including 85 children (43 ASD) aged 5-13 years. MRI images were preprocessed and analyzed in CONN toolbox version 22a. To identify functional network alterations associated with RRB, we conducted an MVPA to decompose the functional connectivity patterns across all subjects into 8 components. Significant clusters for each RBS-R score were then identified using an omnibus F test across all MVPA components in combination with general linear models. Mean-corrected age and performance IQ (PIQ) were included in models as nuisance covariates. Subsequent posthoc seed to voxel analyses were then performed using each significant MVPA cluster as a seed. All analyses were run using Threshold Free Cluster Enhancement with 1000 permutations and a significance threshold of family-wise error corrected p values (p-FWE) < 0.05.

Results:

After correcting for mean-centered age and PIQ, whole-brain MVPA identified 7 significant clusters associated with RBS-R stereotypy subscores. Subsequent seed to voxel analyses revealed high stereotypy scores were associated with high connectivity between anterior default mode network (DMN) regions and a large number of regions encompassing much of the brain. High stereotypy was also associated with increased connectivity between a cluster in the subcallosal cortex and left nucleus accumbens with visual, dorsal attention network, and DMN regions. Stereotypy was also correlated with increased connectivity between the right frontal pole and visual and cerebellar regions, as well as reduced connectivity of the lingual gyrus with other visual regions and the motor cerebellum. MVPA analysis identified 11 clusters with significant associations with compulsive RBS-R subscores, all of which were in visual or cerebellar regions. High compulsive scores were associated with altered connectivity between these clusters and brain regions in a wide variety of functional networks suggesting compulsive behavior may be linked to altered visual and cerebellar network connectivity more generally.

Conclusions:

1. Stereotypy was associated with altered functional connectivity in the anterior DMN, right frontal pole, subcallosal cortex/nucleus accumbens, left cerebellar Crus I, and visual regions.
2. Compulsive behavior was associated with altered visual and cerebellar connectivity.
3. Stereotypy and compulsive subtypes of repetitive behavior exhibit both shared and unique connectivity alterations.

405.251 Identifying Gait Differences in Autistic and Non-Autistic Children Using 2D Video Analysis of Kinematic Parameters

Z. Wang¹, M. Raju², A. Shrestha³, S. Onal⁴, A. Gladfelter⁵ and M. Buac⁵, (1)Industrial and Systems Engineering, Northern Illinois University, DeKalb, IL, (2)Northern Illinois University, DeKalb, IL, (3)Southern Illinois University, Edwardsville, Edwardsville, IL, (4)Industrial Engineering, Southern Illinois University, Edwardsville, Edwardsville, IL, (5)Speech-Language Pathology, Northern Illinois University, DeKalb, IL

Background: Studies investigating gait deviations in autistic children compared to non-autistic children have identified several significant differences (Weiss et al., 2013; Nobile et al., 2011; Vilensky et al., 1981). While 3D motion capture is considered the gold standard for gait analysis, its cost and complexity limit its widespread use.

Objectives: The main objective of this study is to evaluate whether 2D video-based analysis can reliably differentiate between the gait patterns of autistic and non-autistic children. Specifically, the study seeks to identify which kinematic parameters exhibit significant differences and how these parameters align with results from 3D motion capture studies.

Methods: This study involves 16 children formally diagnosed with autism spectrum disorder and 30 non-autistic children, aged 5 to 12 years. Gait data was collected in a controlled clinical setting using a 2D video recording system, capturing side and frontal views with two cameras positioned to capture the full body in motion while participants walked at a self-selected pace. Participants were instructed to walk naturally, and each child completed a minimum of three trials to ensure sufficient data quality. The videos were processed using OpenPose, an open-source tool that identifies and tracks key joint points, hips and knees. Two kinematic parameters- Hip Abduction-Adduction, Knee Abduction-Adduction, were selected for comparison between the autistic and non-autistic groups. T-tests were used to compare the parameters, with Bonferroni corrections applied for multiple comparisons. A power analysis was conducted to confirm adequate sample sizes for detecting significant differences. The results obtained from the 2D video analysis were then compared to literature using 3D motion capture. This comparison allowed for an evaluation of the accuracy and limitations of the 2D method, providing insight into the feasibility of using 2D video analysis as a cost-effective and accessible tool for identifying gait differences in autistic children.

Results: Preliminary findings indicate knee abduction-adduction on the right side showed a near-significant trend, with a T-statistic of 1.867695 and a P-value of 0.07189, suggesting that knee joint motion may play an important role in gait differences in autistic children. Although this result did not reach conventional significance ($P < 0.05$), it warrants further investigation. Hip abduction-adduction, both on the left and right, did not show statistically significant differences, with P-values of 0.088018 and 0.188633, respectively.

Conclusions: This study demonstrates that 2D video-based gait analysis is a promising tool for distinguishing gait patterns between autistic and non-autistic children. Although it does not fully replicate the precision of 3D motion capture, it offers a more accessible and cost-effective alternative for early gait screening in both clinical and research environments. Further analysis is required to investigate additional kinematic parameters, which will help refine the accuracy and broaden the potential applications of 2D video-based analysis.

405.252 Impact of Visual Stimulus Dynamics on Visual-Motor Tracking Error in Individuals with Autism: Age-Related Differences
D. E. Lidstone¹ and S. H. Mostofsky², (1)Kinesiology, Penn State Harrisburg, Middletown, PA, (2)Center for Neurodevelopmental and Imaging Research, Kennedy Krieger Institute, Baltimore, MD

Background: Individuals with autism spectrum disorder (ASD) often experience challenges with visual-motor integration (VMI), particularly when interacting with dynamic stimuli. However, the underlying causes of these difficulties remain unclear, particularly whether they stem from the dynamic nature of the stimuli or from challenges in coordinating movement.

Objectives: (1) To investigate the effects of diagnosis and age on tracking performance under varying stimulus dynamics and (2) to determine if ASD-related VMI difficulties are more influenced by the speed or predictability of visual stimuli.

Methods: Participants included 62 typically developing (TD) individuals (13.8 ± 5.9 years) and 41 individuals with ASD (13.4 ± 5.9 years). To assess dynamic VMI, an isometric grip-force tracking task was used. To normalize force targets, grip-force maximal voluntary contraction (MVC) was assessed for each participant. Next, participants tracked static targets (15% MVC) and dynamic targets (0-25% MVC). The dynamic targets included *slow* (predictable; $2.5 \pm 0\%$ MVC/sec), *fast* (predictable; $5 \pm 0\%$ MVC/sec), and *wave* (unpredictable; $4 \pm 2.8\%$ MVC/sec) (Fig. 1). Tracking accuracy was measured using relative root mean square error (rRMSE). Participants were categorized as “trackers” or “non-trackers” based on their performance. *Non-trackers* were those whose force exceeded ± 3 times the target for longer than one second in more than three trials per condition. The main analysis included 21 ASD *trackers* (age 15.8 ± 6.6 years, 71% male, IQ 114.3 ± 15.6 , MVC 39.4 ± 16.8 Newtons) and 52 TD *trackers* (age 14.5 ± 6.1 years, 52% male, IQ 118.5 ± 12.7 , MVC 37.7 ± 15.1 Newtons).

Results: Compared to ASD *trackers*, ASD *non-trackers* were younger (11.0 ± 3.7 vs. 15.8 ± 6.6 years, $p = 0.008$), had lower IQs (96.8 ± 17.7 vs. 114.3 ± 15.6 , $p = 0.003$), and more severe ASD symptoms (ADOS-CS: 7.3 ± 1.8 vs. 6.0 ± 1.0 , $p = 0.03$). Significant three-way interactions (Group x Speed x Age) were observed for ASD vs. TD (static vs. fast, $p = 0.005$; static vs. wave, $p = 0.03$; static vs. slow, trend-level at $p = 0.08$), with children showing greater difficulty with dynamic vs. static tracking. No significant diagnosis-by-age effect was found for speeded (relative to slow) stimuli (slow vs. fast, $p = 0.17$; slow vs. wave, $p = 0.64$), however, main effects of diagnosis revealed worse tracking of speeded stimuli in the ASD vs. TD group (slow vs. fast, $p = 0.01$) (Fig. 2). Differences in speeded tracking (*fast* - *slow*) showed a trend-level correlation with ADOS-2 total scores ($r = 0.41$, $p = 0.07$) and a significant correlation with SRS-2 total scores ($r = 0.50$, $p = 0.0009$), such that increased error with increased stimulus speed correlated with more severe ASD features.

Conclusions: Compared to TD controls, tracking accuracy in individuals with ASD declined as stimulus speed increased, correlating with core ASD features. Additionally, younger individuals with ASD showed poorer static versus dynamic accuracy compared to TD peers. These findings highlight the importance of considering stimulus speed when assessing and intervening in VMI challenges in ASD.

405.253 Is It Different with Dads?: Exploring Child Dysregulation Behaviors in Fathers Versus Mothers during Play

A. Sanchez¹, S. T. Seese², E. C. Hayashi³ and C. Kasari⁴, (1)Semel Institute for Neuroscience and Human Behavior, University of California, Los Angeles, Los Angeles, CA, (2)University of California, Los Angeles, Los Angeles, CA, (3)Kasari Lab, University of California, Los Angeles, Los Angeles, CA, (4)Education and Psychiatry, University of California Los Angeles, Los Angeles, CA

Background: Caregivers play a crucial role in supporting toddlers with autism spectrum disorder (ASD), particularly when it comes to fussiness, or dysregulation. Dysregulation generally refers to emotional regulation patterns that interfere with normal functioning and well-being, and is a common challenge for all toddlers, including those with autism. Given that few studies have compared child dysregulation behaviors between mothers versus fathers during caregiver-child free play interactions, this study aims to examine the differences in intensity of child dysregulation when interacting with one parent compared to the other.

Objectives: This study aims to examine the differences in intensity of child dysregulation when interacting their primary caregiver (moms vs dads). **Methods:** Data were drawn from two larger randomized controlled trials that comprise the current sample of 149 children with autism and their primary caregivers (N= 131 moms, N= 27 dads). At baseline of the intervention, dysregulation behaviors were coded during a 10-minute free-play interaction between the primary caregiver and child. Dysregulation behaviors were categorized by (a) type and (b) proportion of time (in seconds) of dysregulation and (c) intensity of the dysregulation. Dysregulation behaviors include (a) negativity (b) physical venting (c) idiosyncratic behaviors (d) avoidance (e) distraction (f) verbal repetitive behaviors (g) self-soothing and (h) other-directed comfort seeking. Intensity was rated via a five-point scale, with zero indicating no intensity (e.g., child was calm) and five being intense (e.g., child was crying, screaming). Independent sample t-tests were conducted to explore differences in the intensity of the dysregulation behaviors exhibited by the child during interactions with moms versus dads.

Results: Approximately 50% of all dysregulating behaviors were coded as intense. Children exhibited more intense negative behaviors with dads (N=7, M=.71, SD=.48) compared to mothers (N=59, M=.51, SD=.50), and results of the t-test were significant, $t(64)=-1.024$, $p<.001$, Cohen's $d=-.409$. Children also exhibited more intense physical venting behaviors with dads (N=11, M=.64, SD=.48) compared to moms (N=61, M=.51, SD=.50), and result of the t-test was significant $t(70)=-.776$, $p=.035$, Cohen's $d=-.254$. In terms of idiosyncratic behaviors, children showcased more intense idiosyncratic behaviors with dads (N=4, M=.75, SD=.50) compared to moms (N= 55, M=.45, SD=.50), and results of the t-test were significant $t(57)=-1.136$, $p=.002$, Cohen's $d=-.588$.

Conclusions: Results suggest that children are exhibiting more intense behaviors during interactions with dads versus moms. Future research would benefit from including more dads (given the small sample size) and examining other variables during interactions, including caregiver strategies, to further understand how dads are interacting with their children, and how those strategies relate to child outcomes.

405.254 Males and Females Exhibit Different Patterns of Sensory Processing and Regulation

S. Beeler-Duden¹, S. Lawson², I. Bakshi³, S. A. Green⁴, M. Dapretto⁵ and K. A. Pelphrey⁶, (1)University of Virginia School of Medicine, Charlottesville, VA, (2)Neurology, University of Virginia, Charlottesville, VA, (3)University of Virginia, Charlottesville, VA, (4)Dept of Psychiatry and Biobehavioral Sciences, UCLA, Los Angeles, CA, (5)Department of Psychiatry and Biobehavioral Sciences, University of California Los Angeles, Los Angeles, CA, (6)Department of Neurology, University of Virginia School of Medicine, Charlottesville, VA

Background: Autistic individuals often experience atypical sensory patterns, affecting how they perceive and respond to sensory information (Dunn, 2001). Dunn's Model of Sensory Processing (2007) outlines four patterns based on neurological sensory thresholds (high/low) and behavioral reactions (passive/active). Autistic individuals can exhibit either heightened or decreased sensitivity to stimuli and respond passively with minimal reaction or actively by seeking or avoiding sensations (Meuller & Tronick, 2025; Tomchek & Dunn, 2007). For example, common sounds or textures can be overwhelming, leading to avoidance or emotional distress, while others may seek intense sensory experiences like spinning or deep pressure (Behrmann & Minshew, 2015; Reuben & Parish, 2022). Sensory processing variability is a significant aspect of autism, though the underlying factors remain unclear.

There is growing consensus that sex significantly contributes to symptom variability in autism (Braden et al., 2021; Geschwind & Levitt, 2007; Jack et al., 2021). Researchers often underestimate the prevalence of autism in women leading to skewed samples that may obscure sex differences in sensory processing (Loomes et al., 2017). Sex impacts sensory processing in non-autistic samples with females showing greater sensitivity and slower responses to sensory signals compared to males (Mogil & Bailey, 2010; Spierer et al., 2010). Some evidence suggests autistic females may also have heightened sensitivity compared to their male peers, but these studies over-sample males or focus on specific sensory domains (Kiep et al., 2023; Osorio et al., 2021; Walsh et al., 2018).

Objectives: This study examines how sex influences sensitivity of sensory neurological thresholds and behavioral responses in autism.

Methods: This data was collected as part of an NIH-funded longitudinal study, which sampled an unprecedented number of autistic women. Sensory Profile (SP) self-report data were collected from 175 autistic (90 female) and 80 non-autistic (39 female) participants, ages 10 to 34. The SP data were categorized into four sensory patterns: Low registration, sensory seeking, sensory sensitivity, and sensory avoiding. Analyses were conducted to examine the effect of sex assigned at birth and diagnostic category (autistic vs non-autistic) on sensory processing patterns.

Results: In a series of ANOVAs, all demonstrated significant main effects for the diagnostic category, such that autistic individuals were more likely to have atypical sensory patterns (all p s < .001). Moreover, ANOVAs for low registration, sensory sensitivity, and sensory avoiding patterns demonstrated a main effect for sex, such that all females were more likely to exhibit atypical sensory patterns than males. Additionally, there was a significant interaction between diagnosis and sex for sensory sensitivity such that autistic females were significantly more sensitive to sensory stimuli but had less behavioral responsiveness than non autistic females or males (both autistic and non-autistic).

Conclusions: Overall, the present study suggests that both diagnosis and sex may significantly contribute to sensory sensitivity and behavioral responses. Importantly, we found evidence that sex and diagnosis may have a cumulative impact on the type of sensory patterns exhibited. Thus, sex may also contribute to variability in sensory processing and regulation, a diagnostic criterion and an important feature of autism.

405.255 Motor Difficulties in Children with Neurodevelopmental Conditions: A Report from a Cross-National Study in Belgian and Italian Children with Autism, Attention Deficit Hyperactivity Disorder, and Developmental Coordination Disorder

E. Verbecque¹, C. Johnson^{1,2}, G. Scaccabarozzi³, M. Molteni⁴, A. Hallemans⁵, P. Meyns¹, K. Klingels¹ and A. Crippa⁵, (1)Rehabilitation Research Centre (REVAL), Faculty of Rehabilitation Sciences and Physiotherapy, Hasselt University, Diepenbeek, Limburg, Belgium, (2)Research Group MOVANT, Department of Rehabilitation Sciences and Physiotherapy (REVAL), University of Antwerp, Wilrijk, Antwerp, Belgium, (3)Child Psychopathology Unit, Scientific Institute, IRCCS Eugenio Medea, Bosisio Parini, Lecco, Italy, (4)Child Psychopathology Unit, Scientific Institute, IRCCS Eugenio Medea, Bosisio Parini, Italy, (5)Child Psychopathology Unit, Alessandro Crippa, Bosisio Parini, Lecco, Italy

Background: Beyond the core features of these conditions, altered motor behavior is often reported in neurodevelopmental disorders (NDDs), such as autism, Developmental Coordination Disorder (DCD) and Attention Deficit Hyperactivity Disorder (ADHD). However, the extent to which their motor skills are affected remains unclear. In particular, motor difficulties in autistic children and children with ADHD are rarely recognized, and families may struggle to obtain adequate support. Additionally, motor skill disorders in autistic children may be an expression of comorbid DCD or intellectual disability (ID), which often goes unrecognized.

Objectives: The aim of this study was to explore motor skill difficulties using the Movement Assessment Battery for Children, 2nd edition (MABC-2) comparing typically developing (TD) children with children who have NDDs, and to examine specific profiles among the children with NDDs. **Methods:** We retrospectively evaluated a combined sample ($n=215$) collected in Italy (including children with autism, ADHD, TD) and Belgium (including children with DCD). The sample consisted of 17 autistic children without a comorbidity (autism-only), 40 autistic children with probable DCD (autism+p-DCD), 17 autistic children with ID (autism+ID), 25 children with DCD, 26 children with ADHD and 90 TD children. All participants were assessed with the DCD Questionnaire and the MABC-2; the presence of other pathologies and age at symptoms onset were also controlled. The diagnostic criteria for DCD were assessed in autistic participants following the international recommendations for DCD. Group differences between TD/NDDs and between the NDDs on the MABC-2 scores (total percentile, domain percentile) were assessed with the Mann-Whitney U test (TD/NDDs) or the Kruskal-Wallis test (between NDDs).

Results: The children with various NDDs performed significantly worse than the TD group (Fig. 1A). Within the NDD group, the total score was significantly lower for children with autism+ID compared to those with autism-only ($p<0.001$) and ADHD ($p<0.001$), as well as for children with autism+p-DCD compared to ADHD ($p=0.005$). Among the NDD subgroups, children demonstrated difficulties in different domains (Fig. 1B). Manual dexterity skills were significantly lower in autism+ID compared to any other NDD group ($p<0.02$) and the children with autism+p-DCD also performed worse than the ones with autism-only. Aiming and catching skills were significantly poorer in the DCD group compared to all other NDD groups ($p<0.01$), except for the autism+p-DCD ($p=0.082$), who in turn performed worse than the ADHD group ($p=0.001$). Balance was significantly poorer in both the autism+p-DCD ($p=0.011$) and autism+ID ($p=0.022$) groups compared to the ADHD group.

Conclusions: This cross-national study confirms the extent of motor difficulties in various NDDs and highlights the importance of recognizing the different profiles that may be present based on subgroup characteristics. Children with ADHD show the largest variability in motor skill competence and tend to exhibit the fewest difficulties. In autistic children, comorbid ID or p-DCD may contribute to lower skill levels, but these conditions present distinct challenges, underscoring the need for careful subgrouping of autistic children. Future research is necessary to understand the neural correlates underlying these differences and to determine which types of motor interventions are most effective for these subgroups.

405.256 Motor Profile Differences between Autistic and Non-Autistic Children across Age-Groups

Y. Estrugo¹, R. Poyas-Naharan² and N. Bauminger-Zviely³, (1)Faculty of Education, Bar Ilan University, Ramat-Gan, Israel, (2)Faculty of Education, Bar-Ilan University, Ramat-Gan, Israel, (3)Faculty of Education, Bar-Ilan University, Ramat Gan, NA, Israel

Background:

Significant motor functioning differences between autistic and non-autistic children, are well documented, with autistics demonstrating greater challenges in executing fine (e.g., cutting, writing) and gross (e.g., walking, jumping) motor tasks compared to their neurotypical peers. However, these differences are usually not compared across a broad developmental age-range. Moreover, no study so far presented a within hierarchical motor profile, from simplest to the most complex motor skills in autism and typical development.

Objectives:

This study investigated group (autistic, non-autistic) and age (early-childhood, preadolescence, adolescence) differences in motor functioning. We predicted better motor functioning in the non-autistic group and among older participants. Moreover, we examined within-group differences in fine and gross motor functioning to identify each study-group's hierarchical motor profile. Predicting this profile was difficult due to the limited prior research.

Methods:

This study included 84 autistic children ages 6-16 years, and 64 non-autistic children matched by age, sex, IQ, and mother education across three age groups (early-childhood, 6-8.5 years, preadolescents, 8.5-12 years, adolescents, 12-16 years). The participants' gross (e.g., catching a ball, hopping) and fine (e.g., Curved-line cutting and nailing) motor skills were assessed using the Individual Motoric Observation Scale (IMOS), yielding scores for each motor behavior, gross and fine motor categories, and overall motor functioning. The IMOS score reflected the percentages of success in each task according to proficiency and quality for various appearance and accuracy components.

Results:

Group (autistic/non-autistic) and age (early-childhood/preadolescence/adolescence) differences in motor abilities were computed by a series of multivariate and univariate analyses of variance (MANOVAs, follow-up ANOVAs). One-way ANOVAs were conducted for the IMOS total score. Overall, non-autistic showed more advanced fine and gross-motor abilities than their autistic counterparts. The adolescents age-group outperformed early-childhood participants on most motor tasks (see Table 1). However, the overall motor performance of non-autistic early-childhood participants was similar to that of autistic adolescents. To explore hierarchical motor profiles differences within each study-groups we compared IMOS components' scores using repeated-measure ANOVA for each group. Post-hoc pairwise comparisons used Bonferroni correction to signify the scale of difficulty from the easiest (a) to the complexed (e) motor task in each group. The non-autistic group exhibited a more homogeneous developmental motor profile, with only two levels of difficulty (a,b). Curved-line cutting and ball catching were more challenging than other motor tasks. In contrast, the autistic group displayed a broader range of motor difficulties, thus hopping was the easiest task (a) and ball catching was the most complexed (e) (see Figure 1).

Conclusions:

Findings align with previous studies depicting motor abilities differences between autistic and non-autistic children. Our investigation of the motor development continuum across three developmental age-groups within the autistic group, despite their motor difficulties, is novel, suggesting their potential motor skills advancement. The variation in the motor profile within each study-group, particularly in the sequence of skill acquisition and the range of task difficulties, enhances our understanding and lead to the development of motor intervention programs focusing on more complex motor tasks that present greater challenges for autistic youth.

**405.257** Multisensory Network Functional Connectivity in Children and Youth with Neurodevelopmental Disorders

E. J. Choi¹, K. M. Lyons², M. M. Vandewouw³, E. Anagnostou⁴, J. Crosbie⁵, S. Georgiades⁶, E. Kelley⁷, A. Kushki⁸, R. Nicolson⁹, R. Schachar¹⁰, B. Stojanoski¹⁰ and R. A. Stevenson¹, (1)University of Western Ontario, London, ON, Canada, (2)Psychology, The University of Western Ontario, London, ON, Canada, (3)Bloorview Research Institute, Autism Research Centre, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (4)Bloorview Research Institute, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (5)University of Toronto, Toronto, ON, Canada, (6)Offord Centre for Child Studies, McMaster University, Hamilton, ON, Canada, (7)Department of Psychology, Queen's University, Kingston, ON, Canada, (8)Department of Psychiatry, The University of Western Ontario, London, ON, Canada, (9)Department of Psychiatry, The Hospital for Sick Children, Toronto, ON, Canada, (10)Ontario Tech University, London, ON, Canada

Background: Multisensory integration is an adaptive function that combines information from different sensory modalities into a coherent perceptual Gestalt, enabling individuals to respond to multiple sensory inputs efficiently in daily life. Although atypical multisensory integration has been reported in neurodevelopmental conditions such as Autism and ADHD, little is known about the functional organization of the multisensory network (MSN), nor its relation to other large-scale networks (resting-state networks, RSNs) and whether this functional organization differs across neurodevelopmental conditions. Additionally, how the multisensory networks relate to other sensory issues across diagnoses has not been explored.

Objectives: This study investigated how multisensory regions are functionally organized within the MSN and between the MSN and RSNs in children and youth with ASD, ADHD, and typically development (TD), and its associations with individual's sensory characteristics.

Methods: Resting-state fMRI data from 417 participants collected by the Province of Ontario Neurodevelopmental Network were analyzed (ASD=174, ADHD=130, TD=113; Mean age=11.96±4.10; 32% female). Timeseries were extracted from five regions in the MSN and 51 regions in seven RSNs (See Figure 1A). Non-directional (Pearson correlation) and directional (Granger causality) functional connectivity (FC) metrics were computed within the MSN and between the MSN and RSNs. Sensory Characteristics were measured via the Short Sensory Profile. Diagnostic differences and associations with sensory characteristics were assessed, while controlling for age and sex. Finally, data-driven clusters (k-means and k-medoids depending on data normality) based on the connectivity features were examined in associations with diagnoses and sensory characteristics to characterize group membership.

Results: Both non-directional and directional FC analyses confirmed the thalamus as a hub region within the MSN and between the MSN and RSNs, with no significant differences by diagnosis, although Autism and ADHD groups showed increased functional connectivity overall (Figure 1B 2A). In contrast, sensory characteristics were significantly associated with both non-directional and directional FC within the MSN and between the MSN and RSNs regardless of diagnosis. Our analyses using FC patterns to create data-driven clusters revealed three groups with varying levels of neural connectivity from non-directional FC and two groups from directional FC. Within these data-driven clusters, each diagnosis was proportionately represented. On the other hand, these data-driven clusters mapped on to the overall level of sensory issues reported, such as generalized sensory difficulties and sensory adaptations (Figure 1C, 1D, 2B, 2C). That the data-driven clusters based on FC sorted groups by sensory characteristics well, but failed to sort by diagnosis, suggests that these sensory characteristics and their underlying neurobiology are transdiagnostic in nature.

Conclusions: Although both Autism and ADHD groups exhibited greater sensory difficulties compared to TD group, the functional organization of the MSN was more closely aligned with sensory characteristics than with the diagnostic labels, suggesting that sensory characteristics, and sensory issues more broadly, are transdiagnostic as opposed to specific to Autism. This reflects the heterogeneity and overlaps in multisensory integration at both behavioural and neural levels in Autism and ADHD. This underscores the link between the functional organization of the MSN and real-life sensory difficulties, irrespective of diagnostic categories.

405.258 The Relationship between Sensory Alterations and Restrictive Repetitive Behaviors in Children with Autism Explored with Fourth-Generation Artificial Neural Networks.

E. Carati¹, E. Grossi² and A. Parmeggiani¹, (1)Child Neuropsychiatry, IRCCS ISNB Ospedale Bellaria- Policlinico S. Orsola-Malpighi, Bologna, Emilia-Romagna, Italy, (2)Autism Research Unit, Villa Santa Maria SCS, Tavernerio, Como, Italy

Background:

Restrictive Repetitive Behaviors (RRBs) and sensory features are core symptoms of autism spectrum disorder (ASD); their impact on patients' quality of life warrants extensive literature studying them. Few studies so far have addressed the nature of the interplay between these two traits with a data mining approach.

Objectives:

The aim of the present study was to depict the associations between demographic and clinical variables and the full spectrum of RRBs and sensory processing abnormalities in a sample of children with a diagnosis of idiopathic ASD using data mining techniques belonging to artificial intelligence. The expectation is that this approach would be able to uncover important latent connections between RRBs and sensory abnormalities and other clinical/demographic variables considered.

Methods:

Forty-five patients under 18 years (range: 3–15, median 6) with ASD diagnosis according to DSM-5 entered the study. Demographic information (gender, age), clinical variables (epilepsy, sleep problems, Intellectual Disability (ID), rehabilitation therapy, pharmacological therapy), and Short Sensory Profile (SSP) subscales scores and Repetitive Behavior Scale-Revised (RBS-R) subscales scores have been collected in anonymized form and recorded in an Excel database. To graphically show the most important connections among the 25 variables we used a fourth-generation artificial neural network (ANN) called Auto-CM, that develops weights that are proportional to the strength of the associations of all variables each other. After the training phase, the weights matrix of the Auto-CM represents the warped landscape of the dataset. Subsequently, a minimum spanning tree filter is applied to the weights matrix of the Auto-CM system to obtain a map of the main connections between the variables of the dataset and the basic semantic of their similarities, defined connectivity map.

Results:

Figure 1 show the semantic connectivity map produced by the Auto-CM software. The map (figure 1) highlighted these interesting features: 1) the Low Energy subscale (SSP-VI) has proven to be the central hub of the system; 2) the Self-Injurious Behaviors subscale was directly linked to ID; 3) RRBs was directly linked with sleep disturbance, with Sameness Behaviors (RBS-V) and Ritualistic Behaviors (RBS-IV); 4) sequential links line connecting RBS-R subscales Sameness Behaviors, Restricted Interests, Ritualistic Behaviors, Stereotyped Behaviors, Compulsive Behaviors and the variable male.

Conclusions:

The application of ANNs to our dataset confirmed the well-known association between RRBs and sensory abnormalities; moreover, interesting association between demographic/clinical variables and SSP and RBS-R subscales, previously emerged by classical statistical analysis, were confirmed and deepened. Interesting links emerged between the subscale Self-Injurious Behaviors and Intellectual Disability and between Sleep Disturbance and various RRBs. In conclusion, our study provides new insight into the relationship between RRBs and sensory abnormalities in children with ASD by applying ANNs for the first time in this area.

405.259 Psychometrically-Based Evaluation of a Causal Theory Linking Imitation and Autism Using SPARK

S. McWeeny¹, E. Wodka², B. Caffo³ and J. B. Ewen⁴, (1)Ann & Robert H. Lurie Children's Hospital of Chicago, Chicago, IL, (2)Center for Autism Services, Science and Innovation, Kennedy Krieger Institute, Baltimore, MD, (3)Department of Biostatistics, Johns Hopkins University, Baltimore, MD, (4)Ann & Robert H. Lurie Children's Hospital, Chicago, IL

Background: Imitation skills help children build social-communicative reciprocity and learn social skills. Accordingly, imitation has been identified as a core area of weakness in autism and a potential intervention target. Although the impact of imitation on autism symptomatology has not been fully clarified or supported, other theories focused on “interpersonal synchrony” have gained attention. Specifically, Mostofsky & Ewen (2011) proposed that children learn by watching and performing actions while interpreting sensory feedback to optimize future actions. Disruptions to this process may contribute to autism symptomatology, with its core social and prevalent motor skill deficits. The challenge to evaluating this theory is that it is impossible and unethical to manipulate imitation ability and record social and motor outcomes. We have iteratively improved a statistical approach, involving psychometric and causal-inference aspects, to use observational data to evaluate this theory.

Objectives: We tested a model proposed by Mostofsky & Ewen (2011), which posits that imitation is essential for motor and social skill development in autism. The implication of this model is that imitation can contribute to motor and social skills differences and is thus falsifiable if the relationship between motor and social skills does not depend on imitation.

Methods: Using the SPARK cohort, relevant constructs were created from a mix of the Developmental Coordination Disorder Questionnaire (DCDQ), Social Communication Questionnaire (SCQ), and other background information. 19,188 autistic children aged 5-18 had a complete set of all relevant items. The core premise of the analysis is that motor skills and social skills should be (1) correlated and (2) that this correlation is caused by imitating throughout development. Therefore, covarying for imitation ability should reduce the correlation between social and motor skills. Extensive psychometric work and multiple raters established a subset of DCDQ and SCQ items as valid constructs for social and motor skills, respectively. A two-factor model of social skills and one-factor model of motor skills achieved adequate fit (CFI/TLI > .90, RMSEA < .08), without the need for hierarchical or non-hierarchical bifactor models.

Results: The correlation between social and motor skills was moderate and significant ($r = .34$, $p < .001$, 95% CI [.33 .35]), and the partial correlation between social and motor skills, covarying for imitation was also moderate and significant ($r = .27$, $p < .001$, 95% CI [.26 .28]).

Conclusions: Though covarying for imitation reduced the correlation between social and motor skills, it was a minor absolute change. We argue that a theory in which including a key causative variable only reduces the existing correlation by $r = .07$ is unlikely to be true. The approach utilized here, using a cross-sectional convenience sample, is far from the detail of representational processes that the original authors posited. Understanding the relationship among imitation, motor skills, and social functioning can help develop better models of how these skills develop, and more effectively target interventions to address social and motor functioning.

405.260 Common Neural Activity Patterns for Sensory Processing and Intolerance of Uncertainty in Autistic Children

G. J. Cardon¹, D. Rojas² and S. Ruesch¹, (1)Communication Disorders, Brigham Young University, Provo, UT, (2)Colorado State University, Fort Collins, CO

Background:

Sensory differences are common in autism and can influence a host of behavioral domains. Unfortunately, the behavioral and neural correlates of sensory difficulties remain somewhat elusive, which limits the effectiveness of clinical supports. The brain's ability to predict upcoming sensory events, based on past experience, is central to sensory function, and has been implicated in autism (i.e., predictive coding). In turn, long-term irregularities in prediction of sensory inputs could lead to development of an intolerance of uncertainty (IU). Atypical functioning of both sensory cortices and neural processing outside of these areas (i.e., supramodal) could contribute to such sensory differences. Specifically, predictive function is thought to be subserved by a network of supramodal regions—e.g., cerebellum, pre-motor cortex, temporal-parietal junction, etc. Thus, we propose that irregular function and connectivity in such regions likely contribute to atypical sensory processing and IU in autistic persons. Examining prediction and its neural correlates could provide a useful perspective regarding sensory processing in autism.

Objectives:

We aimed to examine the relationship between behavioral sensory processing, IU, and autistic traits, and the association between these measures and functional connectivity between sensory and supramodal brain regions. We hypothesized that the autistic participants would demonstrate significant relationships between sensory processing, IU, and autistic traits, and that these measures would correlate with connectivity between sensory cortices and nodes in a previously established prediction-related brain network (e.g., Siman-Tov et al., 2019).

Methods:

Participants were 30 autistic children (27 male; mean age=9.13 years) and 26 nonautistic peers (19 male; mean age=9.38). All participants underwent a resting-state functional magnetic resonance imaging scan (rs-fMRI). Parents also completed several questionnaires: Short Sensory Profile (SSP), Intolerance of Uncertainty Scale (IUS-12), and the Social Responsiveness Scale-2nd Edition (SRS-2). One-way analysis of variance (ANOVA) was used to test between-groups differences for each behavioral questionnaire. Furthermore, relationships between the behavioral questionnaires were calculated using partial correlations, controlling for age and autistic traits (when appropriate). Finally, between-groups differences in functional connectivity and associations between functional connectivity and behavioral results were evaluated via multi-voxel pattern analysis (MVPA) in both a combined autistic-neurotypical sample, as well as within each group separately.

Results:

Results revealed that autistic children presented with significantly more sensory atypicalities, greater IU, and heightened autistic traits, compared to nonautistic children. Additionally, correlational analysis revealed behavioral interrelationships between these constructs. We observed significant associations between both behavioral sensory processing and IU and functional connectivity between occipital cortices and the right premotor cortex in the combined sample and within-groups. Distinct, but partially overlapping, functional connectivity results were found to be correlated with autistic traits in both groups.

Conclusions:

Our findings suggest that sensory processing and IU share common brain mechanisms, previously shown to be involved in sensory (esp. visual) function, action planning, and prediction. As such, these results may indicate that sensory processing and prediction are linked, both behaviorally and physiologically, with each other, as well as with autistic traits, regardless of diagnosis. These results may provide clinicians and stakeholders with targets for new and improved supports for autistic people.

Poster Session**406 - Service Delivery/Systems of Care I**

May 1st, 2025, 12:30 PM - 1:30 PM - Hall 4A

406.261 School-Based Services for Adolescents with Autism: Relations with Mental Health Functioning and Post-Pandemic Needs
K. M. Rispoli, L. Ziegelmayr, E. Chatson, G. Lee, M. A. Volker and C. Wahman, Counseling, Educational Psychology, and Special Education, Michigan State University, East Lansing, MI

Background: Mental health conditions are prevalent among autistic adolescents. Fifty-seventy percent have anxiety (Kerns et al., 2020) and they are twice as likely as non-autistic peers to experience depression (Hudson et al., 2019). Needs were exacerbated during COVID-19 and continue to burden families and schools (Kobb et al., 2021; Kotowski et al., 2022). Schools are well-positioned to provide mental health services for adolescents, as they circumvent key such as including transportation challenges, inadequate insurance coverage (Bear et al., 2014). However, little is known about specific school-based services used by autistic adolescents.

Objectives: Aims were to compare service use and quality for adolescents with autism to other conditions, identify needs arising from the pandemic, and investigate how service use relates to mental health functioning.

Methods: Data were from a survey of caregivers of youth with disabilities ($N=72$, ages 12-18 years, $M=14.33$ years, $SD=1.82$). Caregivers were allowed to select multiple disability categories for children, thus co-occurring disabilities are reflected in total counts. Disabilities included autism ($n=23$), ADHD ($n=17$), anxiety ($n=23$), depression ($n=17$), developmental disability ($n=22$), cognitive impairment ($n=13$), learning disability ($n=37$). Youth were predominantly male (61%) and White (57%). Caregivers completed the Strengths and Difficulties Questionnaire (SDQ; Goodman, 1997) to assess youth mental health, and researcher-developed Services and Needs questionnaire rating school services, and quality of services, adolescents received, aligned with state and federal (IDEA 2021) regulations. Caregivers identified needs arising during the pandemic. Preliminary analyses examined descriptive trends. Multiple regression will test associations between services, service quality, disability with mental health functioning.

Results: Across the entire sample, top 10 services accessed by adolescents with disabilities were instructional (56%), social skills (54%), counseling (53%), medical (53%), parenting counseling (43%), school health (43%), guardianship (39%), assistive technology (38%), speech-language therapy (36%), and early assessment (35%). See Table 1 for most frequent use across disability. Service use in autism ($M = 8.79$, $SD = 2.99$) was higher than ADHD ($M = 5.86$, $SD = 2.71$; $t = 3.91$, $p < .001$) and cognitive impairment ($M = 6.41$, $SD = 2.06$; $t = 3.53$, $p < .001$) but lower than learning disability ($M = 13.45$ services, $SD = 4.01$; $t = 5.01$, $p < .001$). Service use did not differ significantly between autism and anxiety ($M = 8.00$, $SD = 2.71$; $t = 1.06$, ns) and depression ($M = 7.69$, $SD = 2.71$; $t = 1.61$, ns) categories. On average, caregivers rated quality of most frequently used school-based services 3.18 on a 5-point scale, with highest quality ratings for medical (3.45), counseling (3.34), early assessment (3.32). Lowest quality were instructional support (3.10), parent counseling (3.03), social skills (2.95). Figure 1 displays post-pandemic needs across disability categories.

Conclusions: Autism school-based service use outpaced other categories (e.g., ADHD) and was similar to anxiety and depression. Services used at high rates for adolescents with autism and other disabilities (e.g., social skills) were rated as relatively lower in quality compared to other, less frequently used services. In the post-pandemic era, school-based service needs for autism are among the highest across disability categories.

406.262 : Does Training Improve Therapist Confidence and Practice in Adapting Cognitive Behaviour Therapy (CBT) to Meet the Needs of Autistic Adults?

A. Russell¹, K. Cooper², P. E. Langdon³, M. Chopra⁴, A. Georgakopoulou⁵ and T. Woodworth⁶, (1)Centre for Applied Autism Research, Psychology, University of Bath, Bath, UNITED KINGDOM, (2)Department of Clinical, Educational and Health Psychology, University College London, London, London, United Kingdom, (3)University of Birmingham, Birmingham, West Midlands, United Kingdom, (4)Centre for Applied Autism Research, Department of Psychology, University of Bath, Bath, Bath, United Kingdom, (5)University of Bristol, Bristol, United Kingdom, (6)Healthy Minds, Worcestershire Health and Care NHS Trust, Redditch, Worcestershire, United Kingdom

Background:

Autistic adults report that psychological therapists being unable to tailor their approach can be a barrier to accessing appropriate mental health support (Adams and Young, 2021). Cognitive Behavioural Therapy (CBT) has been shown to be effective in treating mild to moderate anxiety and depression co-occurring with autism when adapted to meet autistic people's needs (Weston et al., 2016). However, therapists do not routinely receive training in these adaptations and report a lack of knowledge, skills, and confidence to adapt their practice.

Objectives:

We evaluated the impact of a brief, self-directed training in adapting CBT practice for autistic people using mixed methods to investigate (i) changes in CBT therapist confidence following training and (ii) implementation of adaptations in the medium term (5 months).

Methods:

This study was hosted as a study within a trial (SWAT 213) with the clinical trial investigating the effectiveness of a low-intensity CBT intervention for depression (ADEPT-2). Training materials about adapting CBT practice for autistic people were provided to CBT therapists in the Treatment as Usual (TAU) arm and comprised 2 hours of informational content with video role plays to illustrate practice points. Participating therapists completed an online survey, pre (n=109), post (n=66), and 5 months (n=26) after accessing the training materials. The survey asked about therapists' experiences working with autistic people, familiarity with the practice points and included the Therapist Confidence Scale (TCS). At 5 months follow-up, the survey also asked about use of adaptations in practice. Therapists were also invited to join a focus group to further understand their experiences of accessing the training materials.

Results:

The majority of therapists (n=63, 95.45%) endorsed the training as useful for their CBT practice, and 37 (56.06%) reported the training improved their knowledge. A significant improvement in TCS scores was found at follow-up, ($t = -4.023$, $p < .001$) (pre-training mean TCS=42.77 (SD=12.16); follow-up mean TCS 50.88 (SD=10.56)) with an average increase of 24.96%. Of the 26 therapists completing the 5-month follow-up, 15 (57.69%) reported their practice had changed following the training. Five therapists participated in a focus group, and their experiences in applying the training will be explored using thematic analysis.

Conclusions:

The findings of this study provide preliminary evidence that brief, self-directed training can enhance therapists' confidence to adapt their practice to meet the needs of autistic people. The sample size is limited and may be biased to those interested in the training. Findings indicate that therapists can put the training into practice. More systematic evaluation of therapist training is required to increase the accessibility of standard psychological interventions provided in routine care for autistic people.

Russell, A., Langdon, P. and Woodworth V. SWAT 213: Effects of providing information about enhancement treatment as usual on recruitment and retention to trials with autistic adults with depression .

406.263 The Role of Family Quality of Life in the Caregivers of Autistic Adolescents Receiving Treatment for Daily Living Skills

A. Duncan^{1,2} and L. Tadevich^{1,2}, (1)Division of Behavioral Medicine and Clinical Psychology, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (2)College of Medicine, University of Cincinnati, Cincinnati, OH

Background: Adolescence may be a particularly challenging time for autistic teens and their caregivers as they simultaneously navigate developmental expectations including identity development, evolving family dynamics, and increased independence and autonomy, while also considering how their diagnosis of autism may impact their identity and relationships with others. Adolescence is a critical time to examine family quality of life (FQOL) as both autistic teens and their caregivers are navigating the challenges that naturally arise with the transition from high school to adulthood, yet few studies have examined FQOL in the caregivers of autistic adolescents. Further, no studies have examined how a daily living skills (DLS) intervention (i.e., Surviving and Thriving in the Real World - STRW) may impact FQOL by providing support to caregivers and teens.

Objectives: Specific research questions were: (1) What is the profile on the Beach Center FQOL scale for autistic teens?; (2) What demographic, teen, and parenting characteristics are associated with FQOL?; (3) Does the STRW intervention lead to improved FQOL?; and (4) Is FQOL related to change in DLS after receiving the STRW intervention?

Methods: Sixty autistic adolescents and their caregivers completed the 14-week STRW intervention focused on DLS (e.g., hygiene, cooking, cleaning, laundry, managing money). At baseline and post-treatment caregivers reported on their FQOL using the *Beach Center Family Quality of Life* (FQOL Scale) which consists of the Family Interaction, Parenting, Emotional Well-Being, Physical Well-Being, and Disability Support subscales. Measures assessing autism symptomatology, adaptive behavior, internalizing and externalizing symptoms, and parenting constructs were also collected.

Results: Results revealed the following pattern on the FQOL Scale at baseline: Physical Well-Being > Family Interaction > Parenting > Disability Support > Emotional Well-Being. Pair-sampled t-tests revealed that the Physical Well-Being score was significantly greater than the Family Interaction, Parenting, Emotional Well-Being, and Disability Support scores (all p 's < .001); and that the Emotional Well-Being score was significantly lower than the Family Interaction, Parenting, and Disability Support scores (all p 's < .001). The FQOL Scale was significantly correlated with caregiver reported repetitive behaviors and parenting characteristics (i.e., Discipline, Attachment, Involvement, Parenting Confidence, School Satisfaction). The Family Interaction, Parenting, and Overall FQOL scores were significantly improved (all p 's < .03) after completing the STRW intervention. Bivariate correlations revealed a significant relationship between the Emotional Well-Being score at baseline and the change in caregiver reported DLS from baseline to post-treatment ($r = .29$, $p = .03$).

Conclusions: The results highlight the importance of also considering the characteristics of the caregiver and the family system. Many interventions delivered to autistic adolescents rely on the caregiver to provide instruction and coaching, which makes it essential to understand how factors including emotional well-being and access to needed services at school may affect the ability to commit to and implement the treatment plan. The results suggests that families who have ways to relieve stress, have a support system, and have time to pursue their own interests may be better able to support adolescents as they work to build independence and autonomy. Limitations are also discussed.

406.264 A PATH to Neuroinclusive Care

R. Akins¹, A. R. Fitzgerald² and K. H. Owens³, (1)University of California Davis, Davis, CA, (2)UC Davis MIND Institute, UC Davis M.I.N.D. Institute, Sacramento, CA, (3)UCD, SACRAMENTO, CA

Background: The PATH Program (Promoting Accessibility To Healthcare) at UC Davis Health, a system-wide initiative, aims to improve healthcare experiences for individuals with neurodevelopmental conditions (NDC) and their families. Studies show that individuals with NDC face higher healthcare utilization, costs, and unmet needs, along with unique stressors that often lead to care refusals and challenging behaviors. Most healthcare providers receive minimal training on supporting neurodivergent individuals, which contributes to medical trauma and care avoidance. These issues can be addressed through training in patient-centered and neuroaffirming care.

Objectives: Develop a scalable training program for healthcare providers, designed to address common barriers faced by individuals with NDC and foster their participation in their healthcare.

Methods: Using an implementation science framework, a comprehensive hospital training program was created. A needs assessment highlighted key areas for the training, such as environmental and sensory adaptations, visual support strategies and individualized care plans. Feedback from an advisory community group, comprised of providers, patients and caregivers, helped ensure the training reflected real-world needs and experiences. Discussions with hospital stakeholders further emphasized the healthcare disparities faced by neurodivergent individuals and aligned the program with broader institutional diversity, equity, and inclusion goals. Medical providers also contributed insights, ensuring that content delivery was tailored to their needs, while PATH team meetings facilitated the creation of unit-specific materials. The program emphasized the practical application of PATH strategies to foster a more inclusive healthcare environment.

To date, the training has been implemented across settings within the UC Davis Health system: laboratories, vaccination clinics, pediatric primary care, Children's Surgery Center, EEG and Sleep Medicine Clinics, and integrated into the Nursing, Physician Assistant, and Medical School curricula.

Results: Pre-training surveys indicated that 96% of providers had cared for neurodivergent individuals, but 80% had never received formal training. While many entered with some prior knowledge of neurodivergent care strategies, the training led to significant improvements in confidence.

Providers rated their confidence on a scale of 1 (very low) to 5 (very high) before and after the training. Confidence in working with neurodivergent patients increased significantly from pre ($M = 3.23$, $SD = 0.58$) to post ($M = 3.78$, $SD = 0.57$), $t(50) = -4.46$, $p < 0.0001$. Confidence in making environmental adaptations during medical visits also rose from 3.19 ($SD = 0.72$) to 3.82 ($SD = 0.58$), $t(50) = -5.79$, $p < 0.0001$, and confidence in implementing sensory and visual strategies improved significantly, from 3.19 ($SD = 0.88$) to 3.88 ($SD = 0.54$), $t(50) = -6.23$, $p < 0.0001$. The training satisfaction survey revealed providers strongly agreed that the content was relevant to their work and would aid in supporting patients and families.

Conclusions: Healthcare providers often have some baseline knowledge about neurodivergent care, but formal training in evidence-based practices is scarce. This lack of training exacerbates medical trauma and care avoidance. By adopting patient-centered, neuroaffirming care models, healthcare systems can implement strategies that promote more inclusive care environments for neurodivergent individuals. The PATH program serves as an essential step toward achieving these goals.

406.266 A Qualitative Analysis of Applied Behavior Analysis Practitioner's Views and Approaches to Assent-Based Behavior Analytic Therapy for Autistic Children

B. Contreras¹, M. Lovett², J. Castellanos-Bonow³, J. Gesick³ and L. Vega Lopez², (1)Psychology, University of Nevada Reno, Reno, NV, (2)University of Nevada, Reno, Reno, NV, (3)The Learning Consultants, Reno, NV

Background:

Therapies based on applied behavior analysis (ABA) are effective for improving outcomes for individuals with autism spectrum disorder (ASD; National Autism Center, 2015). However, autistic self-advocates argue that ABA-based therapy does not include the patient themselves in the treatment planning process, violating the autonomy and self-determination of the patient (e.g., Wilkenfeld & McCarthy, 2020). The Behavior Analyst Certification Board (BACB) recently elaborated the consent requirements for therapeutic services within their Ethics Code for Behavior Analysts to include assent procedures (BACB, 2020). Despite the acknowledgement that patient assent should be a critical feature of ABA-based therapy, there is minimal research demonstrating assent-based therapy methods that are both effective and practical. Without evidence-based procedures to assess and obtain assent from patients, and procedures for guiding therapeutic decisions when clients withdraw assent, practitioners are at risk of violating patient autonomy.

Objectives:

The purpose of the current research is to conduct practice-based research using a qualitative analysis of how applied behavior analytic practitioners working with autistic children implement assent-based procedures. This study is exploratory and descriptive in nature (i.e., is pilot work to support future research).

Methods:

We are conducting this study using qualitative methods of inquiry; specifically, we are using interpretive description (Thorne, 2016). This study is also being conducted within a community-engaged and practice-based framework. The community partners for this work are active practitioners who provide ABA-based services to children with ASD, and all data are being collected on the site of their practice. We are analyzing 3 sources of data: video observations of ABA therapy sessions (includes a behavior technician and a client), semi-structured interviews with practitioners (includes behavior technicians, behavior analysts, and leadership for the organization), and a document review of the organization's clinical manual. Our current sample size is 9 children (clients) and 10 practitioners (demographic data are shown in Table 1). Our target sample size is driven by information power (e.g., saturation) and was not determined *a priori*. Data collection and analysis are ongoing and we anticipate completing analysis by April 2025.

Results:

Preliminary data analysis has resulted in the construction of an over-arching framework for assent procedures in the context of practice (Figure 1). The left portion of Figure 1 displays the conceptual framework, and the right portion displays the practical framework for embedding assent procedures into ABA-based services. The arrows within the figure indicate connections and bi-directional flows between concepts. These data are preliminary and exploratory, and data collection and analysis are still ongoing.

Conclusions:

One preliminary conclusion based on our analysis is that incorporating assent into ABA-based services for autistic children is complex and involves an interaction of concepts and actions that goes far beyond the definition of assent. Our analysis indicates that there is a key relationship between the culture of the organization that provides services and the assent procedures themselves, and summarizes the interaction across 8 key conceptual areas (the hard-rectangles in the 3rd row of Figure 1). These conclusions are preliminary will be refined through further data collection and analysis.

406.267 A Systematic Review of Perspectives and Service-Use Experiences during the Transition to Adulthood Among the Latine Autistic Population and Their Families

K. Lopez and **S. A. Cortes Coria**, *School of Social Work, Arizona State University, Phoenix, AZ*

Background: Prevalence rates in the diagnosis of autism have shifted with Black, Latine, and Asian children now exceeding the autism prevalence rate of white children. Early intervention programming has received a great deal of attention. Yet, transition-age youth and ethnic/racial ethnic youth who experience a “service cliff” upon leaving high school, have been underexplored. A case example is the Latine population. Improved methods of diagnosis and heightened autism awareness have contributed to increases in the identification of autism among Latine children and youth in recent years. This improvement in early detection of autism and associated efforts in early intervention for Latine children have been promising for young children. The greater number of early diagnoses implies a surge in youth and adult Latine autistic individuals in need of care. However, there is a stark difference in the understanding and support provided to the growing youth and adult Latine autistic populations.

Objectives: The objective of this study was to develop a systematic review of research about perceptions of the transition to adulthood and service use among the autistic Latine population and their families.

Methods: A systematic review was conducted to ascertain the barriers and enablers of healthcare access to services for autistic Latine transitioning to adulthood. Because our review specifically focused on this population, we only included intervention- and service use-based studies with participants ages 18 to 25, Latine, autistic and parents of these transition-age Latine autistics. We systematically searched Google Scholar and PubMed, limiting the publication timeframe between 2013 to 2023. We used the following key terms to find articles: *autism, transition to adulthood, Latino, services, and healthcare*. Exclusion criteria include pediatric studies (< 18 years), non-ASD primary diagnosis, studies of parents of children under the age of 18, review papers (systematic or narrative), book chapters, case studies, commentary articles, opinions, letters, and editorials.

Results: Initially, 21,300 results were included with string search. Limiting the search to 2013-2023 resulted in a cutoff of 3,200 articles. Ten articles remained, of which three were eligible for inclusion in our review. The exclusion of articles was conducted in stages: title and abstract, objectives/research aims, and method scan. After the initial scan, two articles were excluded based on title and abstract content. A more comprehensive scan of articles by authors excluded an additional five articles because these were: a letter on postsecondary support for autistic students ($n=1$), limited inclusion of minorities ($n=4$); primarily of white or non-Latine background) and/or included autistic children (< 18 years of age).

Conclusions: The present study demonstrates a considerable lack of research on Latine transition-age youth and their families. A key finding was the inconsistency in racial and ethnic terms used to identify the population in the articles, such as ‘Hispanic’, ‘Latino’, ‘Latinx’, and ‘Latine’. Given that only three articles were ultimately included in our review it is evident autism research must expand inclusion criteria and outreach to this population. Article themes regarding the transition to adulthood, service use experiences, and directions for future research will be discussed.

406.268 Access Optimization for Autism Specialty Care CentersC. M. Taylor¹, K. Oetjens¹, S. Gai² and J. Wilck², (1)Geisinger, Lewisburg, PA, (2)Bucknell University, Lewisburg, PA

Background: Nationwide, access to care for individuals with specialty care needs is inadequate. According to the Centers for Disease Control and Prevention (CDC), 17.3% of children between 3 and 17 have at least one developmental disability. Timely identification and accurate diagnosis are imperative for accessing appropriate educational and therapeutic interventions. Moreover, diagnosis enables etiologic investigations, including genetic studies, which can impact medical management for children and reproductive planning for their families. Typically, primary care providers identify children at risk for developmental disabilities by eliciting parental concern or conducting routine developmental screening. Currently, the American Academy of Pediatrics (AAP) recommends the use of standardized, formal general developmental screening tools at 9, 18, and 30 months of age in addition to specific screening for autism spectrum disorder (ASD) at 18 and 24 months. Children presenting with developmental delays should then be referred to specialists such as neurodevelopmental pediatricians (NDPs), developmental-behavioral pediatricians (DBPs), or clinical psychologists for further evaluation. In 2016, fewer than 800 DBPs were in the USA, and about 25% of them were nearing retirement age. This has created excessive and arduous wait times for patients to be correctly diagnosed, with wait times in some areas exceeding 18 months for the initial appointment.

Objectives: Our work seeks to expand the ability of specialty care autism clinics to manage patient access. Our project seeks to understand (1) access problems for individuals with autism (2) rural healthcare access specifically and (3) how processes changes have impacted patient care.

Methods: Patient data was extracted from the Electronic Health Record (EHR) to determine waiting times, location, and other patient factors (e.g., age, insurance coverage). The research team extracted, cleaned, and visualized the data from October 2021 to February 2024. The CRoss Industry Standard Process for Data Mining (CRISP-DM) model was followed. Metrics included include the following: (1) Average wait time for a developmental evaluation (with a breakdown based on age and geographic region) and (2) Total number of patients on the waitlist for initial appointments.

Results: In our rural population, we identified the average wait time from referral to evaluation is 224 days with most patients waiting 211 days from the time of referral to evaluation. Of note, implementation of a new model involving intake evaluations decreased the wait time for patients to 133 days. The majority of patients referred to our clinical center are two years old; however wait times are similar across age groups. Implementation of telemedicine models also decreased wait times for most patients.

Conclusions: Using our data mining system, our clinic can identify the effectiveness of our referral and evaluation process. Furthermore, the data visualization tool tracks important metrics, and this visualization could be reproducible at similar centers. In future work, we will further expand our tool to help us better track return evaluations for individuals impacted by autism and developmental disabilities.

406.269 Adapting a Leadership Implementation Strategy for Implementation Teams in Autism ServicesA. R. Johnson^{1,2}, C. K. Josol¹, L. Brookman-Frazee² and A. C. Stahmer¹, (1)Child and Adolescent Services Research Center (CASRC), San Diego, CA, (2)Psychiatry, University of California, San Diego, La Jolla, CA, (3)UC Davis MIND Institute, Sacramento, CA, (4)UC Davis MIND Institute, University of California at Davis MIND Institute, Sacramento, CA

Background: Evidence-Based Autism Interventions (EBIs) are often not used in routine services. The TEAMS Leadership Institute (TLI) is an implementation strategy designed to improve implementation leadership and climate in public service systems (education, mental health) to support EBI use. A state-wide implementation trial of TLI found significantly greater provider EBI fidelity and child outcomes in TLI-trained programs compared to those that did not receive TLI. However, for autism services, TLI required the involvement of multiple team members rather than individual leaders.

We collaboratively developed TLI2 which incorporates a Team Charter Approach derived from team effectiveness research (TER) designed to increase team functioning related to shared cognition (i.e., common understanding of tasks and objectives) and team cohesion (i.e., commitments to each other and the group purpose).

Objectives: This presentation will (1) describe the collaborative approach to adapt TLI1 to include team-based enhancements to TLI2, and (2) characterize team-based mechanisms hypothesized to improve implementation in a scale-out trial of TLI2.

Methods: We used an iterative approach to collaborate with community stakeholders and team effectiveness research experts to co-design a generalizable team charter approach to integrate with TLI. Community partners familiar with TLI participated in focus groups to provide suggestions on the integration of team charters and provided feedback on a subsequent version of TLI2. Using a scale-out trial design (Aarons et al., 2017) 37 implementation support team members from seven programs and school districts participated in the TLI2 trial. They completed a card sort task at baseline to identify alignment in perceptions and roles of key autism EBI implementation support tasks.

Results: Aim 1. Community partners and team-effectiveness research experts emphasized the importance of team composition and systematically identifying implementation support team members. They also recommended fostering open communication within hierarchical systems and collaboratively defining each team member's responsibilities for EBI-specific tasks, ensuring time for task completion and clear role specification. Key adaptations included (1) development of a team charter or implementation plan outlining team goals, roles, and processes; (2) inclusion of team members across the organization, not just leaders; (3) identification of team resources and consultants (e.g., IT); (4) a focus on implementation climate with reduced focus on implementation leadership; (5) use of a card sort assessment to identify implementation tasks and roles.

Aim 2. Baseline data from the TLI2 trial indicated poor initial agreement between team members on potential EBI-specific tasks and roles, indicating an absence of a shared mental model of implementation support tasks. All seven programs developed a team-based implementation plan with role specification across members. We anticipate the integration of the team charter and card sort activities enhances shared understanding of tasks and supports task completion. Implementation process data over six months, including changes in role specification agreement, team processes, and adherence to the implementation support plan, will be presented.

Conclusions: This study highlights a community-partnered approach to developing and adapting organizational-level implementation strategies and the value of integrating team-effectiveness mechanisms. Developing and testing implementation strategies is essential to ensure EBIs reach the intended recipients.

406.270 Addressing Health Inequities for People with Autism and Related Disabilities in the Hospital through Stakeholder Partnerships

S. Iadarola¹, A. Laprime¹, T. Anvari², C. Baker¹, M. Patterson³, E. Baylor⁴, K. Buholtz⁴, K. Cannarozzo¹, S. Creek¹, J. Goodman¹, S. McBride¹, C. Kunz¹, M. Scharf¹ and S. Hochheimer¹, (1)University of Rochester Medical Center, Rochester, NY, (2)Community, Rochester, NY, (3)Rochester Community, Rochester, NY, (4)University of Rochester School of Nursing, Rochester, NY

Background: People with autism and intellectual/developmental disabilities (IDD) deserve the same access to quality healthcare, yet are at increased risk of medical and/or psychiatric conditions as compared to the general population. Autistic patients and patients with IDD report healthcare inequities including less health satisfaction, shorter life expectancy, less access to preventative care, higher chronic health conditions, overutilization of psychotropic medications, and increased mortality (Lin et al., 2021; Lindgren et al., 2021). Although patients with IDD are 9 times more likely to be hospitalized than peers, this population and their caregivers report high levels of dissatisfaction with emergency/inpatient care. Barriers include lack of training, limited resources, competing priorities, ableism, and systemic bias (Ailey, Brown, & Ridge, 2017).

Objectives: This project builds capacity of inpatient nursing staff to understand the medical, social, environmental, and mental/behavioral health needs of patients with autism and IDD, to promote optimal healthcare outcomes. 1) Describe the tiered model of didactic and simulation training; 2) Present data from a pre-intervention survey and associated intervention outcomes.

Methods: We developed the Advancing Supportive Care through Education for Nurses on Disabilities (ASCEND) Program, to build the capacity of inpatient/Emergency Department (ED) nurses to understand the medical, social, environmental, and mental/behavioral health needs of autistic and disabled people. ASCEND is multidisciplinary and includes people with autism/related disabilities and family advocates *as full partners in the initiative*.

Tier 1: Five didactic modules were integrated into the online learning platform for a major regional hospital: Attitudes and Barriers to Care, Adapted Nursing Care, Medical Comorbidities, Mental Health, Managing Crisis. **Tier 2:** Simulations include autism/IDD specific scenarios relevant to their associated presentations, barriers, and biases.

Participants included nurses in pediatric and adult inpatient and ED units who participated in Didactics (n=1079) and Simulations (n=52). They completed standardized measures at baseline (T1) and immediately after training (T2) capturing the following dimensions: disability knowledge, disability healthcare attitudes, clinical comfort, organizational climate, and training satisfaction. Analyses included descriptives on nurse demographics and unpaired samples t-tests to compare domain scores pre/post training. Exploratory analyses were conducted to compare scores on T1 measures by group (e.g., gender, practice context).

Results: Baseline (pre-training) data for Tier 1 (didactics) indicate comparable barriers to care across settings (e.g., medical versus psychiatry, adult versus pediatrics), with a few exceptions (n=244). Nurses working in the medical setting report a better organizational climate than those working in psychiatric settings (p=.04), and female-identifying nurses reported more positive attitudes toward disabled people than male-identifying nurses (p=.008). Baseline scores indicate lowest domain scores for clinical knowledge (M=19.0) as compared to organizational climate (M=31.2), clinical comfort (M=33.2), and attitudes (M=30.3). At T2, participants reported improvements on clinical comfort (p<.01), knowledge (p<.01), and climate (p<.01) domains, but decreases on attitudes (p=.05).

Conclusions: The success of initial development and pilot deployment suggest the feasibility of the model. Pre/post data will indicate preliminary efficacy of the tiered system of training. Scale-up and sustainability is planned, as the ASCEND model will be deployed to at least 10 partner hospitals over the next 3 years.

406.271 An Exploration of Early Intervention and Screening Delays for Asian American Families with Limited English Proficiency

M. L. Covello¹, A. J. Harrison², K. Bowman³, J. A. Brown⁴, R. Lieberman-Betz⁴ and C. O. Vail¹, (1)Educational Psychology, The University of Georgia, Athens, GA, (2)Educational Psychology, University of Georgia, Athens, GA, (3)TEACCH Autism Program; Psychiatry, University of Georgia, Chapel Hill, NC, (4)University of Georgia, Athens, GA

Background:

Immigrant families encounter barriers to healthcare access, resulting in poor health outcomes, especially for autistic children (Lim et al., 2021). The added barrier of limited English proficiency can lead to delays in receiving services (Kim et al., 2023), which is particularly relevant for Asian-American immigrants as the fastest growing immigrant group in the US (PRC, 2021). An Individualized Family Service Plan (IFSP) is the first step in establishing early intervention (EI) services and for children an early autism screening is critical for early diagnosis (Nadel & Poss, 2007). It is essential to understand EI disparities for culturally and linguistically diverse (CALD) families.

Objectives:

Compare delays in receiving an IFSP past the 45-day due date and delays in screening for ASD (at 18 month and 24 months) by race (identifying as “Asian” compared to all other participants) and by primary language (those whose preferred contact language was something other than “English” compared to those who chose “English”) within a large cohort of Georgia EI data.

Methods:

Data was extracted from Georgia’s state-wide EI program, documenting participation between 2018 and 2022. For each enrolled family, EI providers entered sociodemographic information (e.g., race, ethnicity) and service milestones (e.g., IFSP start date). This study focused on a subset of 1,929 families identifying as Asian (1,479 with English as a primary language and 238 with a primary language other than English) compared to the remaining 50,353 identifying as a non-Asian race (39,530 having English as a primary language and 3,359 with a primary language other than English). The proportion of English to Non-English languages was significantly higher in the Asian cohort (12.3% of the Asian cohort compared to 6.7% for the Non-Asian cohort). Variables for race, primary contact language, IFSP delays (days past the 45-day due date), and ASD screening delays (days past 18 and 24 months) were analyzed using R 4.1.0 (R Core Team, 2021).

Results:

In the total sample, significantly higher IFSP delays were found in the overall Non-Asian compared to Asian cohorts ($p=0.013$). However, within the Asian cohort, the Non-English group had significantly higher delays than the English group ($p = 0.002$, Table 1). This difference in delays related to language was not observed within the Non-Asian cohorts ($p = 0.41$). Significantly higher delays in ASD screening at 18-months were found within the Asian cohort, for the Non-English group ($p = 0.03$). This difference across language groups was similarly not observed within the Non-Asian cohort ($p = 0.318$). However, at 24-months, delays were observed across the non-English group within the Non-Asian cohort ($p = 0.004$) but not the Asian cohort ($p = 0.26$).

Conclusions:

While disparities existed for Non-Asian cohorts compared to Asian, when evaluating disparities across race, one may miss potential disparities that exist for those with limited English proficiency. We observed specific delays in the Non-English language group with the Asian cohort. To better understand the mechanisms for these delays, more analysis is needed to ensure that EI services are supporting CALD families in receiving services for their autistic children.

**406.272 Area Deprivation Index in Autism: A SPARK Cohort Study**

M. E. Villalobos^a, P. Carbone^a, A. L. Stuart^a and Z. Tripp^a, (1)Pediatrics, University of Utah, Park City, UT, (2)Univeristy of Utah, Salt Lake City, UT, (3)General Pediatrics, University of Utah School of Medicine, Salt Lake City, UT, (4)Pediatrics, University of Utah, Salt Lake City, UT

Background: Previous research on the impact on neighborhood disadvantage and autism has yielded inconclusive results primarily demonstrating differences in prevalence estimates in more disadvantaged areas and poorer health outcomes overall. These data suggest that children from disadvantaged areas generally experience poorer health outcomes due to lack of available medical care; however, specific mechanisms behind these differences have yet to be studied.

Objectives: The current study aimed to examine the Area Deprivation Index (ADI) in a national cohort (The Simons Foundation SPARK study). We specifically were interested in the effect of ADI on age of evaluation in this national ASD sample.

Methods: The SPARK Version 8 dataset (release date: June 3 2022), comprised of multiple parent questionnaires, was downloaded from SFARI base (<https://base.sfari.org>). A total of 27,928 children under the age of 18 years with ASD were studied. We examined the Area Deprivation Index as it allows for rankings of neighborhoods by socioeconomic disadvantage in a region of interest (e.g., at the state or national level). We chose to use the state level rankings as it allows for comparison a more geographically refined level. We conducted a linear regression to examine the effect of ADI on and age of evaluation in months.

Results: A linear regression analysis was conducted to examine the relationship between age at evaluation (in months) and the state rank decile for the ADI. The coefficient for age at evaluation was -0.51 , which was statistically significant ($t=-4.95$, $p<0.000$). Indicating that for each one-unit increase in the ADI state rank decile, the age at evaluation decreased by approximately 0.51 months. This result suggests a negative relationship between the deprivation index and age at evaluation, meaning that individuals from higher deprivation areas tend to be evaluated at a younger age. The overall model was statistically significant, $F(1, 27,928)=24.49$, $p<0.000$, indicated that the predictors collectively explained a significant portion of the variance in the ADI. However, the model's R^2 value was 0.0009, suggesting that only 1% of the variability in ADI is explained by the ADI rankings. Post hoc analyses will further examine additional predictors for ADI in the SPARK cohort.

Conclusions: In conclusion, the analysis indicates a significant negative relationship between age at evaluation and the ADI state rank decile. While the direction of the relationship suggests that higher deprivation (higher ADI percentile) might be associated with slightly younger ages at evaluation, this effect is small. Given the extremely low R -squared value, this model does not provide strong evidence that socioeconomic deprivation as measured by the ADI is a meaningful predictor of the age at evaluation for a research-based population. The fact that families in this study were part of research study biases the sample to those who may be accessing resources better. However, further investigation with additional predictors may be warranted to better understand the factors influencing ADI in this cohort.

406.273 Ask Me What I Think: Understanding the Needs of Autistic Middle and High School Students

M. Thirion¹, O. Michael², K. S. Dickson³ and J. Locke⁴, (1)University of Washington, Seattle, WA, (2)University of Miami, Seattle, WA, (3)San Diego State University, San Diego, CA, (4)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA

Background: Autistic youth have increased mental health challenges, such as depression, anxiety, and suicide (Howe et. al, 2020) along with poor postsecondary and long-term outcomes in areas like social engagement, employment, and quality of life (Kraemer et al., 2019). In the United States, the public school system is the primary setting in which autistic youth receive services (Brookman-Frazee et al., 2009). However, there are limited school-based evidence-based practices (EBPs) designed to adequately support autistic middle and high school students (Kucharczyk et al., 2015; Locke et al., 2024). One challenge in implementing efficacious school-based EBPs is the absence of reliable tools to evaluate the needs of autistic students and the resources they utilize.

Objectives: The goal of this presentation is to understand identified areas of unmet need from autistic adolescents in middle and high schools, as well as the critical supports that public middle and high schools ought to provide to support their needs.

Methods: We included autistic adolescents in the design of a survey which was later distributed to autistic students to gain insights into their perspectives and needs in middle and high schools. Thirty-four autistic adolescents in middle and high school (67% male, 79% white, average age=13.1, average grade=7.4) completed a "How Can We Support You" survey electronically via Research Electronic Data Capture (REDCap). The survey was designed in partnership with an autistic advisory board. Design modifications included: icons, definitions of core constructs, questions about desired areas for improvement in school, supports they currently receive and would like to access, and how effectively their needs were being met in school. For this presentation, we focus on the areas of identified need. Participants received \$20 for completing this survey, which took approximately 15 minutes to complete.

Results: Autistic adolescents in middle and high school primarily identified mental health and executive functioning as their top areas of need, prioritizing these over academics, behavior, and daily living skills. Specific areas of identified executive functioning needs included attention challenges, time and task management, and mental health needs included addressing mood and anxiety. Very few students indicated that they do not want support from their schools in any areas of need that were identified.

Conclusions: As a field, we ought to listen to and include autistic voices throughout the research process. We have much to learn from the autistic community. We posit the following tips and potential solutions to improve support for autistic adolescents in middle and high schools: 1) public middle and high schools need to prioritize mental health and executive functioning for autistic adolescents; 2) intervention developers need to redesign evidence-based efficacious mental health and executive functioning programs for use in middle and high schools, because there are not enough programs to effectively address these needs; and 3) autistic adolescents should be included in the design process of these programs, and one method to achieve this is by conducting surveys or assessments to collect their input on their needs.

406.274 Assessing the Information Needs and Support Methods for Caregivers of Children with Developmental Disabilities: A Focus on Media and Digital Resources

M. Joo¹, N. Kang², J. Yoon³, H. Yoo⁴, H. Hong⁵, S. H. Kim⁶, S. Park⁷, J. Lim⁸, Y. Jeon⁹, Y. Hwang³, S. Lee³ and **D. S. Moon²**, (1)Psychiatry, Jeju National University Hospital, Jeju-si, Jeju-do, (2)Psychiatry, Jeju National University Hospital, Jeju-si, Jeju-do, Korea, Republic of (South), (3)Jeju National University Hospital, Jeju-si, Jeju-do, Korea, Republic of (South), (4)Psychiatry, Seoul National Univ Bundang Hospital, Seongnam, Korea, Republic of (South), (5)Department of Industrial Design, Korea Advanced Institute of Science and Technology (KAIST), Daejeon, Chungcheongnam-do, Korea, Republic of (South), (6)School of Psychology, Korea University, Seoul, Seoul, Korea, Republic of (South), (7)Moa mind institute, Seoul, Korea, Republic of (South), (8)Lumanlab, Seoul, Korea, Republic of (South)

Background: This study addresses the increasing prevalence of developmental disabilities, the growing need to support and empower caregivers of children with developmental disabilities, and the rising demand for remote services among these caregivers. However, caregivers often face challenges in accessing reliable and accurate information online, making it difficult to find resources that meet their specific needs. Therefore, it is crucial to understand caregivers' current usage patterns and specific needs for remote services to develop tailored resources that effectively support this population.

Objectives: The study aimed to evaluate the needs and preferences of caregivers of children with developmental disabilities across four key areas: general information about caregivers and children, methods of acquiring developmental disability-related information, usage of YouTube video content, and experience with mobile apps specifically designed for caregivers of children with developmental disabilities. Insights gained from this research will inform the development of practical strategies for future app development to effectively support caregivers.

Methods: A nine-month online survey was conducted from January to September 2024, targeting caregivers of children aged 3 to 12 years with developmental disabilities. The survey, designed to assess caregivers' needs and experiences, was distributed through various channels such as outpatient clinics, the developmental center's homepage, interactive events, and community sharing to ensure broad coverage. Descriptive analysis was employed to quantify the preferences and experiences of caregivers, with results presented in proportions.

Results: Among the 82 respondents, the majority were mothers of children aged 3 to 12 with Autism Spectrum Disorder (ASD), intellectual disability (ID), or other developmental disorders (Table 1). They primarily accessed information through website searches (25.6%) and YouTube (19.5%). The most preferred methods were internet posts or video subtitles (36.6%) and videos (35.4%). Although over 70% of respondents frequently used YouTube due to its accessibility and diverse content, their overall satisfaction was low (37.1%). This was because of the unreliability and lack of specificity in the content, which often failed to meet their children's needs (Table 2), highlighting YouTube's limitations as a reliable information source. The most frequently sought information focused on enhancing language and communication skills (23.2%), supporting daily living and self-care abilities (23.2%), and fostering social interaction and peer relationships (22.0%). The most frequently requested video topics were related to children's development, including language, social, and cognitive skills (35.4%). Additionally, respondents expressed a strong interest in a mobile app featuring practical tools such as daily routine management and behavior guidelines (41.5%).

Conclusions: The study highlights that caregivers of children with developmental disabilities urgently need reliable, customized digital resources, particularly those focusing on language, social skills, and daily living skills. Addressing these needs requires the development of verified, tailored solutions that offer practical support tools. Resources that offer structured guidance on daily routines and behavior management, for instance, could significantly enhance caregivers' ability to support their children effectively. Incorporating these elements into a mobile app specifically designed for caregivers could potentially provide a practical, accessible, and convenient way to meet these needs.

406.275 Associations between the Timing of Early Intervention/Early Childhood Special Education Relative to the Timing of Autism Diagnosis and Caregiver Mental Health: Findings from the National Survey of Children's Health 2016-2020

L. Sun¹, L. M. Robinette² and S. A. Keim³, (1)Center for Biobehavioral Health, Abigail Wexner Research Institute, Nationwide Children's Hospital, Columbus, OH, (2)Center for Biobehavioral Health, Abigail Wexner Research Institute at Nationwide Children's Hospital, Columbus, OH, (3)Center for Biobehavioral Health, The Abigail Wexner Research Institute at Nationwide Children's Hospital, Columbus, OH

Background:

Early Intervention (EI) and Early Childhood Special Education (ECSE) are important for children suspected of autism. However, the timing of EI/ECSE relative to autism diagnosis and its impact on caregiver mental health are not well understood. We hypothesized that the timing of receiving EI/ECSE before versus after autism diagnosis may influence the developmental trajectory of autistic symptoms and thus impact caregiver mental health.

Objectives:

To estimate the proportions of children receiving EI/ECSE before versus after autism diagnosis and the proportions of caregivers with "good" and "poor" mental health status. To examine associations between EI/ECSE timing and caregivers' mental health while controlling for other characteristics.

Methods:

Analysis used the National Survey of Children's Health (NSCH) (2016-2020), including children aged 2-8 years with an autism diagnosis who received EI/ECSE (N=1,151). Caregiver questionnaires asked about EI/ECSE timing, caregivers' mental and physical health status (dichotomized into "good" =excellent/very good/good or "poor" =fair/poor), and demographics. Survey-weighted logistic regression models examined associations between EI/ECSE timing and caregiver mental health, controlling for covariates.

Results:

Approximately 27.7% (95% CI [22.4%, 32.9%]) of children received EI/ECSE before autism diagnosis. Caregivers' mental health was reported as "Good" for 89.3% and "Poor" for 10.7%. EI/ECSE timing relative to autism diagnosis was not associated with caregivers' mental health (aOR = 1.2, 95% CI [0.6, 2.5]). Factors associated with decreased odds of "Good" mental health included whether the child currently has autism (aOR = 0.13, 95% CI [0.03, 0.6]), has ever received special services to meet the child's developmental needs such as speech, occupational, or behavioral therapy (aOR = 0.06, 95% CI [0.05, 0.9]), and higher education level versus high school and less (some college: aOR = 0.17, 95% CI [0.04, 0.6]; college degree: aOR = 0.14, 95% CI [0.03, 0.6]). Caregivers' "Good" physical health strongly predicted "Good" mental health (aOR = 30.8, 95% CI [13.0, 73.3]). Child age and sex, current EI/ECSE receipt status, insurance coverage, age of autism diagnosis, having received autism treatments in the past 12 months, currently taking autism medications, caregivers' employment, government assistance (cash and food stamps), and caregiver-reported emotional support with parenting showed no associations with caregivers' mental health.

Conclusions:

The timing of receiving EI/ECSE before autism diagnosis was not associated with the caregiver's mental health. Current autism diagnosis, receipt of special services, and higher parental education level were associated with decreased caregiver mental health. Caregivers' good physical health has the strongest association with their good mental health. It is notable that a child receiving special services/therapies, which is typically considered a supportive factor, was associated with decreased caregiver mental health, reflecting the challenges faced by caregivers of autistic children with complex needs. Future research should explore additional mechanisms to support caregiver mental health throughout the autism diagnosis and intervention process.

406.276 Autism Assessment Confidence and Knowledge Change Among Primary Care Providers Trained to Provide Diagnostic Evaluations

L. Gooding¹, O. J. Lindly², L. Blankenship³, R. Vega-Juárez⁴, A. J. Martin⁵, K. Zuckerman⁶ and K. Freeman⁶, (1)Northern Arizona University, Flagstaff, AZ, (2)Health Sciences, Northern Arizona University, Flagstaff, AZ, (3)Oregon Center for Children & Youth with Special Health Needs, Oregon Health & Science University, Portland, OR, (4)Oregon Health & Science University, Portland, OR, (5)Division of General Pediatrics, Oregon Health & Science University, Portland, OR, (6)Pediatrics, Oregon Health & Science University, Portland, OR

Background: Early autism diagnosis often enables U.S. children and their families to access important services and supports. Unfortunately, workforce shortages in professionals qualified to conduct such diagnostic evaluations contribute to long waits for many families. To address this, primary care providers (PCPs) are increasingly being trained to deliver such care within the medical home.

Objectives: We evaluated changes in autism assessment confidence and knowledge among PCPs participating in a 36-hour training course designed to prepare them to deliver diagnostic evaluations of patients ages 18 to 47 months suspected of having ASD in their medical home. This program is part of a Medicaid strategy to increase access for marginalized populations.

Methods: Twenty-four PCPs were enrolled (see Table 1 for demographic characteristics). Training included completion of an asynchronous online autism training available through the American Academy of Pediatrics and a two-day in-person training during which the PCPs learned to administer the Screening Tool for Autism in Toddlers and Young Children (STAT), and a diagnostic interview based on the DSM-V autism criteria. A self-administered electronic survey was used pre- and post-training to determine autism evaluation confidence and knowledge. The Primary Care Autism Self-Efficacy (PCASE) survey was adapted to measure PCP confidence in the following six domains: autism screening and identification, assessment, referral, testing, concurrent psychiatric condition management, and additional areas (e.g., providing anticipatory guidance, partnering with families). The 36 PCASE items were rated on a six-point Likert-type scale, with a score of one indicating no confidence and a score of six indicating highly confident/expert. The PCASE full scale and subscales demonstrated good internal consistency reliability ($\alpha = 0.85$ to 0.94). Autism knowledge was measured using the following two items: "How knowledgeable are you about autism?" and "Generally, how knowledgeable are primary care providers about autism?". These two items were each rated on a five-point Likert-type scale with a score of one indicating strongly disagree and a score of five indicating strongly agree. Given the distributional properties of the variables, we computed descriptive and bivariate statistics along with paired t-tests and Cohen's D.

Results: PCASE results demonstrated a statistically significant ($p < .05$) increase in PCP confidence with autism assessment for the total score and five of the six subscales (see Table 2). In addition, a statistically significant increase was found in PCPs' mean knowledge about autism.

Interestingly, the mean general knowledge of PCPs was at follow-up versus baseline, though this difference was not statistically significant.

Conclusions: Results suggest improvements in PCP autism assessment confidence and knowledge between baseline and follow-up, consistent with other research involving training PCPs to complete such diagnostic evaluations. Future Autism Assessment Capacity Project (AACP) research will include analyzing data from an additional PCP follow-up survey (post ECHO series) and integrating these PCP survey findings with patient assessment data gathered toward the end of training activities. This and other similar PCP training initiatives may help increase access to timely autism diagnostic services for U.S. children.

406.277 Autism Care Continuum: Exploring Specialty Services across the Lifespan within U.S. Academic Medical Centers

A. Khuu¹, Z. Williams², A. Senanayake³, M. Caniello¹, S. Shukla¹ and K. O. Gotham¹, (1)Psychology, Rowan University, Glassboro, NJ, (2)Vanderbilt University, Nashville, TN, (3)Rowan University, Glassboro, NJ

Background: Autistic people experience disproportionately high rates of co-occurring mental health problems both in general and in adulthood (Lugo-Marín et al., 2019; Uljarević et al., 2020), contributing to increased healthcare utilization and costs (Ames et al., 2021; Zerbo et al., 2019). Yet, autistic people—particularly adults—often report high unmet service needs in the face of mental healthcare access barriers (Nicolaidis et al., 2013) including geographic limitations (Drahota et al., 2020), shortage of trained clinicians who feel confident working with this population (Maddox et al., 2020), and the absence of an integrated delivery system (Maddox et al., 2021). Despite preliminary evidence for high and unmet service needs in the autistic population, we lack empirical evidence on the prevalence and accessibility of autism specialty services in the United States. This is true even for those services affiliated with academic medical centers (AMCs), generally recognized for their cutting-edge research and high-quality healthcare services.

Objectives: We aim to identify and characterize autism specialty services provided by U.S. AMCs along the east and west coasts to identify potential gaps in service provision in what may represent the strongest available specialty services for autism. Specifically, we aim to highlight gaps in care by age groups and types of services offered.

Methods: The study team screened the Centers for Medicare & Medicaid (CMS) 2023 Reporting Cycle Teaching Hospital List for hospitals that qualify as an AMC. To qualify, hospitals needed to be directly affiliated with a university or college located on the U.S. east or west coasts. The study team conducted a systematic online search of each qualifying AMC to identify whether it has a department and/or clinic/program that advertises autism-focused services. Data were extracted from AMC service line websites to document types of services provided to autistic people and age ranges of eligibility for each. This study focused on description of intensive population-based data collection; thus, descriptive summary statistics were utilized to characterize types of services offered and age ranges of eligibility.

Results: A total of 121 AMCs along the east and west coasts of the U.S. were identified from the CMS list. From these institutions, 67 departments and clinics/programs were found to offer autism specialty services. Most departments and clinics/programs served the pediatric population (73%), only 7% focused on adults. The most common type of service offered is diagnostic assessment. See Figure 1.

Conclusions: At AMCs that provide autism specialty services, the vast majority of clinical efforts are focused on autistic youth. Few centers provide specialized services dedicated to adults, supporting the idea of a "service cliff" for the post-pediatric population (Roux et al., 2015). Of the types of services offered across age ranges, diagnostic assessments are the most common. Few centers offer post-diagnostic support and specialist care, and this service gap is even greater for autistic adults. This study highlights startling disparities in the provision of autism specialty services, particularly for autistic adults, even at institutions that are expected to provide among the strongest empirically-based services for autistic people.

406.278 Autism Diagnoses in Primary Care: Echo Autism Washington

A. Bravo¹, J. Gerds², G. Stobbe³ and J. Fossum⁴, (1)College of Education, University of Washington, Seattle, WA, (2)Department of Psychiatry & Behavioral Sciences, University of Washington, Seattle, WA, (3)Seattle Children's Autism Center, Seattle, WA, (4)School of Psychology, Family, and Community, Seattle Pacific University, Seattle, WA

Background:

Project Extension for Community Healthcare Outcomes (ECHO) is a telementoring program that connects primary care providers (PCPs) with subject matter experts (SMEs). ECHO™ sessions include PCP case presentations and SME didactics aimed at enhancing PCP capacity for specialized care. Autism spectrum disorder (ASD)-focused ECHOs began at the University of Missouri and have demonstrated success in increasing PCP self-efficacy, adherence to ASD screening guidelines, and diagnostic capabilities (Mazurek et al., 2017; Sohl et al., 2017; Gerds et al., 2024).

Objectives:

This pilot exploratory study evaluates the impact of PCP participation in *ECHO Autism Washington* on PCP capacity for diagnosing ASD and delivering ongoing care. The study compares the diagnostic experiences and access to care for families whose children received ASD diagnoses from *ECHO Autism Washington* PCPs versus those diagnosed at a specialty clinic in Seattle, WA.

Methods:**Provider Survey**

ECHO PCPs ($n=13$) completed a survey about diagnostic services provided to patients about whom they discussed during an *ECHO Autism Washington* case presentation. The survey contained questions about PCP practice patterns, ASD diagnostic methods, and subsequent care.

Caregiver Survey

ECHO PCPs distributed a survey to caregivers of patients diagnosed with ASD during or after their participation in ECHO (ECHO Caregivers). Caregivers of patients diagnosed at a specialty clinic served as a comparison group (Clinic Caregivers). Seven ECHO Caregivers completed the survey and were matched demographically with seven Clinic Caregivers from a pool of twenty-nine. The survey included a modified Patient Satisfaction Questionnaire-18 (PSQ-18; Marshall & Hays, 1994), demographic questions, and questions about services accessed post-diagnosis.

Results:**Provider Survey**

The most commonly recommended services by PCPs during initial diagnoses included special education, applied behavior analysis, speech-language pathology, and occupational therapy (69%). Additionally, 69% of ECHO PCPs continued care after diagnosis, which included mental health services, support with pursuing Developmental Disabilities Administration services, revisiting applied behavior analysis, working with school districts, transitioning to adult care, guardianship discussions, sleep hygiene, and school attendance.

Caregiver Survey

A Welch two-sample t-test compared PSQ-18 scores between ECHO and Clinic Caregivers. Although not statistically significant ($t(11)=0.93$, $p=0.37$), ECHO Caregivers reported higher satisfaction ($M = 1.62$, $SD = 0.95$) compared to Clinic Caregivers ($M = 1.17$, $SD = 0.86$), with an effect size of Cohen's $d=0.50$ indicating a medium effect.

Another exploratory Welch two-sample t-test compared wait times (time from initial developmental concern to ASD diagnosis) between groups. No significant difference was found (ECHO: $M=33.86$ months, $SD=34.01$; Clinic: $M=46.00$, $SD=61.51$; $t(7)=-0.43$, $p=0.68$), although Clinic Caregivers reported longer wait times (Cohen's $d=0.25$, small effect).

Additional analyses will be presented within the poster.

Conclusions:

This pilot study suggests that families may experience slightly higher satisfaction with ASD diagnostics and somewhat reduced wait times when receiving local care from *ECHO Autism Washington* PCPs. Findings suggest that caregivers were equally satisfied with PCP vs. specialty care diagnostics, and ECHO PCPs may be well-situated to follow-up on care recommendations and provide continued support for families. However, more research is needed given the exploratory nature of analyses.

406.279 Autism Screening in a Large, Diverse Primary Care Setting

A. Wainer¹, E. Wolodiger² and T. Markossian³, (1)Department of Psychiatry and Behavioral Sciences, Rush University Medical Center, Chicago, IL, (2)Psychiatry and Behavioral Sciences, Rush University Medical Center, Chicago, IL, (3)Department of Public Health Sciences, Loyola University Chicago, Chicago, IL

Background: Although universal screening for autism spectrum disorder (ASD) in toddlers is recommended and promotes early evidence-based intervention, barriers to screening and referral persist, particularly for minoritized children. One strategy to address this challenge is to integrate systematic screening into primary care, but there are concerns about adding workload and inefficiencies into the already stressed primary care system, especially for those clinics serving diverse and high needs families. Indeed, much of research examining autism screening in primary care has taken place in clinics serving majority non-minoritized populations. The Building Early Connections (BEC) program, housed at an academic medical center located in the heart of Chicago's historically underserved West Side community, sought to address these concerns by leveraging automated electronic health records (EHR) workflows and decision algorithms to support efficient and equitable autism screening.

Objectives: The goal of this work is to increase access to autism-specific screening and referral, improve tracking and documentation of screening results, and limit the burden on primary care physicians.

Methods: Beginning in 2020, BEC embedded the Survey of Well-Being for Children (SWYC), including the autism-specific screener the Parent's Observation of Social Interaction (POSI), into the EHR across five large primary care clinics in the RUMC system. The EHR pre-visit questionnaire functionality was used to automate screener selection, distribution, and scoring of the tool prior to well-child visits. Screening results and interpretation automatically populated into EHR notes before the visit to enable more focused discussion about findings and next steps with families. Automated clinical decision support ensured proper referral pathways for positive screening. Screening and referral data for children ages 18 to 30 -months were collected and analyzed from the EHR for the 34-month period after project implementation. Visit efficiency was tracked using Press Ganey Top Box scores.

Results: The sample consisted of 7,247 children (85% minoritized backgrounds, 57% public health insurance). Twenty two percent of these children screened positive on the POSI. Of those who screened positive, 26% were immediately referred for internal behavioral health supports and 22% were immediately referred to external Part C Early Intervention services. Press Ganey Top Box scores for moving through your visit increased from 81.6 in 2020 to 86.7 in 2022 which may be used as a proxy of measurement for increasing well child visit efficiency.

Conclusions: BEC successfully automated autism screening and referral pathways into the EHR in a way that did not add burden to the existing workflows and improved efficiency of well-child visits. This work offers an important contribution to the literature by describing implementation of systematic autism screening in primary care clinics serving majority minority populations

406.280 Autism Stigma: How Interactions in Childcare Centers Limit Information Sharing and Delay Autism Screening for Children
A. C. Austin¹, E. Frick², K. Moorcones¹, K. Mann³, G. Perez Liz², A. T. Wieckowski³, D. L. Robins³, E. F. Koku¹ and E. McGhee Hassrick⁴, (1)Drexel University, Philadelphia, PA, (2)A.J. Drexel Autism Institute, Drexel University, Philadelphia, PA, (3)A.J. Drexel Autism Institute, Philadelphia, PA, (4)A.J. Drexel Autism Institute, Drexel University A.J. Drexel Autism Institute, Philadelphia, PA

Background:

Autism screening in toddlers is based on caregiver report of a child's usual behaviors. In addition to parents, early childhood education providers (ECEPs) and directors in childcare settings may be critical informants about children's development and behavior. Stigma theory suggests that interactions about social identities that have been 'discredited' – such as autism – can lead to rejection and social isolation, not only for the person with the discredited identity, but also those close to them, including caregivers and family members. However, little is known about how parents', directors', and ECEPs' beliefs reinforce or attenuate autism stigma, and how these processes might hinder or help early detection of autism.

Objectives:

Use qualitative methods to investigate interactions between ECEPs, directors, and caregivers that may influence autism screening in childcare settings.

Methods:

We conducted semi-structured interviews (n=6 caregivers, 5 ECEPs, 2 directors) and field observations (n=4) within two childcare centers, along with accompanying field notes. Interviews were audio-recorded and transcribed verbatim and a coding scheme was established based on precoding summaries using all transcripts; coders achieved interrater reliability ($\kappa \geq 80\%$). Next, we used qualitative data analysis software (NVIVO) to code transcripts and conducted thematic analysis using the extended case method yielding insights at taxonomic, thematic, and theoretical levels.

Results:

Informational exchanges about developmental delays and autism among caregivers, ECEPs, and directors formed a triad characterized by limited exchanges between ECEPs and caregivers, robust exchanges between ECEPs and directors, and carefully mediated exchanges between directors and caregivers (Figure 1). The ways in which ECEPs carefully managed the flow of information to caregivers, such as actively avoiding the term "autism", implies underlying stigma dynamics. Findings from thematic data analysis also indicated that caregivers exercised agency in how they responded to efforts by ECEPs or directors to investigate their child's potential developmental delays or autism. We identified four types of caregiver responses of varying levels and dimensions of stigma from two groups of caregivers whose children were or were not experiencing behavioral challenges (Table 1). Three types of caregiver responses were identified for children experiencing behavioral challenges, including "Yes, let's talk about autism", "Yes to general services but no to autism diagnosis", and "Refused discussion about autism or services". One type of response was identified for children not experiencing behavioral challenges, including "Yes, open to screening". Stigma levels varied from high to low, and responses that initially exhibit lower perceived stigma also indicate the awareness of the potential stigmatizing impact of autism. This awareness was revealed either by participants taking a supportive role in better understanding autism or by avoiding association by not looking into autism screening or assessment.

Conclusions:

ECEPs have a unique relationship with the caregivers and children that they serve. Caregivers' responses to ECEP's communicating child development concerns vary widely and include apprehension, hopefulness, confusion, and denial. The bidirectional relationship between ECEPs and caregivers can facilitate access to intervention services but is heavily impacted by stigma. Future research should explore this relationship in childcare centers across different geographical locations and populations.

406.281 Policy Priorities of Autism Communities in Europe

S. N. Binte Mohd Ikhsan¹, R. Holt¹, S. Baron-Cohen², C. Allison², A. N. Ruigrok¹, T. Parsons³, J. Man⁴, K. Gibbs⁵ and E. Bullock⁵, (1)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, United Kingdom, (2)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, Cambridgeshire, United Kingdom, (3)Autism Centre of Excellence, Cambridge, Cambridge, United Kingdom, (4)ORS Group, New South Wales, NSW, Australia, (5)University of Cambridge, Cambridge, Cambridge, United Kingdom

Background: Despite increasing rates of autism prevalence and diagnosis worldwide (Zeidan et al., 2021; Russell et al., 2021), autistic people in Europe still experience serious challenges in various aspects of life (Malik-Soni et al., 2022; Vogan et al., 2017). Significant changes are essential in improving autistic people's experiences, meeting their needs and protecting their rights in diverse areas ranging from education (Platos and Pisula, 2019) to social inclusion (Holmes, 2024).

Objectives: We conducted the 10 Points for Change study to understand the priorities and needs of the autism community in Europe. Outcomes from the study will be used to identify the top 10 priority areas for change for autistic people, reported by autistic participants, carers and professionals in autism-related organisations.

Methods: Our study included two phases – a series of focus groups that helped outline topics of importance among autistic people, and an online survey investigating participants' experiences and suggestions for change with regards to these topics. Following three focus groups, each involving 5-6 autistic people and/or parents of autistic people, we shortlisted 19 areas of priority for autistic people (see **Fig. 1**). The online survey, open from November 2020 to February 2024, recruited autistic participants, parents/carers and people working in the field of autism aged 16 or above and residing in European Union (EU) member states and the United Kingdom (UK). Participants were asked to 1) indicate which areas needed to change for autistic people, 2) explain their experiences in the selected areas, 3) describe suggestions for improvements in these areas, and 4) rank all 19 areas of priority in order of importance. Questions 3 and 4 were open-ended.

Results: Overall, 1,706 participants from the EU and the UK completed the survey (mean age 41.68, age SD 13.33, age range 16-97; 27.90% male, 65.59% female; 6.51% other gender; 47.57% autistic individuals, 35.67% parents/carers, 16.76% members of autism-related organisations). Most participants indicated public awareness and understanding of autism as a crucial area for change (83.15%; see **Fig. 2**) followed by education (82.97%), employment (80.40%), mental healthcare (78.58%) and social inclusion/support (73.90%). However, when asked to rank all 19 themes in order of importance for change (1 = most important, 19 = least important, so the mean rank might not necessarily reflect how many people indicated an area as critical for change), education was of highest priority (mean rank 4.95) followed by government funding for autism-specific services (6.11), public awareness and understanding of autism (6.61), employment (6.75) and social inclusion/support (8.44). Further analysis will be performed on participants' responses on experiences and suggestions for change.

Conclusions: It is crucial for us to listen to the experiences of autistic people, carers and professionals in the field of autism and seek their suggestions for improvement to enhance autistic people's quality of life. This study indicated that significant changes are needed to services, social support and awareness, and the findings will be presented to EU policymakers to inform the design of policies that will better serve the autism community in Europe.

406.282 Autism-Related Services As a Predictor of Quality of Life in Autistic Adolescents

A. Mulqueen¹, K. Nelson¹ and A. Jobin^{1,2}, (1)California State University, San Marcos, San Marcos, CA, (2)Child and Adolescent Services Research Center, San Diego, CA

Background: Understanding factors related to autistic adolescents' quality of life is critical to informing clinical practices that effectively improve adolescent subjective well-being, yet most of the research examining autism-related services has focused on changes in autism symptoms (Chezan et al., 2022; Gerber et al., 2011). Further, there is limited research examining quality of life in autistic, gender-diverse samples.

Objectives: The aims of this study were to (1) characterize parent-reported adolescent quality of life (PRA-QoL) and autism-related services from parents of autistic adolescents who are gender-diverse or cisgender, and (2) examine enrollment in autism-related services as a potential predictor of PRA-QoL.

Methods: Data were drawn from a larger-scale survey-based study of parents whose adolescents are autistic, gender-diverse, autistic and gender-diverse, or non-autistic and cisgender. Parents of autistic adolescents who are gender diverse or cisgender ($n = 45$) were included. Measures examined in the secondary analysis included the parent report version of the Peds Quality of Life Inventory Generic Core Scales (PedsQL; Varni, 1998) and descriptive questions for parents regarding autism-services their adolescent was receiving. Analyses included descriptive statistics and regression analyses. In addition to examining autism-related services as a predictor of overall PRA-QoL, descriptive and exploratory analyses characterized these factors and the influence of autism-related services on the PedsQL subscales (e.g., emotional, social, academic, and physical functioning).

Results: Sixty-two percent of parents (62.2%) in this sample reported that their adolescent was receiving autism-related services, with a greater percentage of parents in the cisgender autistic adolescent group reporting services compared to parents of autistic, gender diverse adolescents. There was variability in the type of services being received, with many parents reporting multiple concurrent services. The most reported services included mental health treatment (42.9%), occupational therapy (32.1%), behavioral therapy (32.1%), speech and language therapy (21.4%), academic services (21.4%), and social support services (21.4%). Mean parent reported adolescent quality of life scores on the PedsQL were in the below-average range ($M = 49.36$) with a standard deviation of 12.87. Regression analyses indicated that autism-related services significantly predicted PRA-QoL, $F(1,43) = 7.60$, $R^2 = .15$, $p = .009$, with enrollment in autism-related services being associated with higher PRA-QoL.

Conclusions: Most parents reported that their adolescents were receiving autism-related services and that their youth were engaging with multiple services. Enrollment in autism-related services positively predicted current parent-report adolescent quality of life. These data suggest that community-based services may have a positive impact on quality of life in autistic adolescents. Broadly, this research contributes to the literature on QoL for autistic adolescents, especially in gender-diverse samples, which is understudied. Importantly, data for this study were captured at a single time point, limiting the ability to infer directionality of relationships, and were based on informant report. Important next steps include longitudinal study designs and the collection of self-reported adolescent quality of life.

406.283 Barrier and Facilitator Beliefs about Providing Ongoing, Integrated Care for Autistic Children and Their Families: A Qualitative Exploration of Community Pediatricians' Perspectives in Ontario

S. Park^{1,2}, L. Kanigsberg¹, G. Ferguson¹ and M. Penner³, (1)Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (2)Institute of Medical Science, University of Toronto, Toronto, ON, Canada, (3)Autism Research Centre, Bloorview Research Institute, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada

Background: Autistic children and their families report a high need for ongoing, integrated, and family-centered care to support their needs throughout their care journey. Community healthcare providers (HCPs) are uniquely positioned to fill this service gap due to their early and ongoing connections with families. However, many community HCPs do not feel equipped to provide this care. Project ECHO Autism (Extension for Community Healthcare Outcomes) is an evidence-based program that builds capacity for best-practice autism care in community settings, and offers an opportunity to educate and support community HCPs in providing ongoing integrated care. Understanding community HCPs' barrier and facilitator beliefs about providing ongoing integrated care can help to inform strategies to best support and empower community HCPs, and using a framework rooted in behaviour change such as the Theoretical Domains Framework (TDF) facilitates this process.

Objectives: Identify community pediatricians' barrier and facilitator beliefs about providing ongoing integrated autism care.

Methods: Eight general pediatricians (6 female; 2 male) practicing in seven health regions across Ontario participated in semi-structured focus groups over Zoom. Interview questions were guided by the TDF. Two coders first identified barriers and facilitators to providing ongoing integrated care. Barriers and facilitators were then mapped onto one of the 14 domains of the TDF. For each barrier and facilitator, a belief statement was generated to convey the central underlying belief based on participant responses. Coding and belief statements were checked and discussed between the two coders.

Results: We identified a wide range of barrier and facilitator beliefs about providing ongoing integrated care. Several barriers and facilitators were identified in the *Knowledge, Social and Professional Role, Beliefs about Consequences, and Environmental Context and Influences* domains of the TDF. Some notable barrier beliefs were related to a lack of in-depth knowledge about the service landscape, challenges in setting boundaries and defining responsibilities in community-based practice, the lack of guidance in service navigation, and the confusing and constantly changing nature of the service system. Some beliefs that facilitate the provision of ongoing integrated care included how ECHO Autism provides a source of knowledge for resources and tools for managing co-occurring conditions with autism, understanding one's role in navigating and coordinating services for families, as well as the belief that ongoing care is valuable in a family's care journey.

Conclusions: Our findings suggest there are many possible barrier and facilitator beliefs to address in supporting community HCPs in their ability and confidence to provide ongoing integrated care. For instance, a comprehensive resource with up-to-date information about services in a community could be valuable in helping community HCPs navigate the confusing and changing service landscape. With these results, our team will consult with broader knowledge users, including autistic advocates and families, to develop toolkits supporting ongoing autism care.

406.284 Barriers and Facilitators to Suicide Risk Screening for Autistic Youth

P. E. Cervantes¹, L. A. Palinkas² and S. Horwitz³, (1)Department of Psychiatry, Virginia Commonwealth University, Richmond, VA, (2)Herbert Wertheim School of Public Health and Longevity Science, University of California San Diego, San Diego, CA, (3)Department of Child and Adolescent Psychiatry, NYU Langone Health, New York, NY

Background: Routine suicide risk screening has been recommended across US pediatric care settings. However, the needs of autistic youth are rarely considered, and disparities in the implementation of screening across autistic and non-autistic youth exist. While essential to inform strategies to promote implementation, data are limited on barriers and facilitators to suicide risk screening for autistic youth.

Objectives: We used a mixed method research design to elucidate possible implementation challenges focusing on the perspectives of mental health (MH) clinicians and caregivers, since barriers perceived by these individuals may prevent screening.

Methods: Sixty-five MH clinicians serving 7-to-17-year-olds completed an online survey inquiring about their experience with and attitudes toward suicide risk screening for autistic and non-autistic youth. Forty-five caregivers of autistic youth also completed a survey on their experience with and attitudes toward screening. Twenty percent of respondents were subsequently selected to participate in qualitative interviews. Quantitative data were analyzed descriptively. Factors related to perspectives were further explored using Chi-squared tests, *t*-tests, and non-parametric tests when indicated. Results will be updated and extended to include qualitative findings after data collection ends in January 2025.

Results: Despite reporting having less training and lower confidence when screening autistic compared to non-autistic patients ($p<0.001$), nearly all clinicians (98.2%) reported screening experience with both groups, and screening primarily when suicide symptoms are present or suspected (autistic patients: 75.4%; non-autistic patients: 77.2%). Clinicians were more likely to screen non-autistic compared to autistic patients because suicide risk factors are present ($p=0.046$) and because screening is part of their routine, required by leadership, and encouraged by national guidelines/recommendations (all $p<0.006$). Alternatively, clinicians more strongly agreed that they may not screen autistic compared to non-autistic youth for the following reasons: presenting concern is not suicide-related, discomfort using available screening tools, limited availability of a screening protocol, and limited referrals and resources when risk is identified (all $p<0.009$). Regarding caregiver perspectives, 65.1% reported that their child had been screened previously. Youth who were younger, had not experienced suicide symptoms, and had not received outpatient MH services were less likely to be screened (all $p<0.03$). Most caregivers (63.6%) believed clinicians should screen at every visit. While most reported comfort with screening (81.8%), comfort levels varied by whether the child had a co-occurring psychiatric diagnosis ($p=0.015$). Most common reasons for discomfort were worry their child will become distressed, fixate or hyperfocus on suicide-related topics, and ask questions the caregiver is unable to answer following screening.

Conclusions: Caregivers are largely comfortable with suicide risk screening and support more regular screening than clinicians endorse implementing. The fact that clinicians primarily screen autistic and non-autistic youth when presenting concerns are suicide-related is problematic, as autistic youth with suicide risk often have diverse MH presentations. Therefore, clinician education is warranted. Reported caregiver concerns should also guide community education efforts and future research on iatrogenic risk specific to autism. Organizational (e.g., availability of a screening protocol, leadership support) and systems-level (e.g., lack of referral options) barriers were noted and require urgent attention to promote care advancements.

406.285 Battling the Bottleneck for Autism Spectrum Disorder Diagnosis: Long-Term Follow-up of Primary Care Community Trainees

A. V. Van Hecke¹, K. A. Koth², S. A. Lehman¹, M. Carlson³, L. Jepson⁴, A. Leventhal⁴ and N. L. Johnson⁵, (1)Psychology, Marquette University, Milwaukee, WI, (2)Medical College of Wisconsin, Milwaukee, WI, (3)Education, Marquette University, Milwaukee, WI, (4)Next Step Clinic, Milwaukee, WI, (5)Nursing, Marquette University, Milwaukee, WI

Background: Primary Care Practitioners (PCPs) in the US widely do not diagnose ASD (Martinez et al., 2018). Solely referring families to ASD specialty clinics with long waiting lists results in delayed identification and access to supports and intervention. Efforts to train PCPs in streamlined ASD diagnosis within Primary Care (PC) are growing (Ahlers et al., 2019; Hine et al., 2018, 2020).

Objectives: The study aimed to understand the long-term outcomes of PC trainees in a study replicating the methods of Hine and colleagues. Participants were trained in streamlined ASD diagnosis of “uncomplicated” (i.e., high screening scores and low comorbidities) toddlers and participated in a year-long learning community about ASD, which consisted of topical meetings and case consultations monthly.

Methods: PCP (n=9) trainees were recruited from a mid-sized midwestern city and consented utilizing an Internal Review Board-approved protocol. See Table 1 for demographics. Participants completed online demographics and an adapted version of the Practice Behavior Questionnaire (PBQ: Hine et al., 2021) pre STAT™ (Screening Tool for Autism in Toddlers & Young Children) initial training sessions, and one year later. The adapted PBQ assessed: knowledge of screening/diagnosis of ASD, intention to diagnose ASD, attitudes on appropriateness of PC ASD diagnosis, comfort level with ASD, and number of children evaluated for ASD using the STAT in the primary care setting.

Results: Data presented here refers to pre STAT™ training and at long-term follow-up, one year after STAT training and learning community participation. From pre to follow-up, trainees’ attitudes shifted to rating in-house ASD diagnosis as more appropriate, $t(8) = -2.00, p < .05$, Cohen’s $d = .67$, and rated feeling more comfortable distinguishing ASD from general developmental concerns ($t(8) = -2.53, p < .05$, Cohen’s $d = .84$); and making a formal ASD diagnosis ($t(8) = -8.49, p < .05$, Cohen’s $d = .283$). However, trainees reported feeling *less* comfortable over time connecting families of autistic children to mental health services ($t(8) = 2.31, p < .05$, Cohen’s $d = .77$). Trainees were more likely to endorse attempting an in-house diagnosis vs. referring a patient to a specialist one year after STAT™ training [Wilcoxon rank(9) = $-2.5, p < .05$; 22% likely to attempt in-house diagnosis at pre compared to 88% likely at follow-up]. Rates of in-house ASD diagnoses significantly increased one year following the initial training ($t(8) = -1.941, p < .05$, Cohen’s $d = .65$).

Conclusions: ASD diagnostic training improved ASD attitudes, knowledge, and numbers of children diagnosed with ASD in PC. Trainees were less confident in their ability to connect families of autistic children to mental health services, perhaps reflecting the many discussions had at monthly meetings about the limitations of available mental health services specific to the ASD population in the area. Trainees at an FQHC serving non-English speaking families showed the most increases and fewest barriers to incorporating ASD diagnosis in PC. ASD diagnosis and care within PC, in place of the bottleneck of specialty clinic wait-lists, has potential for improving and streamlining diagnostic flows and awareness of available supports, especially for marginalized populations who experience inequities in access to ASD care.

406.286 Best Practice Guidelines for the Identification and Care of Individuals with Autism: An Evaluation of Clinical Practices and Service Acquisition

R. P. Goin-Kochel^{1,2}, D. Oyvendes³, A. M. Lyons-Warren^{3,4}, C. N. Murali^{3,5}, H. Harris^{1,2}, L. N. Berry^{1,2}, E. Klinepeter^{1,3}, E. Dalton^{1,3}, E. A. Storch¹ and M. Maletic-Savatic^{1,6}. (1)Baylor College of Medicine, Houston, TX, (2)Meyer Center for Developmental Pediatrics & Autism, Texas Children's Hospital, Houston, TX, (3)Texas Children's Hospital, Houston, TX, (4)Pediatrics, Baylor College of Medicine, Houston, TX, (5)Baylor College of Medicine, Houston, TX, (6)Jan and Dan Duncan Neurological Research Institute, Texas Children's Hospital, Houston, TX

Background: Evidence-based practice guidelines support providers in the provision of care that leads to the most favorable outcomes. However, these outcomes are predicated on providers' adherence to such guidelines, as well as patients' follow-through with clinical recommendations. Chart-review studies suggest that not adhering to practice-based guidelines at the points of autism screening and diagnostic evaluation at least partially explains the autism-detection gap (i.e., the time between first concerns about behavior/development and eventual diagnosis). It is possible that inactions/delays at other steps in this process (e.g., referrals for intervention, completion of referrals) further impede care. However, little is known about how often real-world pediatric practice adheres to evidence-based guidelines in the identification and management of autism.

Objectives: To evaluate autism screening, diagnosis, and referral patterns among a pediatric patient cohort in Texas Children's Pediatrics (TCP), one of the largest primary care pediatric healthcare systems in the U.S., as well as these patients' completion of referrals.

Methods: We examined health records of children (aged 16-36 months) seen in any Houston-based TCP practice for either well-child or sick visits between July 1, 2022, through June 30, 2023. From these charts, we quantified 55,565 unique patients and stratified by scores from all available administrations of the *Modified Checklist for Autism in Toddlers* (M-CHAT). We also assessed child age and visit type at each M-CHAT (i.e., well-child vs. sick), and child demographics. Results were analyzed descriptively.

Results: Among the 55,565 children, 51,736 (93.1%) received a first M-CHAT (M age = 20.1 months, $SD = 3.6$), 36,957 (66.5%) received a second M-CHAT (M age = 25.3 months, $SD = 2.7$), and 4,282 (7.7%) received a third M-CHAT (M age = 30.5 months, $SD = 3.3$). 978 (1.9% of 1st M-CHAT), 687 (1.9% of 2nd M-CHAT), and 126 (2.9% of 3rd M-CHAT) scored as high risk for autism (>7), which calls for immediate autism assessment or referral for autism-specialist evaluation. 3,103 (6.0% of 1st M-CHAT), 1,561 (4.2% of 2nd M-CHAT), and 285 (6.7% of 3rd M-CHAT) scored as moderate risk for autism (3-7); these children should receive the M-CHAT follow-up interview to guide referral recommendations. Proportions of M-CHAT completion among eligible children, score distributions, visit types for M-CHATs, and demographic information is in Table 1.

Conclusions: First M-CHAT screening rates were high (93.1%) and most occurred during well-child visits at an average age of 20.1 months. These results align with guideline recommendations to screen at the 18-month check-up. However, there was a 28% decrease in the administration of a second M-CHAT (66.5%). Although not recommended as part of screening guidelines, some of these children received a third M-CHAT, which may have been driven by clinician/parent concerns about behavior/development, as 50% more children scored at high risk (>7) on a third M-CHAT compared to first and second M-CHATs. Next-step assessments will characterize referral practices associated with M-CHAT scores, caregiver completion of those referrals, and autism-diagnostic status to identify process gaps for subsequent intervention.

406.288 Bridging the Gap in Dentistry: Harnessing Behavioral Health to Improve Oral Health Outcomes for Autistic Youth

S. N. Richardson¹, R. Bradley¹, E. Shah², A. P. Houck³, L. B. Quetsch⁴, D. W. McNeil⁵, C. B. McNeil⁶, K. Divaris⁵ and C. Lilly⁶. (1)University of Arkansas, Fayetteville, AR, (2)The University of Arkansas, Fayetteville, AR, (3)Stony Brook University, Stony Brook, NY, (4)University of Florida, Gainesville, FL, (5)University of North Carolina, Chapel Hill, NC, (6)West Virginia University, Morgantown, WV

Background: Autistic children have unique dental healthcare needs. Oral complications stemming from poor tongue and motor coordination, high sensitivity to toothpaste and flossing, and sensory reactions to fluoride, amalgam, and other dental products are common. Autistic youth are also prone to dental-related emotional (e.g., dental fear and anxiety) and behavioral (e.g., noncompliance, disruptive behavior, avoidance) symptoms. There is also a substantial gap in pediatric and autism-focused training for dental providers, and caregivers report significant challenges in finding dental practitioners who treat autistic children. Taken together, autistic youth and their families face barriers to accessing timely, equitable oral healthcare. Unfortunately, delayed oral healthcare may increase the likelihood of distressing and invasive dental procedures for autistic children. Child behavioral symptoms combined with limited pediatric training among providers may result in a pattern of negative dental interactions, which impacts child and family engagement in oral healthcare more broadly.

Objectives: This project will utilize extant literature to conceptualize child, family, and provider factors implicated in oral healthcare disparities among autistic youth and their families. We will present a novel intervention project funded by the National Institute of Dental and Craniofacial Research/National Institutes of Health, which aims to enhance dental providers' non-invasive behavioral strategies by teaching positive skills that target child compliance and comfort during visits.

Methods: A systematic review of peer-reviewed research was conducted to conceptualize factors implicated in the oral healthcare experiences of autistic children. In response to the gap in training for dental providers, a team of psychologists and dental providers collaborated to develop Dental-Child Interaction Training (DCIT), a research-informed training program drawing on principles from Parent-Child Interaction Therapy. Dental providers (N = 10) in a southern state participated in a pilot training focused on child behavioral health principles. Workshop outcome measures included skills assessments, provider satisfaction with the training, qualitative feedback, and the Usage Rating Profile-Intervention. **Results:** Findings from the literature review underscored a complex interaction of child, family, and provider factors implicated in oral healthcare treatment disparities among autistic youth. The findings also supported the utility of behavioral interventions among general pediatric healthcare providers and the extension of applied trainings to dental practitioners. Initial results from the DCIT training workshop reflected improvements in skills knowledge and utilization among participating dental providers from the pre-training ($M = 62$) to post-training ($M = 88$) knowledge assessment. Providers also reported high rates of satisfaction with the training.

Conclusions: There is a critical need for specialized training among dental providers to address the unique needs of autistic children. The pilot DCIT workshop demonstrated that a one-day training can improve provider skills. Results also showed acceptability and feasibility among providers, suggesting that wider implementation could enhance the quality of dental care for autistic youth. In the coming years, DCIT will be expanding trainings to reduce oral health disparities and improve dental experiences for youth and families. Future efforts will adapt DCIT to specifically address dental provider skills in working with autistic youth to reduce distress, increase comfort, and promote long-term positive dental practices.

406.289 Bringing Research to the People: Initial Feasibility, Acceptability, and Reliability of Cognitive, Molecular, and Neurophysiological Testing Completed in the Home of Individuals with Fragile X Syndrome

L. A. De Stefano¹, W. S. McKinney², A. Corsmeier¹, A. Dapore¹, C. Gross¹, C. A. Erickson³ and L. M. Schmitt¹, (1)Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (2)Cincinnati Children's Hospital Medicine Center, Cincinnati, OH, (3)Psychiatry, Cincinnati Children's Hospital Medical Center, Cincinnati, OH

Background: Fragile X syndrome (FXS) is the leading single-gene cause of intellectual disability and autism spectrum disorders. Many studies are underway to understand phenotypic variability and treatment response in FXS, but these studies are generally limited to individuals who can complete comprehensive in-person research batteries at major data collection sites such as hospitals. Numerous factors, including those associated with disadvantaged backgrounds (e.g. low socioeconomic status, rurality) and those directly related to the FXS phenotype (e.g., agoraphobia, irritability) prevent individuals from participating in traditional research visits, which limits the generalizability of findings.

Objectives: We aimed to assess the feasibility, acceptability, and reliability of *in-home completion* of a battery of measures typically collected in the laboratory.

Methods: Thus far, we have completed 14 home visits within a 100-mile range of our laboratory. Participants with FXS (13 males, 1 female; 14-65 years) completed IQ testing, NIH Cognitive Toolbox, 128-channel resting state electrophysiology (EEG), and venipuncture blood draw to quantify fragile X messenger ribonucleoprotein (FMRP). Participants were asked to complete a follow-up survey to establish acceptability of data collection. To test reliability of data collection, we compared home visit data to data collected in the laboratory within the past 2 years.

Results: We found high feasibility and acceptability of home visits, with all participant families providing positive feedback via follow-up survey. Test-retest reliability was high for IQ testing (nonverbal $r = .93$, verbal $r = .87$, Deviation IQ $r = .79$), FMRP assay ($r = .94$), and for absolute EEG band power (all $rs > .9$). Test-retest was moderate for selected NIH Toolbox measures ($rs .46-.70$).

Conclusions: With high feasibility, acceptability, and data reliability, our evidence suggests that home research visits provide a promising alternative to traditional laboratory visits. Following our successful pilot, we are now in the process of determining the extent to which home research visits can be (1) included as part of clinical trials, to reduce participant burden; (2) used to increase phenotypic, racial, ethnic, and socioeconomic diversity within research samples; (3) simplified by the using a travel-friendly EEG amplifier.

406.290 Building Clinical Skills in Neuroaffirming Care through Simulation

M. Olana^{1,2}, A. Ip^{1,3,4}, A. Kawamura⁵, K. Boerner⁶, C. Chadwick¹, K. Szeto¹, C. Pawliuk^{2,7}, L. Prichard-Mandl¹, C. Benson-Mandl¹, K. Blain³ and F. Al-Shakarji¹, (1)BC Children's Hospital, Vancouver, BC, Canada, (2)University of British Columbia, Vancouver, BC, Canada, (3)BC Autism Assessment Network, Vancouver, BC, Canada, (4)Department of Pediatrics, University of British Columbia, Vancouver, BC, Canada, (5)University of Toronto, Toronto, ON, Canada, (6)BC Children's Hospital; BC Children's Hospital Research Institute, Vancouver, BC, Canada, (7)BC Children's Hospital, Sunny Hill Health Centre, Vancouver, BC, Canada

Background: The manner a professional shares an autism diagnosis with a family can have an important and long-lasting impact on the family's overall experience of the diagnostic process and perception of autism. Neuroaffirming care focuses on understanding and supporting an individual's strengths and challenges and promoting their well-being and inclusion in society. What neuroaffirming care looks like will vary for every individual and family over time and relies on the clinician being able to integrate and adapt their expertise to different individuals' experiences, worldviews, and perspectives. Simulation-based learning models as a teaching tool has the potential to promote adaptive expertise in neuroaffirming care in experienced clinicians through immersive scenarios where clinicians can learn new skills, make mistakes, and reflect.

Objectives:

- Explore simulation using standardized patients to promote applying adaptive expertise to develop skills in neurodiversity affirming care within the specific context of sharing an autism diagnosis.
- Explore how a simulation-based learning model can promote the use of neurodiversity affirming language and behaviours in experienced clinicians.

Methods: We will use an exploratory case study design to assess participants' observed and perceived learnings from the simulation. Participants will be recruited from the BC Autism Assessment Network and include community pediatricians, psychiatrists, psychologists, nurse practitioners, and speech and language pathologists. Participating clinicians will go through three different case scenarios and share an autism diagnosis with standardized patient caregivers of a child or youth over a videoconference platform. These cases scenarios and learning objectives were created based on priorities in neuroaffirming care identified from literature and our community partners (an autistic youth, a neurodivergent adult, parents of autistic children who have had different experiences with the autism diagnostic process, and a community pediatrician). De-identified field notes, simulation session transcripts, and transcripts from participant's pre- and post-simulation interviews will be analyzed using a reflexive thematic analysis to explore the participants' observed and perceived learning from the simulation.

Results: The simulation is expected to run November 2024 and results will be analyzed by spring 2025. Discussions with community partners on their experiences with receiving an autism diagnosis resulted in preliminary themes pertaining to clinician communication and interpersonal skills including: Highlighting both the child's strengths and areas of challenges, and avoiding pathologizing language, the importance of tone and being empathetic in listening and responding to parents' concerns, exploring parents' understanding and acceptance of the autism diagnosis, and counselling parents on next steps.

Conclusions: It is critical that experienced clinicians also have opportunities to continue building their skills and confidence so that they can provide neuroaffirming care that is supportive of autistic individuals and their family at a critical time on a family's journey. The results of this project can have important impacts both on how we collaborate with families and on continuing professional education. Additionally, with community partners as co-investigators, we ensure that the goals of the neurodivergent community are at the forefront. Sharing decision-making power in research with community members helps foster mutual trust, transparency, and translation of findings into existing services.

406.291 Caregiver-Perceived Barriers to Care: Experiences of Emotion Dysregulation and Service Needs in Autistic Children

M. J. Crown¹, K. B. Beck², E. Rutenberg³, C. M. Conner², J. Chang⁴ and C. A. Mazefsky², (1)Department of Occupational Therapy, Boston University, Boston, MA, (2)Department of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, PA, (3)University of Pittsburgh, Pittsburgh, PA, (4)University of Pittsburgh School of Medicine, Pittsburgh, PA

Background: Emotion dysregulation, difficulty monitoring and modifying emotional reactivity and sustained negative emotion, is highly prevalent among autistic people. Autistic youth are 4-7 times more likely to experience clinically elevated emotion dysregulation compared to the general population. Further, it is associated with higher rates of crisis services, psychiatric hospitalization, and aggression. However, few studies have explored caregiver perceptions of the challenges and barriers getting support for their child's emotion dysregulation.

Objectives: The objective of this study was to identify the needs and barriers of receiving services for emotion dysregulation in autistic youth and young adults, from the perspective of caregivers.

Methods: Sixteen caregivers of autistic youth and young adults (aged 7-31 yrs) completed a 60-minute semi-structured interview. Participants were predominantly female (75%) and white (75%). Relationships to the autistic child included biological parents (81%), foster parents (13%), and family member acting as the primary caregiver (6%). Six participants (37.5%) had children with high support needs due to co-occurring intellectual disability, limited to no speaking ability, and/or several behavioral concerns or aggression. Participants were asked to share recent stories of their child's emotion dysregulation and experiences seeking care for their needs. Interviews were transcribed and a grounded theory analytic approach was used for coding and thematic analyses. Four coders, including one autistic adult, generated the initial codebook using a consensus approach. For this analysis, coders focused on discussions of service experiences and needs related to emotion dysregulation, and the analysis was grouped into themes and subthemes. Autistic adults were involved in all aspects of this project.

Results: When asked to describe their child's emotion dysregulation, caregivers indicated that sensory sensitivities and unexpected changes (44%) were most common contributors to dysregulation in healthcare and home environments. Exclusionary discipline from school personnel (e.g. involvement of school police, suspension, dismissal) and bullying from peers were the most reported causes to dysregulation in schools, with half of the sample noting this led to verbal and/or physical aggression. When asked about emotion dysregulation services, caregivers overwhelmingly described a glaring unmet need; "my child has nothing" was a quote that epitomized this theme. Caregivers expressed that services across all settings were a poor fit for their child's needs. Further, caregivers of children with high support needs uniformly shared that their child was excluded from mental health and community-based services. Caregivers (56%) expressed fear for their child's future, specifically limited access to care and safety of their child and others during dysregulation.

Conclusions: Autistic people are often excluded from services and when provided access, caregivers note them to be an inadequate fit. Caregivers, as a result, experience significant stress from their child's dysregulation that persists over time. Creating environments (i.e., classrooms, healthcare) that are inclusive and sensory affirming may help reduce the frequency of dysregulation which may, in turn, alleviate caregiver-related concerns for both them and their child's well-being. Future work should consider partnering with autistic people, parents, and providers to co-design services that are effective for emotion dysregulation with attention to common causes of dysregulation in various settings.

406.292 Caregivers' Experience with Family-Centered Service Delivery across Services in Their Community for Individuals with Autism and Other Developmental Disabilities

H. N. Zeri^{1,2}, J. Ware² and W. S. Neo¹, (1)Psychological Sciences, Purdue University, West Lafayette, IN, (2)John Martinson Honors College, Purdue University, West Lafayette, IN

Background: Family-centered care is a service approach that emphasizes the integral role families play in their child's service provision. This approach has been shown to promote positive service outcomes, improve overall satisfaction, and enhance quality of life. The Measure of Processes of Care (MPOC-20) is a validated and widely used measure that examines caregivers' perceptions of service delivery by assessing five core aspects of family-centered care. Furthermore, prior research has indicated that families of individuals with autism and developmental disabilities highly value and would benefit from family-centered care, though it may not be consistently implemented across service settings. Despite the global use of the MPOC-20 and the importance of family-centered care, to our knowledge, no studies have evaluated family-centered care in day habilitation (DH) services, a Medicaid-funded Home and Community-Based Service (HCBS) that serves over 519,000 individuals in the U.S.

Objectives: Our study aimed to examine how "Providing Specific Information about the Child" (Factor 3) and "Respectful and Supportive Care" (Factor 5) differ across DH and four other commonly used service categories (In-School Therapeutic - IT, Community-Based Therapeutic - CT, Professional Healthcare - PH, Community Supports - CS). We also compared how all five aspects of family-centered care varied within DH services, including "Enabling and Partnership" (Factor 1), "Providing General Information" (Factor 2), and "Coordinated and Comprehensive Care" (Factor 4) in addition to Factors 3 and 5.

Methods: Forty-three caregivers (90.7% female) of individuals diagnosed with autism (58.1%) and/or intellectual disability (55.9%) aged 6-28 years ($M = 16.0$, $SD = 5.8$; 65.1% male) who accessed DH participated in the study. Caregivers completed the full MPOC-20 for DH services and an abbreviated MPOC-20 (Factors 3 and 5 only) for IT, CT, PH, and CS services. We used separate one-way ANOVAs to test whether Factor 3 and Factor 5 scores differ across service categories and conducted post-hoc Tukey tests to probe significant effects. We also used paired t -tests to compare all pairs of factor scores within the DH service category.

Results: Factor 3 score did not vary across service categories ($F = 0.78$, $p = .544$), while Factor 5 score was significantly different across service categories ($F = 5.38$, $p < .001$). Post-hoc comparisons revealed that this omnibus effect for Factor 5 was driven by DH ($p < .001$) and PH ($p = .007$) each having higher scores than IT. Within DH, scores were significantly different for all pairs of factor scores ($ps < .003$), except for the pairs of Factors 1 and 4 ($p = .170$) and Factors 2 and 3 ($p = .351$).

Conclusions: Our findings suggest that while services may not differ in information provision, they vary in providing respectful and supportive care. Specifically, DH and PH services excel in providing respectful and supportive care when compared to IT services. Additionally, DH services may also be especially effective in facilitating caregiver-provider partnership opportunities, while being less skilled in providing general or diagnostic-related information. This study underscores the need for further research to examine inter-service differences in providing family-centered care.

406.293 Characterizing Referral Patterns to a Multidisciplinary Autism Clinic

R. K. Greene, H. Franklin and K. Atkins, Oregon Health & Science University, Portland, OR

Background: Recent increases in prevalence estimates of autism spectrum disorder (ASD) are thought to be due to increased awareness of ASD clinical presentations. Updated prevalence estimates (Maenner et al., 2023) suggest some racial disparities in identification have waned (e.g., more timely identification of Hispanic and Asian/Pacific Islander children and females) while others persist (e.g., Black children are significantly more likely to be identified if they have co-occurring intellectual disability (ID) or global developmental delay (GDD)). However, increased awareness contributes to a significant increase in demand for diagnostic series, stretching waitlists nationally and necessitating critical examination of clinical practices.

Objectives: Examine patterns of patients referred to a major metropolitan multidisciplinary Autism Diagnostic Clinic.

Methods: This sample included 8,867 patients aged 0 to 18 years who were referred to an interdisciplinary, outpatient autism diagnostic clinic between January 2018 and December 2023. Patient demographic information and diagnostic impressions were extracted from the electronic medical record using an automated process. Chi-square tests assessed group differences across demographic variables. Multinomial logistic regression was used to model age at referral, categorized as 0-4, 5-11, and 12+ years. Predictors included individual, healthcare, and language demographics.

Results: Across all age groups (0-4, 5-11, and 12+), age at referral showed significant differences across various demographic characteristics based on bivariate analyses. Individuals assigned male at birth were referred at younger ages than females ($p < 0.01$). A higher proportion of females presented for evaluation in the 12-18 age (38.7% female) range compared to the younger cohorts (% female: 0-4 years – 25.9%; 5-11 years – 25.3%; $p < 0.01$). Across patients requiring an interpreter, those identifying as white, non-Hispanic were referred later than any other racial or ethnic group.

Multinomial logistic regression analyses (Table 2) revealed significant predictors of age at referral. Children with GDD/ID had lower odds of being referred in older age groups, with those aged 5-11 years having 66% lower odds compared to the 0-4 group, and those aged 12+ having 71% lower odds. Public insurance was associated with 31% lower odds of referral at age 12+ compared to private insurance. Hispanic children had lower odds relative to White Non-Hispanic children of being referred in the older age groups, with odds reduced by 36% for the 5-11 age group and 50% for the 12+ group. Male children had 60% lower odds of being referred at age 12+ compared to females.

Conclusions: These findings suggest children with GDD/ID and males in general continue to be referred earlier. Hispanic youth are referred less often than white peers once they reach 5 years and older, and children with public health insurance and males are less commonly referred after 11 years old. Patients requiring interpreter services for certain primary languages may be referred later than others.

406.294 Characterizing Team- and Implementation-Related Factors in a Leader-Focused Implementation Strategy for Autism Interventions in Children's School and Mental Health Services

E. Rangel¹, A. Jobin², A. C. Stahmer³, A. S. Lau⁴ and L. Brookman-Frazee⁵, (1)Child and Adolescent Services Research Center, San Diego, CA, (2)California State University, San Marcos, San Marcos, CA, (3)UC Davis MIND Institute, University of California at Davis MIND Institute, Sacramento, CA, (4)Psychology, University of California Los Angeles, Los Angeles, CA, (5)Psychiatry, University of California, San Diego, La Jolla, CA

Background: The TEAMS trials consisted of two linked randomized Hybrid Type 3 implementation trials that tested implementation strategies paired with autism evidence-based interventions (EBI) in children's mental health agencies and schools (Brookman-Frazee & Stahmer, 2019). The TEAMS Leadership Institute (TLI) is a leader-focused implementation strategy targeting implementation leadership and climate to facilitate autism EBI implementation. TLI included a 360-assessment of implementation leadership and climate, a pre-implementation workshop with leaders, and data-informed development of an implementation climate and leadership plan. Leaders from each program/district engaged in regular coaching calls to plan implementation and monitor implementation. Programs/districts randomized to receive TLI demonstrated significantly better provider fidelity and child outcomes compared to programs/districts that did not receive TLI.

Objectives: The current study uses mixed qualitative and quantitative analyses to (1) characterize which strategies leaders identified to create a climate for EBI implementation and (2) examine leadership team composition, processes, and functioning over 6 months of training and implementation.

Methods: Data were drawn from implementation leadership teams from 36 programs/districts randomized to the TLI condition. Qualitative Content Analysis (Elo & Kyngäs, 2008; Gale et al., 2013) was used to identify the forms (goals and actions) and functions (implementation climate or leadership subdomains) of the implementation plans. Twenty audio-recorded coaching calls will be transcribed and thematically coded using deductive qualitative analysis (Bingham et al., 2023) to further identify implementation support goals and strategies utilized by leaders. Team-related factors are being characterized according to established models of team effectiveness (e.g., Mathieu et al 2020).

Results: Across the 36 programs participating, there were 53 implementation plans. Teams were comprised of an average of 2.3 leaders, and they participated in an average of 8.8 coaching calls (range 3-15) over 6 months. Most plans (98%, $n=52$) included at least one goal focused on functions within the implementation climate domain. The most common climate functions were "Recognition" ($n=52$), "Rewards" ($n=36$), and "Focus" ($n=33$). Common forms included 1) staff-informed and tangible rewards, 2) public recognition of staff efforts, and 3) public endorsement of EBI. Plans also included leadership goals (58%, $n=31$). The most common leadership functions were "Proactive" ($n=28$) and "Knowledgeable" ($n=21$).

Common forms included 1) proactively problem solving and 2) gaining hands-on experience in EBI. Team composition varied by program/district. Further data examining team-related factors and the themes that arose from the TLI coaching call themes will be discussed.

Conclusions: Leaders developed implementation plans prioritizing rewards, recognition, and focus while emphasizing proactive and knowledgeable leadership. These findings highlight key strategies for enhancing the implementation of autism interventions across school and mental health settings and within leader teams supporting implementation, suggesting areas for future research and practice.

406.295 Clinical Profile of School-Aged Students with Autism Spectrum Condition in the Chilean Public Education System: A Case-Control Study

J. A. Pereira^{1,2,3}, C. G. Tapia³, P. A. Munizaga⁴, V. Meyer³, B. C. García³, P. I. Medina³, D. Torres³ and V. A. Monardes³, (1)Psychiatry, Pontificia Universidad Católica de Chile, Santiago, Chile, (2)Instituto para el Neurodesarrollo y Bienestar, Santiago, RM, Chile, (3)Corporación Municipal de Peñalolén, Santiago, RM, Chile, (4)Corporación Municipal Peñalolén, Santiago, RM, Chile

Background: Specialized evaluations of children and adolescents suspected of having Autism (ASC) are typically carried out by public or private health programs and are often focused on the preschool stage.

Objectives: In order to develop comprehensive specialized support programs for individuals with a diagnosis or suspected diagnosis of autism at school age, it is essential to delve deeper into their clinical description.

Methods: This study presents a descriptive analysis of the clinical profile of students referred for specialized neurodevelopmental evaluations from 15 regular schools (8,040 students) in a representative district of Greater Santiago, Chile. The clinical profile of those with a diagnosis of autism (AG) versus those without a diagnosis of autism (CG) was compared.

Results: AG is composed of 53 students (17% female; M: 11.57, SD: 3.15; R: 6 to 18 yo) while 134 students compose the CG group (26.87% female; M: 12.06, SD: 3.46; R: 5 to 20 yo). AG showed a higher comorbidity burden (no comorbidity: 15.6%; 1 comorbidity: 33.3%; 2 or 3 developmental comorbidities: 51.0%) compared to CG (no comorbidity: 37.7%; 1 comorbidity: 35.2%; 2 or 3 developmental comorbidities: 27.0%), $\chi^2(2)=14.45$, $p=0.0007$. The most frequent comorbid diagnosis in the AG was ADHD (66%), followed by borderline intellectual functioning (BIF) (28%), mild Intellectual Disability (Mild ID) (20%), Developmental Language Disorder (DLD) (9%), and Mod ID (7%). The CG was mainly characterized by ADHD (91%), followed by Mild ID (20%), BIF (17%), Specific Learning Disability (SLD) (17%), and DLD (5%). There was no association between autism diagnosis and the presence of mental health diagnoses (i.e., anxiety disorders or mood disorders) (AG: 9%; CG: 11%), $\chi^2(1)=0.2222$, $p=0.64$. An association was found between school delay and ASC, $\chi^2(2)=7.307$, $p=0.0259$, as well as between transfers from regular to special schools and autism diagnosis, $\chi^2(3)=10.97$, $p=0.0119$. However, this association was not due to a link between autism and global cognitive impairment (i.e., Mild ID, Mod ID or BIF), $\chi^2(1)=0.05046$, $p=0.8223$.

Conclusions: The comparison between these neurodivergent groups highlights that school-aged students with an ASC show a greater need for support compared to other neurodivergent groups within the public education system in Chile, and likely in other Latin American and international contexts. Although, no differences in mental health burden between the groups were observed, there appears to be underreporting of challenges in this area, possibly due to normalization of the emotional distress and behavioral expressions in this population. On the other hand, the reason why the female gender is underrepresented in referrals for evaluation will be studied and poses challenges for gender-related equal opportunities. While larger prospective studies are needed, this study provides insight that justifies allocating and organizing resources for specialized evaluation and support for students with autism diagnoses in the school setting.

406.297 Consumer Perspectives on Applied Behavior Analysis Service Delivery

N. M. Badgett^a, B. Contreras^a, L. Boyd^b and M. Čolić^c, (1)Special Education, University of Utah, Salt Lake City, UT, (2)Psychology, University of Nevada Reno, Reno, NV, (3)University of North Florida, Jacksonville, FL, (4)Department of Special Education, University of Hawaii at Mānoa, Honolulu, HI

Background: Applied Behavior Analysis (ABA) is the application of behavioral principles to affect meaningful behavior change and is widely recommended for autism intervention. However, concerns have been raised by autistic self-advocates about potential coercion, lack of assent from autistic children, and possible long-term mental health effects (e.g., PTSD; Kupferstein, 2018). A mainstay of ABA research and practice is social validity, or formal evaluation by stakeholders (i.e., consumers, clients) of intervention goals, procedures, and outcomes (Wolf, 1978). While autistic children and adolescents are the most common direct recipients of ABA services, their representation in social validity data is limited (Huntington et al., 2023). The field has yet to consider criticism from autistic self-advocates as an important source of social validity data that can guide improvement of the implementation of ABA.

Objectives: To explore the perspectives and experiences of autistic adults, behavior analytic professionals, and parents and caregivers of individuals with autism in relation to ABA service delivery.

Methods: This participatory research is being completed by a team consisting of behavior analysts, autistic adults, and parents of individuals with autism. Data presented in this poster include findings from three parallel surveys completed by autistic adults, behavior analysts, and parents and caregivers of individuals with autism. Surveys data collection will be completed in November of 2024, and preliminary findings are included in this submission. Data analysis will consider descriptive and correlational outcomes of survey data to identify consumer perspectives on service delivery as well as predictors of positive or negative perspectives or experiences (e.g., are positive experiences more likely when an individual has high support needs autism?).

Results: The current preliminary dataset includes autistic adults ($N = 13$), Caregivers ($N = 35$) and Behavior Analysts ($N = 57$). Data varied across participants regarding their opinions about ABA. Among autistic individuals, opinions were more divided; however, the majority of autistic adults endorsed the 'yes' and 'sometimes' options for ABA's positive effects. Caregivers also had mixed opinions, though most expressed positive sentiments about the effectiveness of ABA. Behavior analysts generally had strong positive views about the impact of ABA services. Overall, participants expressed positive opinions about the work ethics of behavior analysts, as reflected in the endorsement of 'yes' and 'sometimes' responses. However, some autistic adults and caregivers selected 'no' to all statements, indicating that not all participants believe behavior analysts consistently work to support autistic individuals and their families ethically.

Conclusions: While perspectives on ABA vary across consumer groups, negative perspectives are more common among autistic adults. As autistic people are the primary consumers of ABA, their feedback should be incorporated to improve services. Additionally, as parents and caregivers' perspectives may represent the extent to which ABA was meaningful for individuals in their care who have high support needs, it is important that their experiences be included in critical feedback of ABA service delivery to improve outcomes and social validity of practices.

406.298 Leveraging a Modern Technology Platform to Build a Pathway to Equitable Care for Autism

T. Odegard^a, A. M. Estes^a and J. Ide^b, (1)Data Science and Software Development, Rprime, AS360, NavigatorSRVS, Inc., Seattle, WA, (2)Speech and Hearing Sciences, UW Autism Center, Seattle, WA, (3)University of Washington Autism Center Institute on Human Development and Disability, University of Washington Autism Center, Seattle, WA

Background: It is now possible to diagnose autism as soon as the behavioral characteristics of autism emerge, usually in the second year of life, and to provide children with individualized teaching so they can develop the skills they need to communicate and have a high quality of life. However, families and children often face significant barriers to timely diagnosis, effective intervention and accessing the support they need. A critical step to ensuring equitable access to care is to identify the geographic distribution of autism resources. Mapping resources is a critical step toward directing service expansion efforts where they are needed most.

Objectives: The goal of this study was to provide a proof-of-principle approach to determining autism resource distribution across Washington state using a caregiver-facing resource navigation database.

Methods: This project utilizes data from a centralized, online database, AS360.org, with searchable clinical resources, educational materials, community forums, and age-based checklists. It codes the location, type, and other characteristics of clinical resources that can be input directly by community service providers. The number of resources increases as providers add information. AS360 is architected on Web2 HTML 5 and React-based technology enabling cross platform (desktop, tablet, mobile) user-experience, enterprise-grade security, and protected user access. It implements dynamic CMS database technology tied to CRM technology to manage users, community, access and content. Heat mapping and geographic analysis for proximity of people and resources was applied to understand resource scarcity and abundance alongside demand. The current results (Figures 1 & 2) are based on 500+ locations across Washington state.

Results: The heat map (Figure 1) illustrates the density of clinical resources across Washington state. This platform is elastic enabling for the data to drive the boundaries geographically and attribute wise. This means as locations from other countries, states, or cities arrive in the engine, the analytics automatically widen to cover new regions at rapid scale. The point map (Figure 2) illustrates a second way that users can visualize resources geographically.

Conclusions: This project demonstrates the utility of employing an autism resource database built with current technology to identify the geographical distribution of clinical resources. At this time, AS360.org can be used by groups in any city, state, or country to develop a resource database for their community. This information can support caregivers, providers, and policy makers with real-time information that is needed to provide autistic children with the best possible support and quality of life. Future research by policy makers and business owners can use AS360.org to determine areas of clinical resource scarcity through Gap Analysis, a method typically applied to commercial real estate that can be used to understand where clinical resources are lacking and where there may be future demand. Through Gap Analysis, AS360 has the potential to identify underserved populations so resources can be deployed for social benefit.

406.299 Cultural Adaptation Practices in Autism Services: A Mixed Methods Study

A. D. Duenas¹ and L. R. Gomez², (1)Counseling, Educational Psychology, and Special Education, SDSU, East Lansing, PA, (2)University of Florida, Gainesville, FL

Background:

The Applied Behavior Analysis (ABA) therapy system faces multiple ethical challenges that directly impact marginalized communities. Most ABA-based interventions were not developed for and with diverse populations in mind (Bak et al., 2023; Steinbrenner et al., 2021; West et al., 2019), cultural adaptation methods and models are required to uphold the values of cultural humility and responsiveness. Culturally adapted interventions for Latine families of autistic children improve parents' participation and engagement in interventions (Buzhardt et al., 2016; Chlebowski et al., 2018; Magaña et al., 2017). Research highlights the need for cultural adaptations in ABA-based services, including both surface and deep structure adaptations (Sivaraman & Fahmie, 2020). Previous survey studies seeking to understand the perspectives of ABA practitioners on culturally responsive practice have found that practitioners agree on the need for and importance of cultural responsiveness trainings. However, although they report having limited training in this area, they feel highly skilled at working with individuals from diverse backgrounds (Beaulieu et al., 2022).

Objectives:

The current mixed methods study sought to understand the knowledge, use, barriers, and facilitators to cultural adaptation practices of ABA across social and cultural structures (ABA field, agencies, communities, and individuals); considering the eight EVF dimensions of cultural adaptation and the cultural competence continuum (Cross, 1989).

Methods:

An explanatory sequential mixed methods approach (QUANT – QUAL) was used to answer research questions, where quantitative data were collected via survey methods, followed by qualitative data to deepen our understanding of cultural adaptation knowledge and practice across four different groups (i.e., clinical directors, BCBAs, and RBTs.). The qualitative data involved a subset of survey respondents using semi structured interviews. Mixed methods were required in this case, as we were interested in understanding barriers and facilitators to cultural adaptation in practice that required qualitative data methods.

Results:

We received 667 unique responses to the survey, 200 were from BCBAs, 219 were from BCaBAs, 49 were BCBA-D's, and 199 Registered Behavior Technicians. Twenty seven percent of respondents were working directly with clients (behavior technicians), while 35% were in a supervisory role, and 38% were clinical directors. The majority of respondents identified as male (58% n=386), female (40%, n=267) and 2% (n=14) as non-binary. Overall, in regards to cultural adaptation practices related to language, content, methods, process, people and contexts, and goals respondents reported that they were somewhat knowledgeable (M=2.06; SD=.89) and that they somewhat frequently used these interventions in their practice (M=2.1; SD=.95). Thematic analysis revealed the organizational and individual level barriers and facilitators to cultural adaptation in practice. Barriers included attitudinal, resource, policy, and cultural mismatch of ABA-based strategies. Similarly, facilitators included attitudes and values at the organizational and individual level, resources and knowledge, and policies.

Conclusions:

Individual and organizational level factors must be considered to improve culture-match of ABA based interventions within the existing service system.

406.300 Cultural Adaptation and Application of Acceptance and Commitment Therapy for Parents of Children with Autism

C. Wang¹ and **Y. Liang²**, (1)Department of Social Psychology, School of Sociology; Autism Research Center, Nankai University, Tianjin, Tianjin, China, (2)Nankai University, tianjin, tianjin, China

Background: **Acceptance and Commitment Therapy (ACT)** is a mindfulness-based behavioral intervention widely used to enhance psychological flexibility and improve mental health.

Objectives: This study aims to investigate the effectiveness of ACT for parents of children with autism.

Methods: Using the translated version of the ACT intervention manual and guided by the Ecological Validity Model (EVM), Study 1 involved focus groups and personal interviews to gather data, which was analyzed through thematic analysis. Based on the findings, cultural adaptations were made to the intervention manual, with revisions in four key dimensions: language, metaphor, content, and methodology. Study 2 tested the effectiveness of the revised intervention program through a randomized controlled trial involving 43 mothers of children with autism—21 in the intervention group ($M_{age}=43.05$, $SD_{age}=8.692$) and 22 in the control group ($M_{age}=39.09$, $SD_{age}=5.335$). The intervention group received the revised program over 7 weeks, with one 90-minute session per week, while the control group remained on a waiting list for the intervention. Pre- and post-intervention measurements were taken using the Acceptance and Commitment Comprehensive Assessment Questionnaire, the Depression-Anxiety-Stress Scale, and the Positive and Negative Affect Schedule. Participants also completed an evaluation questionnaire at the end of the group sessions.

Results: The results showed significant differences between the intervention and control groups in terms of psychological flexibility, depression, and positive affect. Mothers in the intervention group experienced a significant increase in psychological flexibility ($p = 0.017$), a notable decrease in depression levels ($p = 0.010$), and a significant rise in positive affect after the intervention ($p = 0.019$). Additionally, participants who completed the intervention reported high levels of satisfaction with the group sessions ($M = 4.52$).

Conclusions: In conclusion, the revised ACT intervention program was effective in enhancing psychological flexibility and improving the psychological well-being of parents of children with autism. However, further improvements to the program are necessary to better meet the needs of parents and achieve even better outcomes.

406.301 Deficit-Focused Clinical Reports Are Associated with Negative Impressions of Prospective Autistic Clients By Speech Pathologists Compared to Neurodiversity-Affirming Reports

A. M. Schwartz¹, **A. DiNardo²**, **L. Murphy³**, **L. Ramirez²**, **K. Trice¹**, **K. Ho²** and **M. Graham¹**, (1)Department of Physical Therapy, Movement & Rehabilitation Science, Northeastern University, Boston, MA, (2)Northeastern University, Boston, MA, (3)Peer Projects, Beverly, MA, (4)Department of Psychology, Northeastern University, Boston, MA, (5)Boston University, Boston, MA

Background: Non-autistic clinicians have direct power over autistic individuals and contribute to creating and institutionalizing ideas about autism (Friedman, 2023). Research has suggested two factors compete: systemic language describing autism perpetuates institutionalized ideas while direct experience tempers stereotypes. For example, Obeid and colleagues (2021) demonstrated White college students are more likely to identify a Black child than a White child as having Conduct Disorder, a label associated in their data with even higher stigma than ASD, but Black students trended in the opposite direction. Thus, experience counterbalances stereotypes about autism and other identity markers such as race or gender, contributing to clinical impressions of prospective clients.

Objectives: In this study, we compare the effects of reading neurodiversity-affirming (NDA) writing and more clinical experience on producing more compassionate expectations of new clients to the effects of reading deficit-focused (DEF) writing and having less clinical experience on forming negative expectations. Outcome measures included self-reported social acceptance of specific autistic individuals described, the accuracy of diagnostic impressions, and the stigma associated with incorrect impressions. Perceptions of autistic males and females are also considered as an important identity marker that shapes a priori clinical perceptions of autistic persons.

Methods: One hundred and twenty SLPs (50 trained clinicians and 70 student clinicians) were randomly assigned one of two versions of paired vignettes about real autistic clients (2 girls and 2 boys). Vignettes were written by the clients' actual clinicians in either style. Participants selected a category that best fit their impressions from options including: Autism (ASD), 4 higher stigma labels such as conduct disorder, and 3 lower stigma labels such as Anxiety. Participants also responded to a social distance scale (SDS) asking them about their willingness to accept the individual described into their social lives (adapted from Gillespie-Lynch et. al., 2022 via Bogardus, 1933). All clients had a diagnosis of autism and none of the other diagnostic labels listed.

Results: Most clinicians (77-78%) correctly identified ASD regardless of writing style. Of incorrect assignments, DEF writing resulted in significantly more high-stigma miscategorizations ($X^2=31.56$, $p<.001$), for boys over girls ($X^2=27.12$, $p<.001$). DEF writing led to significantly less social acceptance of only males ($t(104)=4.217$, $p<.001$). Boys also received more high-stigma miscategorizations regardless of writing style ($X^2=37.34$, $p<.001$).

More experienced clinicians correctly classified significantly more descriptions (84%) than students (72%) ($X^2=8.84$, $p=.003$). Of incorrect assignments, less experience was associated with more high-stigma categorizations ($X^2=13.42$, $p<.001$), but experience did not improve social acceptance.

Conclusions: The language used to describe a client in a clinical report influences how clinicians perceive an autistic child before treatment starts. This study explored the impacts of NDA and DEF writing styles on the likelihood of misdiagnoses, higher stigma misdiagnoses, and social acceptance of autistic individuals from clinical descriptions alone. This study also highlighted the possible contributions that DEF language interacts with existing stereotypes about gender to result in more negative interpretations of autistic behaviors in male clients.

406.303 Differences in Part-C Early Intervention Provider-Reported Evidence-Based Practice Use and Self-Efficacy across Four States

L. E. Duvall, **H. Tokish**, **I. Babore** and **B. R. Ingersoll**, Psychology, Michigan State University, East Lansing, MI

Background:

The Part C Early Intervention (EI) system provides publicly-funded community infrastructure for autistic (ASD) toddlers to receive specialized interventions in the United States (Stahmer & Aarons, 2009). Part C employs diverse providers with a wide array of training and professional experiences, which vary significantly between states (Pickard et al, 2024). However, little is known about how these differences impact the delivery of ASD-specific evidence-based practices (Autism EBPs), such as parent coaching and NDBIs.

Objectives:

Characterize differences between Part C EI provider professional characteristics (disciplinary background, degree, years of experience, employment status, perceived support of CEUs) across four states and examine how these characteristics relate to providers' Autism EBP use and self-efficacy in providing care to autistic children.

Methods:

Part C EI providers participating in ongoing RCT examining the effectiveness of a parent-mediated social communication intervention completed a survey about their professional background and frequency of use of common NDBI strategies (e.g., imitation, modeling, prompting), provider coaching strategies, and self-efficacy regarding knowledge, comfort, and confidence working with autistic children. Differences in providers' professional characteristics by state were examined via one-way ANOVA or Chi-square as appropriate. Multiple regression was used to examine whether provider characteristics were related to their self-reported use of NDBI and parent coaching strategies, and self-efficacy in providing care to autistic children.

Results:

Significant differences across states were observed for provider discipline ($\chi^2(15, N = 151) = 77.456, p < 0.001$), employment status ($\chi^2(3, N = 97) = 59.303, p < 0.001$), years of experience in the field ($F(3,150) = 7.451, p < 0.001$), and years of employment with their current agency ($F(3,150) = 11.185, p < 0.001$). There were no significant differences in educational degree, ability to pursue CEUs, use of NDBI strategies ($F(3, 146) = 2.480, p = 0.063$) or use of parent coaching strategies across states ($F(3, 146) = 1.229, p = 0.302$). However, there was a significant difference in provider-reported ASD self-efficacy ($F(3, 146) = 3.710, p = 0.013, \eta^2 = .071$), with providers from MA reporting lower self-efficacy than IL. Multiple regression indicated that providers' ability to pursue CEUs was significantly associated with their self-reported use of coaching strategies ($\text{Beta}=.28, t=2.67, p=.009$). Having an "other" disciplinary background (e.g., physical therapy, music therapy) was associated with lower self-efficacy ($\text{Beta}=-.32, t=3.10, p=.003$) and more years of professional experience were associated with higher self-efficacy ($\text{Beta}=.35, t=2.95, p=.004$). No professional characteristics were associated with provider self-reported NDBI use.

Conclusions:

Findings suggest that there are a number of differences in professional characteristics of EI providers across states. As some of these characteristics are related to use of Autism EBPs and confidence to provide high-quality intervention, they should be measured and considered in training efforts within the EI system.

406.304 Does Early Intervention Service Acquisition Vary across Diagnostic Groups When Accounting for Sociodemographic Factors?

L. Iglio¹, C. J. Zampella¹, S. Craig¹, R. Abdullah¹, K. K. A. Acheampong¹, R. M. Benecke¹, A. Y. Flanagan¹, L. S. Cubit¹, R. T. Schultz², W. Guthrie¹ and K. L. Ramsey¹, (1)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (2)The Center for Autism Research/CHOP, Philadelphia, PA

Background: Early Intervention (EI) aims to support the developmental needs of children with disabilities and delays during early childhood; however, systemic barriers based on sociodemographic factors may affect accessibility of these services. Families from lower socioeconomic (SES) backgrounds experience more limited access to specialized care, fewer psychoeducational resources, and delays in accessing EI. Race- and sex-based inequities in autism diagnosis and presentation also affect when children are referred for services. Although legislation requires that EI be freely available, there is limited knowledge of how the interplay between SES, race, and sex affects utilization of EI services in autistic versus non-autistic children.

Objectives: Examine rates of EI utilization by 24 months of age among children with an older biological sibling who is either typically developing (typical likelihood of autism; TL) or diagnosed with autism (elevated likelihood of autism; EL), with a focus on the impact of sociodemographic factors.

Methods: Participants included 112 children enrolled in a longitudinal study based on EL ($n=50$) or TL ($n=62$) status. Participants received diagnostic classifications of typically developing (TD; $n=78$), autism (ASD; $n=18$), developmental delay (DD; $n=3$), or both autism and DD (ASD+DD; $n=13$) (age range of diagnosis=24-54 months; mean=27.47). Parents completed questionnaires regarding sociodemographic factors and EI enrollment at 12 and 24 months. Analyses examined how rates of EI utilization by 24 months of age varied as a function of autism likelihood (EL/TL), diagnostic outcome, SES, race, and sex. Given the large number of predictor variables, chi-square analyses were conducted first to determine which variables were significantly associated with EI utilization; these were then included in a generalized linear model (GLM). Tukey's HSD post-hoc tests were conducted for pairwise comparisons.

Results: Chi-square tests indicated that SES ($\chi^2=13.32$, $p=0.04$), diagnostic outcome ($\chi^2=26.03$, $p<0.001$), and autism likelihood ($\chi^2=4.82$, $p=0.03$) were significantly associated with EI utilization. The GLM including these variables as predictors indicated that only diagnostic outcome was significant when accounting for the others ($F=9.83$, $p=0.002$, $\eta^2=0.09$). Post-hoc tests revealed significant differences between TD vs. ASD ($\bar{d}=-.46$, $SE=.106$, $p<.001$) and TD vs. ASD+DD ($\bar{d}=.54$, $SE=.122$; $p<.001$), with TD using EI less than ASD and ASD+DD.

Conclusions: Although SES was associated with EI utilization overall, this relationship was no longer significant when accounting for diagnostic outcome. Small sample sizes and negative skew in SES (skewness=-.886, $SE=.228$), with most participants in the upper-middle to upper-class range, likely influenced findings; future research will benefit from a larger, more socioeconomically diverse sample. Children with ASD or ASD+DD were more likely to access EI services prior to diagnosis, suggesting the presence of earlier developmental markers of autism, and that diagnostic outcomes, particularly related to autism, are stronger at predicting EI access than sociodemographic factors in this sample. Future work should explore (1) whether EI enrollment prior to age 2 is a helpful predictor of future autism diagnosis, particularly in a sample that includes more non-autism developmental delays, and (2) associations between diagnostic outcomes and even earlier EI enrollment (e.g., by 12-months-old) and/or specific EI service types (e.g., speech, occupational therapy).

406.305 Early Autism Diagnosis in Primary Care: Empowering PCPs to Assess Autism in Toddlers

S. N. Wozniak-Kelly¹, J. S. Miller¹, R. Kommarreddi¹, T. Davis², E. Elliott³, E. Everly³, N. Jaffe⁴, B. Picard⁵, J. Reken⁵, A. Swiatek⁶, F. Xin⁷ and A. Bennett¹. (1)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (2)Children's Hospital of Philadelphia, Philadelphia, PA, (3)Karabots Pediatric Care Center, Children's Hospital of Philadelphia, Philadelphia, PA, (4)CHOP Primary Care, Cobbs Creek, Children's Hospital of Philadelphia, Philadelphia, PA, (5)Developmental Behavioral Pediatrics, Children's Hospital of Philadelphia, Philadelphia, PA, (6)Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, (7)Center for Healthcare Quality and Analytics, Children's Hospital of Philadelphia, Philadelphia, PA

Background: The shortage of autism specialists is a major barrier to timely diagnosis and intervention for young children. As early diagnosis is critical for effective intervention, enhancing the diagnostic capabilities of primary care providers (PCPs) is essential. By training PCPs to recognize and diagnose autism in toddlers with a high likelihood of autism, we can capitalize on the momentum of universal screening practices in primary care and strengthen care within the child's medical home. By equipping PCPs with the right tools, we can reduce the age at which children receive a diagnosis, facilitate earlier access to interventions, and alleviate the burden on specialists.

Objectives: To evaluate diagnostic outcomes following autism evaluations performed by PCPs.

Methods: 21 PCPs (termed "Autism Champions") in 11 primary care practices were trained in early autism diagnosis, including an autism developmental history, administration of the Screening Tool for Autism in Toddlers and Young Children (STAT), and completion of the Childhood Autism Rating Scale-2 (CARS-2). Referrals included children who score 8 or greater on the Modified Checklist for Autism in Toddlers (M-CHAT-R/F), and the patient experience was a 60-minute evaluation with a Champion followed by a 30-minute feedback session one week later. Children who scored positively on the STAT and CARS, and who met all DSM-5 criteria per clinical judgment were given a diagnosis and referred to community-based interventions. Children who did not meet all the program's criteria for diagnosis were referred to Developmental and Behavioral Pediatrics (DBP) for a specialist evaluation. Autism Champions met twice monthly with autism diagnostic specialists to discuss complex cases, documentation, billing, and community resources.

A follow-up study is underway to evaluate diagnostic status and connection to services 6+ months after evaluation. Interviews about the diagnostic process will be recorded, transcribed, and analyzed thematically.

Results: Since 2022, 535 patients have been referred to a Champion, and 394 have been evaluated. 75.4% ($n=297$) were diagnosed with ASD by a Champion, and 24.6% ($n=97$) were referred to DBP. The average age at evaluation was 30 months. Initial results from the follow-up study suggest 100% diagnostic agreement by record review and/or remote video assessment ($n=16$ to date, with follow-up data still being collected).

Conclusions: Training primary care providers to conduct autism evaluations in very specific populations, and with standardized tools like the STAT and CARS2 shows promise in improving early identification and decreasing the age at diagnosis. Integrating autism diagnostic evaluations into primary care can help address the shortage of specialists and facilitate quicker access to early intervention services. Initial outcomes indicate strong diagnostic agreement. Further research is needed to explore the long-term effects of PCP-led evaluations on service access and developmental outcomes.

406.306 Early Diagnostic Response Model (EDRM) Phase One: Increasing Access to Early Autism Assessment through a University Partnership with Early Intervention (EI)

A. J. Schwartz¹, M. J. Morrier², S. Griswell³, G. Engel⁴, R. Eloy⁴, A. Furey⁵, A. K. Platner⁶ and C. Rice⁷, (1)Department of Psychiatry & Behavioral Sciences, Emory University School of Medicine, Decatur, GA, (2)Department of Psychiatry & Behavioral Sciences, Morrier Consulting LLC, Decatur, GA, (3)Division of Women, Children, & Nursing Services, Department of Public Health, Atlanta, GA, (4)Emory University, Atlanta, GA, (5)College of Arts and Sciences, Emory University, Atlanta, GA, (6)Franciscan Children's, Brighton, MA, (7)Division of Human Development and Disability, Centers for Disease Control and Prevention, Atlanta, GA

Background: Early diagnosis of autism spectrum disorder (ASD) is critical, as it leads to improved communication and daily living skills and ensures access to essential ASD-specific interventions. However, lengthy waitlists, a dearth of diagnostic clinicians, and the need to travel long distances often make it hard for parents to get timely evaluations. The Early Intervention (EI) system, established under Part C of the Individuals with Disabilities Education Act (IDEA), provides an opportunity to screen and refer children at-risk for ASD for further evaluation, especially outside of metropolitan areas. In 2018, EI providers across the state received training in ASD-specific screening which resulted in many children being identified as needing further evaluation, but they were not able to obtain an assessment. Telehealth technology presents a valuable alternative to traditional in-person assessments (IPA), particularly for families with limited access to diagnostic services.

Objectives: Evaluate a telehealth autism assessment pilot, Early Diagnostic Response Model (EDRMPhase1), that partners with EI providers across the state. Children enrolled in EI in specified health districts, mostly rural, that scored high-risk on the *M-CHAT-R/F* were referred to a university for an in-depth telehealth assessment. Evaluation of EDRMPhase1 included the number of assessments, time from referral to feedback/report, clinician confidence, and final diagnoses as well as acceptance of the assessment pilot by parents and EI providers.

Methods: Analyzed using SPSS EDRMPhase1 demographics, including number assessed, resulting diagnosis(es), days in the assessment process, and feedback from caregivers and EI providers.

Results: During EDRMPhase1, from 6/01/2022 to 10/21/2024, a total of 192 referrals were made to the pilot with 85.5% completing or currently enrolled. Of the completed evaluations (N=142), the average age at referral was 21.42 months (SD=4.45), majority were male (N=94, 66%), Black (N=75, 53%) and had Medicaid insurance (N=162, 89%). As a result of the assessments, 100% were diagnosed with ASD, and a majority were also diagnosed with Global Developmental Delay (N=107) and nonverbal (N=84) or used single words (N=53). Average time from referral to intake to assessment to feedback/report was only 38 days (SD=1.01). On a 5-point scale (5 is Strongly Agree), caregivers (N=62) reported feeling the assessment was comprehensive (M=4.76, SD=0.50), confident in the results (M=4.76; SD=0.67), and glad EI providers were involved (M=4.63, SD=0.64). EI providers (N=54) also reported feeling the assessment was comprehensive (M=4.89, SD=0.31), confident in the results (M=4.79, SD=0.51), and that being involved was helpful (M=4.63, SD=0.71).

Conclusions: The findings from EDRMPhase1 underscore the success of a telehealth pilot that partners with EI providers. EI providers play a critical role in helping identify at-risk children for ASD and supporting timely access to assessments and therefore intervention. By partnering with EI providers who are trained in ASD-specific screening, the model successfully used a telehealth protocol to provide ASD assessments to address barriers such as long wait times and geographical constraints, particularly for racially and geographically underserved populations. Not only were the telehealth assessments acceptable to both caregivers and EI providers, but with EI providers included, families had access to additional support post-diagnosis.

406.307 Echo Autism Community Connections Program

S. Shelton¹, A. Brewer Curran², K. Boles³, K. Sohl⁴ and V. Nanclares-Nogues⁵, (1)University of Missouri, Columbia, MO, (2)Department of Pediatrics, University of Missouri, Columbia, MO, (3)Child Health, University of Missouri, Columbia, MO, (4)ECHO Autism Communities, University of Missouri School of Medicine, Columbia, MO, (5)Pediatrics, University of Missouri - Columbia School of Medicine, Columbia, MO

Background:

For the past decade, ECHO Autism Communities has worked to professionally develop and provide specialized training to primary care physicians and psychologists to increase access to autism evaluation and diagnosis. An increase in access is what was desired. However, there is the growing recognition that community-based diagnosticians face challenges in providing the necessary support for patients and families. Navigating complex support systems can be difficult. This includes accessing services like the Regional Office, evidence-based therapies, special education, and resources for parents and siblings. In late 2022, ECHO Autism Communities created a solution to address this support gap, launching the ECHO Autism Community Connections program which has been found to be very successful for patients, families, and clinicians alike.

Objectives:

- Increase client self-efficacy in accessing recommended high-quality, best-practice information/resources, services, and supports.
- Reduce clinician burden in supporting newly diagnosed clients as they learn about and access common clinician recommendations.

Methods:

Participants who received professional development through the ECHO Autism: Advocates program were recruited as ECHO Autism Community Connections (EACC) Connectors to support patients/families diagnosed with autism by community-based diagnosticians. Connectors received additional training through resource documentation reviews, videos, and call shadowing.

Clinicians refer patients/families to EACC following diagnostic appointments to support them for up to 12-months as they connect to recommended resources. Patients/families are contacted by Connectors approximately 6 times during program participation. Progress summaries are documented and shared with the diagnostician and the patient/families after each connection. Program satisfaction data is collected from patients/families following program completion and from diagnosticians semi-annually.

Results:

Data collection will continue through February 2025. To date, 62 patients/families have finished the program. Completed satisfaction surveys thus far indicate that 100% of patients/families agree or strongly agree that the Connector's guidance was helpful and 100% understood the recommendations from their clinician and felt confident in the ability to access community supports and services. Prior to participation, 68.8% of patients/families reported feeling overwhelmed about the next steps compared to only 18.8% after program completion.

Diagnosticians also reported a high satisfaction with the program with 100% reporting that it helped to support patients/families in getting connected to recommended resources and 83.3% shared it helped them be better informed about patient needs.

Conclusions:

Preliminary data concludes that the EACC program is a feasible model that has been successful in developing a trained team of Connectors who are currently supporting patients/families throughout the state of Missouri. Patients/families who have completed the program report an increase in their ability to understand and access recommended services and resources after receiving a new diagnosis of autism. Diagnosticians report overall satisfaction with the support their clients receive after diagnosis in connecting with recommended resources. This collaborative approach enhances the quality of care and fosters a supportive community. As a result, patients/families can thrive, leading to better outcomes for autistic individuals.

406.308 Echo Ukraine: Supporting Ukrainian Children and Families Coping with the Challenges of War

R. E. Nickel¹, H. Sanford Keller², L. E. Schmidt³, N. Kogutiak⁴, Y. Kulchytska⁵ and T. Hrynshak⁵, (1)Pediatrics, Oregon Health Science University, Eugene, OR, (2)Institute on Development & Disability, Oregon Health & Sciences University, Portland, OR, (3)Child & Adolescent Psychiatry, Oregon Health Sciences University, Portland, OR, (4)Vasyl Stefanyk Precarpathian National University, Ivano-Frankivsk, Ukraine, (5)Psychology, Vasyl Stefanyk Precarpathian National University, Ivano-Frankivsk, Ivano-Frankivsk, Ukraine

Background: The purpose of our project is to build the capacity of Ukraine's mental health and educational service providers to care for children with mental health conditions and developmental disabilities, in particular children with Autism Spectrum (ASD). In 2017, our group of USA professionals began collaborating with colleagues in 3 cities in Ukraine to present annual workshops. We established ECHO Ukraine in 2019 as a collaboration between USA and Ukrainian specialists (content experts) and switched to monthly virtual ECHO sessions through Zoom videoconferencing as part of the international ECHO project. The ECHO model (Extension for Community Healthcare Outcomes) is recognized as an evidence-based mentorship and training model to build capacity among community providers.

Objectives: Our objective is to expand the capacity of Ukrainian mental health, health and educational providers to care for children with mental health conditions and developmental disabilities including ASD with special focus on children who have experienced trauma related to Russia's war on Ukraine.

Methods: The administrative home of ECHO Ukraine is the Vasyl Stefanyk Precarpathian National University in Ivano-Frankivsk (IF). The participants in the project include pediatricians, child psychiatrists, psychologists, social workers, speech pathologists, teachers and university students, most from western Ukraine where IF is located. Our expert panel includes USA and Ukrainian professionals and parents. Each ECHO session includes a case presentation submitted by one of the participants. The case is discussed and recommendations are provided. This is followed by a brief didactic which matches the primary topic of the case. One ECHO session a month is focused on cases of children traumatized by the war. We highlight strategies providers can easily teach and families implement to address mental health issues related to the war. Sessions are archived allowing access to providers who cannot participate on a given day. We conduct post-ECHO surveys of participants including questions on # of internally displaced children in their practice, satisfaction with topics and materials presented, and strategies providers have shared.

Results: To date we have conducted 34 ECHO sessions with more than 150 participants, many are regular participants. Participants represent many regions of Ukraine including Ivano-Frankivsk, Lviv, Chernivtsi, Kyiv, Zhytomyr, Poltava, Dnipro, and Kharkiv. They are psychologists, teachers, speech therapists, child psychiatrists, and other health care providers. Participants report caring for up to 15 internally displaced children in their practices. They also report high satisfaction and increased knowledge with sessions; for example, asked whether sessions met their needs, 79% participants rated sessions met their needs very well and 21% well. 100% of participants report incorporating information and materials from our last 3 sessions in their practices. Data collection on # of strategies shared by participants with families and child outcomes is on-going.

Conclusions: We present ECHO Ukraine project information to highlight an effective method for continuing professional education even during wartime. We are continuing our qualitative research on the effectiveness of our approach. It has been a remarkably cost-effective approach as participants are only charged a small administrative fee which has been waived during the war.

406.309 Efficacy, Implementation Pace, Accelerators and Inhibitors of a Train-the-Trainer Model for the W.H.O. Caregiver Skills Training in the Public Health System

G. de Leonardi¹, C. Ferrante¹, T. W. CST Team² and E. Salomone^{1,2}, (1)Department of Psychology, University of Milan-Bicocca, Milan, Italy, (2)Department of Mental Health and Substance Abuse, World Health Organization, Geneva, Switzerland

Background: Common barriers to successful implementation of evidence-based parent-mediated interventions (PMIs) in public healthcare include lack of trained professionals and incompatibility with existing service delivery systems. Train-the-Trainer models (TtT) hold great potential for dissemination; however, little is known about large-scale implementation of TtT models for PMIs.

Objectives: To describe the design and implementation of a TtT model for the WHO Caregiver Skills Training (CST) in the Italian National Health Service (INHS). Specifically, we examined the model's: a) efficiency (fidelity, completion rate and pace); b) feasibility; and c) accelerators and inhibitors of long-term sustainability.

Methods: Twenty-eight clinicians (psychologists, child neuropsychiatrists, speech-and-language therapists, occupational therapists) from 10 Regions participated in a 4-phase TtT adapted from the standard WHO model (Table 1). At endpoint, participants rated the feasibility of phase-specific training components on 0-4 scales and participated in focus groups. Thematic analysis identified accelerators and inhibitors of long-term sustainability in routine practice; subsequently, these were classified by domains of the Consolidated Framework for Implementation Research (CFIR).

Results: Across Phases, 8 (28%) participants were lost: 7 dropped out (extended leave: n=3, lacking institutional support: n=4) and 1 did not meet fidelity criteria (Phase 2). Twenty trainees (72%) qualified as Master Trainers (MTs; Phase 4); of these, 15 (75%) completed facilitator training within 1 year. Most MTs completed each phase within the expected timeline (Table 1). In Phase 3, the 80% cutoff for fidelity of strategy use was met on average with 2.65 submissions ($SD=1.14$; range: 2-6); 89% of group sessions met full integrity criteria. Respondents to the post-training survey (n=18) reported high levels of post-training satisfaction ($M=3.92$, $SD=0.07$) and readiness to train facilitators ($M=3.42$, $SD=0.51$) but intermediate levels of institutional support across phases ($M=2.60$, $SD=0.28$; lowest for Phase 4: $M=2.19$, $SD=1.38$). Overall feasibility ratings were in the mid-range ($M=2.05$, $SD=0.30$). Implementation accelerators included characteristics of the individuals (motivation, readiness to change, experience) and of the intervention (response to patients' needs, accessibility, perceived efficacy). Most of the inhibitors were related to inner setting and outer setting factors, and some process components: training structure (facilitators recruitment, compatibility and adaptability to workload), INHS organization (including structural characteristics, communications, leadership engagement, available resources and lack of integration in current care pathways) and the need for formal recognition of MTs (credits, incentives, partnerships and policy) (Figure 1).

Conclusions: While highly appreciated by MTs, the TtT model's efficiency and overall feasibility was impacted by two main factors: lack of institutional support at key stages and significant constraints related to the limited time available for additional activities on top of their high regular workload. In some sites, this led to delays in pilot implementation and recruitment of facilitators. Additional challenges with the potential to threaten the scale up and long-term sustainability included the intensity of execution of facilitator training, due to geographical distance, excessive turnover, and lack of formal agreements and policies. Possible solutions may consider the adaptation of facilitator training to remote delivery, stipulating interorganizational agreements, and providing intrinsic/extrinsic incentives for more effective engaging of MTs as implementation "champions".

**406.313** Evaluation of Autism Training for Emergency Medical Providers

L. Donnelly¹, L. K. Baker², F. Guo¹, E. Okparaekwe¹, A. Alejandro³, G. Wu³, B. Filton¹ and S. Horwitz⁴, (1)Department of Child and Adolescent Psychiatry, NYU Langone, New York, NY, (2)Hassenfeld Children's Hospital at NYU Langone, New York, NY, (3)NYU Langone, New York, NY, (4)Department of Child and Adolescent Psychiatry, NYU Langone Health, New York, NY

Background: Medical providers receive minimal training in autism spectrum disorder (ASD), and it is essential that all medical personnel can optimally care for their autistic patients. Few studies assess the effectiveness of autism-specific behavioral health trainings for emergency providers. As part of a city-wide behavioral health initiative, we created and conducted an autism training for a specialized group of emergency medical providers. Through this initiative, emergency medical services are deployed, without police officers, following 911 mental health calls. The purpose of this initiative is to de-escalate and provide support and resources in response to mental health crises.

Objectives: Evaluate a targeted presentation for emergency medical providers on ASD and assess differences in responses by trainee age and level of education.

Methods: We created a 90-minute autism training that was delivered virtually (during the COVID-19 pandemic) and in-person to specialized medical providers, including emergency medical technicians, paramedics, and social workers. The training concentrated on: 1) understanding the range of autism phenotypic presentations across the lifespan; 2) tips for assessing and interviewing autistic individuals following a 911 call; 3) evidence-informed strategies to support autistic individuals in crisis situations, such as using visuals and accommodating sensory needs; and 4) use of case presentations to support understanding. Following the training, we collected sociodemographic information and attendees completed the following scales: modified version of the Confidence in Coping with Patient Aggression Instrument (Thackrey 1987), assessment of knowledge of evidence-informed strategies for working with autistic youth (Donnelly et al., 2023), and a modified version of the Appeal subscale of the Evidence-Based Practice Attitude Scale (EBPAS; Aarons 2004).

Results: Results indicated that attendees ($N = 86$) found the training to be appealing ($M = 4.38$ on 5-point Likert scale). Trainees with master's degrees indicated that the training made more sense to them and was more intuitively appealing to them in comparison to trainees with other levels of education ($p < .05$). No significant differences were observed by age or education level in terms of attendees' confidence levels. However, we observed a trend towards significance as attendees with an associate's or bachelor's degree reported higher levels of comfort in working with autistic patients than attendees with a high school or master's degree ($p = .05$). Trainees with a master's degree identified the highest level of correct responses on the autism knowledge assessment ($p < .05$), although no differences were observed across age groups.

Conclusions: Overall, emergency medical providers found the training to be engaging and appealing, a promising result given the lack of available trainings on autism for medical professionals. We observed differences in confidence and knowledge by level of education; however, this finding does not necessarily represent attendees experience in the field. Although the training was well-received, the range of responses on the post-training knowledge assessment suggests that additional trainings are necessary to comprehensively support autistic individuals during 911 mental health calls.

406.314 Evaluation of Community Implementation of the World Health Organisation-Caregiver Skills Training (WHO-CST) Program in a Lower-Middle Income Country

K. Sengupta¹, D. Zaveri², A. Rudra³ and S. Nayar³, (1)Ummeed Child Development Center, Mumbai, Maharashtra, India, (2)Ummeed Child Development Center, Mumbai, India, (3)Auckland University of Technology, Auckland, New Zealand

Background:

In recent years, multiple parent-mediated early intervention models have shown to be feasible and effective in controlled settings, yet research on long-term sustainability is limited. Based on a task-shifting approach, the World Health Organization Skills Training (WHO-CST) is a structured caregiver-mediated intervention developed to expand access to early intervention for children with neurodevelopmental conditions like autism, especially in under-resourced regions. It is currently in various stages of adaptation and implementation across more than 35 countries globally, including India, where it was introduced in 2017.

Objectives:

This study is one of the first to evaluate community implementation of the WHO-CST program in India by community-based organizations trained between 2020-22 by exploring stakeholder perspectives on (i) outcomes for the three stakeholder groups- organizational heads, facilitators, and caregivers (ii) factors influencing implementation and sustainability of the program.

Methods:

The WHO-CST was field-tested in India, culturally adapted, and translated into three Indian languages between 2017-20. Between 2020-22, three master trainers subsequently trained 26 facilitators nominated by ten community-based organizations (therapy-centers and special-needs schools) from different Indian cities on the WHO-CST curriculum, followed by supervision using video-feedback to attain fidelity. The current study utilized a mixed-methods approach, including a survey and 28 semi-structured qualitative interviews with heads of organizations, facilitators, and caregivers. Reflexive thematic analysis was used to identify themes inductively instead of using pre-existing implementation frameworks to allow space for novel culture-specific concepts or factors to emerge.

Results:

Nine out of ten organizations implemented the WHO-CST once; only four have since sustained it successfully. Of the 26 facilitators trained across ten sites, 11 no longer work with the organizations; seven facilitators continue to offer the WHO-CST at their sites.

Qualitative analysis identified four broad themes in the following areas: 1) WHO-CST was appreciated for its novelty and for *bridging the gap* in knowledge and skills for all stakeholders, with each group identifying specific ways in which the program helped build caregiver skills to promote communication and better understand behaviors of concern in children with autism and other communication delays; 2) the program is *inclusive* and can potentially be implemented across diverse community settings like therapy centers, schools, and clinics; 3) *implementation was challenging* as it required a significant investment of time and effort, with organizational heads and facilitators identifying complexity of various components of the WHO-CST training, acquiring competence, and the logistics of managing the program as crucial factors that impacted organizational decisions to continue with the WHO-CST and 4) heads and facilitators felt that prolonged *commitment and organizational investment* is needed to implement and sustain WHO-CST.

Conclusions:

All three stakeholder groups acknowledged the immediate benefits of the WHO-CST. Though the WHO-CST program addresses gaps in specialized services for children with autism in LMICs, several factors need to be considered for its sustainability. The duration and intensity of the training needs to be re-evaluated along with increased attention to crucial implementation factors like adequate logistical planning and support required to sustain such an intensive program by community-based organizations.

406.315 Examining Caregiver Stress, Confidence, and Child Externalizing Behaviors across an Early Intervention (EI) Program
S. M. Larsen¹, A. B. Schwartz¹, J. Ball¹, C. J. Black¹, C. A. Mootz¹, J. Winter², A. Lemelman¹ and H. R. Brown¹, (1)Center for Autism and the Developing Brain, Weill Cornell Medicine, White Plains, NY, (2)Center for Autism and the Developing Brain, Center for Autism & the Developing Brain, NYP, White Plains, NY

Background: Caregivers of children with autism spectrum disorder (ASD) generally experience elevated levels of stress compared to caregivers of typically developing children (Bonis, 2016). Caregiving stress and level of parenting efficacy have been found to impact children's problem behaviors in different ways (Rodriguez et al., 2019; Strauss et al., 2022). Early Intervention (EI) for ASD sometimes includes caregivers, but research primarily focuses on child outcomes (Sandback et al., 2023). Our EI program includes caregiver-focused services such as caregiver coaching, support groups, and psychoeducation groups, in an effort to promote caregiving skills and feelings of efficacy. We sought to evaluate caregivers' stress and confidence levels in their own caregiving skills and examine how these impact child externalizing behaviors.

Objectives: The present study aims to investigate changes in caregivers' stress following participation in an EI program, as well as potential correlations between stress, confidence, and child externalizing behaviors.

Methods: Data collection is ongoing. Presently, data was obtained from 36 families who participated in our ASD clinic's EI program. At the beginning of EI, participants ranged in age from 21.7 to 37.6 months ($M=29.22$, $SD=4.18$). Most participants were boys ($n = 26$; 72.2%). Racial make-up included White (61.1%), Black or African American (16.7%), Asian (13.9%), and other or missing (5.6%). Caregivers completed measures upon entrance to the EI program and at completion approximately six months later, including the Parenting Stress Index Short Form (PSI-4-SF), the Child Behavior Checklist for ages 1.5-5 (CBCL), and questions regarding caregiving confidence from our clinic's intake and post-program questionnaires.

Results: Before the EI program, confidence in caregiving skills and caregiver stress were not related ($ps > .181$). However, after EI completion, increased caregiving confidence was significantly related to decreased stress across all domains (PSI Parental Distress: $r(21) = -0.62$, $p = .003$, PSI Parent-Child Dysfunctional Interaction: $r(21) = -0.81$, $p < .001$, PSI Difficult Child: $r(21) = -0.68$, $p < .001$). These findings remained true even when controlling for initial stress and confidence levels ($\beta = -0.65$, $p = .047$; $\beta = -0.83$, $p < .001$; $\beta = -0.60$, $p = .007$). Many child externalizing behaviors were associated with higher caregiver stress across subdomains (see Table 1). Before the program, caregiver distress was associated with children's ADHD symptoms and attention problems. After EI, caregiver distress was associated with children's ADHD symptoms, attention problems, aggressiveness, and more emotional symptoms.

Conclusions: These findings have implications for understanding how EI programs impact not only children with ASD, but their caregivers as well. Our findings indicate that as caregiver confidence increases following participation in an EI program, stress levels decrease. Further, the results demonstrate that higher caregiver stress is associated with higher levels of child externalizing behaviors. While the sample size is too small to evaluate mediation models, these findings may suggest that elevated stress levels hinder effective caregiving, therefore increasing child externalizing behaviors. It is also possible that challenging behaviors increase stress levels and lower caregiving confidence. Future research, with larger samples, is needed to understand the directionality of these relationships. The results suggest that placing a greater emphasis on caregiving self-efficacy may be beneficial in improving EI programs for families.

406.316 Examining Dental Resident Learning Following Participation in an Interdisciplinary, Neuro-Affirming Training Program
T. Rosen^{1,2}, **V. M. Colantuono^{2,3}**, H. Bradley², B. Keech² and B. Garvin², (1)Department of Psychiatry, Drexel University College of Medicine, Philadelphia, PA, (2)St. Christopher's Hospital for Children, Philadelphia, PA, (3)Nemours Children's Health, Wilmington, DE

Background: Dentists report difficulty in completing dental examinations for autistic patients due to behavioral, social communication, and sensory differences (Chandrashekhar & Bommangoudar, 2018). There is a need to promote neuro-affirming care in dental settings (Lai et al., 2011). However, due to lack of training in autism and evidence-based behavior strategies, dental providers often feel ill-prepared to treat this population (Alumran et al., 2018).

Objectives: An interdisciplinary team consisting of a physician, behavior analyst, psychologists, attending dentists, and dental residents established a sensory-friendly dental program (SFDP) and corresponding training initiative at an urban hospital primarily serving Medicaid patients from minority ethnic and racial backgrounds. The initiative aimed to provide neuro-affirming dental care by training dental residents in evidence-based behavioral health strategies (e.g., ABA, CBT, sensory-based) to support autistic patients.

Methods: Anonymous surveys were administered to dental residents at the conclusion (n=7) of their training year. Questions examined feasibility and acceptability of SFDP, and learning outcomes for dental residents. Likert scale questions were rated on a 5-point scale ranging from 1 (strongly disagree) to 5 (strongly agree).

Results: Residents reported agreement (n=4, 57.1%)/strong agreement (n=3, 42.9%) to feeling comfortable treating autistic patients; agreement (n=2, 28.6%)/strong agreement (n=5, 71.4%) regarding SFDP feasibility and acceptability; agreement (n=1, 14.3%)/strong agreement (n=6, 85.7%) that all residents should participate in SFDP; agreement (n=2, 28.6%)/strong agreement (n=5, 71.4%) to better understanding autistic traits impacting dental care; agreement (n=1, 14.3%)/strong agreement (n=6, 85.7%) to feeling better equipped to provide care to autistic patients; agreement (n=2, 28.6%)/strong agreement (n=5, 71.4%) to feeling better equipped to work with caregivers of autistic patients; agreement (n=2, 28.6%)/strong agreement (n=5, 71.4%) to better understanding the purpose of SFDP behavioral strategies; agreement (n=4, 57.1%)/strong agreement (n=3, 42.9%) to feeling better equipped to implement SFDP strategies; agreement (n=4, 57.1%)/strong agreement (n=3, 42.9%) to feeling the didactic lecture was helpful; agreement (n=2, 28.6%)/strong agreement (n=5, 71.4%) that the collaborative review/intake discussion before appointment was helpful; agreement (n=3, 42.9%)/strong agreement (n=4, 57.1%) that collaborating with the BH team during patient appointments was helpful; agreement (n=2, 28.6%)/strong agreement (n=5, 71.4%) that observing the BH consult during appointment was helpful; agreement (n=1, 14.3%)/strong agreement (n=6, 85.7%) that debriefing with the BH team after appointment was helpful; and strong agreement (n=7, 100%) that observing an autism evaluation in BH clinic was helpful. Residents endorsed the individual benefit from each training area (Figure 1).

Conclusions:

Neuro-affirming training in pediatric dental residency programs may lead to increased comfort and skills working with autistic patients. These results highlight the importance of behavioral health collaboration with dentistry to prepare dental residents to adapt care for autistic patients.

406.317 Examining the Barriers and Facilitators to Service Provision for Autistic People in Ireland: A Survey of Psychiatrists
L. Gallagher^{1,2,3}, L. Crane⁴, T. Dinneen⁵, N. Ibrahim⁶, N. Mulryan⁷, A. Harris⁸, N. Bolshakova⁹, L. O'Rourke¹⁰ and E. Pellicano¹¹, (1)Psychiatry, University of Toronto, Toronto, ON, Canada, (2)Psychiatry, Hospital for Sick Children, Toronto, ON, Canada, (3)Child, Youth and Family Services Division, Centre for Addiction and Mental Health, Toronto, ON, Canada, (4)University of Birmingham, Birmingham, Birmingham, United Kingdom, (5)The Hospital for SickKids, Toronto, ON, Canada, (6)Cavan General Hospital, Cavan, Cavan, Ireland, (7)Avista, Dublin, Ireland, Ireland, (8)AsIAm, Dublin, Dublin, Ireland, (9)Trinity College Dublin, Dublin, Dublin, Ireland, (10)Mater Misericordiae University Hospital, Dublin, Dublin, Ireland, (11)Clinical, Health and Educational Psychology, University College London, London, London, United Kingdom

Background: Autistic people have high levels of mental ill-health and an increased risk of suicide across the lifespan. Yet autistic people report difficulties communicating with healthcare professionals and accessing a range of healthcare services. At the same time, mental healthcare workers in other jurisdictions are reporting links between confidence when working with autistic patients and the degree of autism knowledge and training they can access.

Objectives: To examine what factors helped or hindered Irish mental healthcare colleagues when working with autistic healthcare service users.

Methods: An online survey using quantitative and qualitative metrics was circulated among psychiatrists who are members of the College of Psychiatrists of Ireland, both in training and at consultant level, from December 2021 to May 2022. 128 psychiatrists completed the full survey.

Results: Knowledge of autism was high among psychiatrists, but self-efficacy scores were variable, particularly in relation to care pathways. Self-efficacy was better among psychiatrists with caseloads of children and youth or individuals with co-occurring intellectual disabilities. Reflexive thematic analysis identified three key themes relating to capacity and training of mental health professionals, ways to improve mental health services provision for autistic people and the critical need for co-creation and neurodiversity affirmative care.

Conclusions: The study highlighted critical systemic and professional challenges in providing mental health care to autistic people in Ireland. We provide recommendations for reducing these challenges and to enable the development of inclusive, evidenced-based care to autistic people across the lifespan.

406.318 Examining the Reach of a Web-Based Service Navigation Tool for Black Families of Autistic Children
A. S. Rhames¹, K. Shah¹, K. McCloskey², N. Dulaney³, K. Tribié Reid³ and C. corsello Orahovats¹, (1)The TEACCH Autism Program, The University of North Carolina, Chapel Hill, NC, (2)Office of Health Equity and Community Health, Novant Health, Charlotte, NC, (3)MedNorth Health Center, Wilmington, NC

Background: Despite reports of increased prevalence rates of autism spectrum disorder (ASD) among Asian or Pacific Islander, Hispanic, and Black children, Black families continue to experience disparities in access to autism-related services (Liu et al., 2023). Researchers highlight the importance of culturally sensitive resources to aid Black families at various points along the diagnostic evaluation process and beyond (Fannin et al., 2024). Thus, a web-based service navigation resource was created in partnership with stakeholders from the Black community to aid in increasing Black families' connection to early intervention services, with a specific emphasis on rural Black families.

Objectives: The purpose of the current study is to examine the feasibility and viability of this web-based resource. In particular, this study aims to assess 1) whether this tool reaches families in rural areas 2) regional differences in device types used to access the website, and 3) regional differences in webpages visited by families.

Methods: Google Analytics, a web-based analytic tool, was used to track and measure user traffic to the website. The individual metrics relevant to the study's objectives included pageviews, which were further broken down by city/state-level data and device type. Metrics were compiled and analyzed via a Chi-square test (aim 2) and regression analysis (aim 3) to answer the research questions.

Results: Results indicated that the web-based resource reached 40 rural counties in the targeted state (50%). Of users from rural areas, 61% visited from a desktop and 39% from a mobile device. In urban areas, 64% visited from a desktop and 34% from a mobile device. Of users from suburban areas, 82% visited from a desktop and 17% from a mobile device. There was a significant difference in device type used for access between regions ($\chi^2=34.47$, $df=2$, $p<.001$). Specifically, hits from suburban regions were significantly more likely to be via desktop rather than mobile, compared to hits from rural regions (OR = 3.08, 95% CI 1.91, 4.97) or urban regions (OR = 2.54, 95% CI 1.82, 3.60). There were no significant differences in device type between rural and urban counties ($p=.41$).

Analysis of Google Analytics data also indicated that the top 3 webpages that are most visited include 1) the main webpage, 2) "What is BFAST?", and 3) Build Your Team. Compared to rural counties, urban counties were significantly associated with approximately one additional hit per 10,000 residents ($p=.03$, 95% CI 0.09, 2.13). There were no significant differences in hits per 10,000 residents between rural and suburban counties ($p=.07$, 95% CI -0.05, 1.40). When outliers were excluded, these results did not meaningfully differ.

Conclusions: This study provides preliminary confirmation that a web-based service navigation tool for Black families of autistic children has the ability to reach families living in rural areas. While Black families in rural areas continue to face barriers to accessing autism-related services, web-based service navigation resources may aid in closing gaps in access to knowledge and resources. Implications related to regional differences will be further discussed, in addition to study limitations and future directions.

406.319 Examining the Relationship between Treatment Usage and Executive Functioning Among Autistic Youth

A. C. Castillo¹, R. G. McDonald², H. Lynch¹, N. Cifuentes¹, S. Khawar³ and E. Kang², (1)Montclair State University, Montclair, NJ, (2)Department of Psychology, Montclair State University, Montclair, NJ, (3)Department of Pediatrics/Masonic Institute for the Developing Brain, University of Minnesota - Twin Cities, Minneapolis, MN

Background: Recently, executive functioning (EF) has become an area of focus among research in autistic youth, with literature suggesting that EF problems likely contribute significantly to developmental and mental health outcomes in autism (Pellicano, 2012). Among specific barriers examined regarding access to treatment services for autistic youth, EF was found to be one of three key barriers (Adams et al., 2021). Despite this, limited research has examined how treatment usage might differ for autistic children with EF challenges. This information can provide important insights into key considerations when considering and tailoring various treatment modalities for addressing challenges in autistic children with EF difficulties.

Objectives: The current study seeks to clarify the relationship between participation in psychosocial and medical treatment services and EF in a community sample of autistic youth.

Methods: Fifty-seven autistic youth (Mage=10.65, SDage=3.28; 71% male; 47.7% White, 19.9% Asian/South Asian/MENA, 4.6% Black, 21.5% Multiracial) from a Northeastern US region participated in the current study. All participants met research criteria for autism or autism spectrum on the ADOS-2. Parents reported on history of receiving services and EF (Behavior Rating Inventory of Executive Function-2; Gioia et al., 2015), which yielded Emotion Regulation Index [ERI], Behavior Regulation Index [BRI], and Cognitive Regulation Index [CRI] scores.

Results: Of the fifty-seven autistic youth, parents indicated 55% receiving school-based IEP services, 58.1% psychiatric treatment, and 36% medical treatment, either currently or in the past. Psychiatric treatment services included inpatient (5.6%), early intervention (EI; 55.6%), applied behavior analysis (ABA; 54.5%), social skills training (SST; 65.8%), speech therapy (ST; 85.4%), occupational therapy (OT; 88.1%), and individual counseling (IC, broadly defined; 82.9%). Medical treatment services included medication (58.1%) and medical intervention (MI; 36.8%). Medications were reported as prescribed for mainly ADHD, anxiety, and depression. Miscellaneous treatment services were reported by 19% of the autistic youth sample. Point-biserial correlations indicated that CRI correlated with receiving ST ($r=.46$, $p<.01$) and OT ($r=.49$, $p<.01$). BRI correlated with receiving EI ($r=.40$, $p<.05$), ABA ($r=.45$, $p<.05$), ST ($r=.40$, $p<.05$), OT ($r=.41$, $p<.01$) and PT ($r=.47$, $p<.01$). ERI was positively correlated with receiving ABA ($r=.44$, $p<.05$) and PT ($r=.44$, $p<.05$). Use of SST, IC, and MI were not significantly related to EF.

Conclusions: Results suggest that most autistic youth in the current sample are receiving various services. However, it is notable that approximately half of the autistic youth sample had not received any past or current treatment services, despite the majority being socioeconomically advantaged. Moreover, our findings suggest associations between specific EF challenges and receiving certain treatment services in autistic youth, with behavioral EF challenges associated with more treatment approaches. Specific EF challenges have been shown to indirectly and directly affect quality of life via challenging behaviors, implicating the importance of effective treatment (Frazier et al., 2022). Given differences in EF challenges may relate to receiving specific treatment interventions, future research should consider factors that impact treatment decisions in order to take a more tailored approach to planning how to best support autistic youth based on specific EF challenge profiles.

406.320 Exploring Teacher Affect Among Neurodiverse Students in TK-5th Grade General Education Classrooms

J. Vega Garcia^{1,2}, S. L. Birkeneder^{1,2}, A. Garcia¹, H. Fann¹, B. A. Baldwin¹ and N. J. Sparapani³, (1)School of Education, University of California, Davis, Davis, CA, (2)UC Davis MIND Institute, Sacramento, CA, (3)Human Development Graduate Group, University of California, Davis, Davis, CA, (4)University of California, Davis, Davis, CA, (5)UC Davis MIND Institute, University of California, Davis, Sacramento, CA

Background: Teacher affect is a feature of teacher talk evaluated by observing teachers' facial expressions, vocal tones, body posturing, and body movements (McLean & Connor, 2017). Although limited, studies found positive teacher affect within general education settings is associated with academic outcomes (e.g., Burić, 2019). There is limited understanding of whether and how teacher affect varies within interactions involving autistic students.

Objectives: This study explored variability in affect among autistic student and nonautistic students and links between affect with relationship quality and teacher perceptions of student developmental skills and behaviors within TK-5th grade general education inclusive classrooms.

Methods: Participants were recruited as part of a 4-year study examining teacher-student interactions among neurodiverse students in general education classrooms (R324A210288). Trained staff administered a battery of academic measures, teachers completed questionnaires, and video observations were collected. Participants for this study included general education teachers ($N = 17$) and their autistic and nonautistic students ($N = 40$; $M_{age} = 6.7$; $SD = 1.49$). Baseline scores from the DAS-II (Elliot, 2007) were used to assess cognitive skills, the Vineland-3 (Sparrow et al., 2016) to assess adaptive behavior, and the STRS-SF (Pianta, 2001) to assess student-teacher relationship quality. Using video observations from the first two years of the larger study, we examined teachers' affect following students' communication initiations using the *Autism Teacher Affect Measure* (ATAM; Vega Garcia & Sparapani, in preparation), an adapted observational tool (McClean & Connor, 2024). The ATAM provides a frequency count of teachers' responses (contingent, not contingent) and affect types (positive, negative, neutral).

Results: Preliminary data is reported on 14 autistic TK-5th grade students ($M_{age} = 6.8$; $SD = 1.71$) and their 14 teachers. Students exhibited a range of communication initiations directed toward their teachers or not clearly directed; teachers responded to 37% of their initiations, on average. The majority (76%) of these responses were contingent (following the student's lead) and positive (i.e., content or warm). 19% of the teachers' responses showed negative affect (i.e., dismissive or harsh)—this talk was often used to redirect student behavior. See Table 1. 12 students received at least one contingent, positive response from their teachers, while 6 received at least one non-contingent, negative response (Table 2). Using Spearman correlations, a negative, moderate relation between contingent, positive responses and cognitive functioning approached significance ($r = -.51$, $p = .06$). There were no significant relations with teacher affect, students' adaptive skills, and relationship quality when controlling for cognition.

Conclusions: This study provides a snapshot of teachers' response and affect types following their students' communication initiations. Whole class instructional constructs might limit teachers' capacity for individual responding; hence, this finding needs further investigation. Negative response patterns might indicate a misinterpretation of student communication, which is consistent with the current literature (e.g., Hosotani & Imai-Matsumura, 2011). Non-significant findings might be due to the small sample size. We plan to include a larger sample of neurodiverse students as a next step.

406.321 Exploring the Impact of Child Opportunity on Engagement in Services and Diagnostic Timelines for Young Autistic Children in Rural Areas

L. Woolf¹, J. R. Steinbrenner² and S. W. Nowell³, (1)Health Sciences, Division of Speech and Hearing Sciences, The University of North Carolina at Chapel Hill, Chapel Hill, NC, (2)Health Sciences, University of North Carolina at Chapel Hill, Chapel Hill, NC, (3)Health Sciences, Division of Speech and Hearing Sciences, UNC Chapel Hill, Chapel Hill, NC

Background:

Autism is a neurodevelopmental condition marked by challenges in social communication and repetitive behaviors, with early diagnosis linked to better outcomes for young children (Maenner et al., 2023). However, disparities in access to autism-related services persist in rural areas due to geographic and socioeconomic barriers (Malik-Soni et al., 2022). Community factors including rurality and community resources may impact the timing of diagnosis and service access and use. This study examines the relationship of community factors with age of diagnosis and service engagement for autistic children aged 12-60 months across three US states (North Carolina, Missouri, and Kansas).

Objectives:

1. Investigate how community factors influence age of autism diagnosis.
2. Explore the association between community factors and engagement in autism-related services.

Methods:

This study is a secondary data analysis from the Following Language Growth in Autism at Home (FLASH) study, which includes 269 children (192 male, 77 female) aged 12-60 months from North Carolina, Kansas, and Missouri. The participants are racially/ethnically and socio-economically diverse (46% non-white; 37% families with household income < \$40K). The sample will be expanded to include participants from a national cohort through telehealth recruitment, with an anticipated additional 150 children from diverse geographic areas.

The community factors will be measured in two ways: the Child Opportunity Index (COI) and the National Center for Health Sciences (NCHS) Urban-Rural Classification Scheme. COI scores are determined by US Census tracts (~1,500 housing units and 4,000 people). We used the overall COI score and three COI subscales of education, health and environment, and social and economic domains. The NCHS Urban-Rural Classification Scheme is a system used to categorize US counties, based on population size and urbanization, into 6 different categories. The dependent variables are number of visits for several autism-related services (e.g., SLP, OT, ABA) and age of autism diagnosis in months.

We used regression models to examine associations between overall COI and individual COI sub-scores (education, health and environment, social and economic) and service engagement (number of sessions). For the conference, we will also examine community factors impact on age of diagnosis controlling for autism symptomatology. We will also expand all analyses to include approximately 125 additional participants that were recruited across the US through the SPARK database.

Results:

Preliminary analyses showed that the education domain significantly predicted speech-language and ABA therapy sessions, while the social and economic domain was associated with physical therapy and ABA sessions, indicating that lower opportunities in these areas were linked to reduced engagement. The overall COI score was also significantly associated with increased ABA sessions, whereas the health and environment domain did not predict engagement across services.

Conclusions:

The findings suggest that focusing on specific COI domains is more effective in understanding disparities in service use. This approach aims to provide a more comprehensive understanding of how community factors influence diagnosis and service engagement, ultimately guiding efforts to promote equity in autism care.

406.322 Exploring the Landscape and Effectiveness of Teacher Trainings on Autism Spectrum Disorder: A Systematic-Narrative Hybrid Review

D. C. Martino¹, A. S. McLucas² and A. Scarpa¹, (1)Department of Psychology, Virginia Tech, Blacksburg, VA, (2)Virginia Tech, Blacksburg, VA

Background: The rising prevalence of autism spectrum disorder (ASD) has led to an increase in students on the autism spectrum in schools, underscoring the need for teachers who are prepared to support the learning and behavior of these students. Despite this need, teachers worldwide report limited knowledge about ASD and low self-efficacy to support autistic learners. ASD professional development (PD) opportunities for teachers may address this issue; however, research is needed to identify best practices for designing effective and accessible PD opportunities for this population.

Objectives: The present review aims to 1) provide a better understanding of the existing landscape of teacher PD on ASD and 2) identify which content (e.g., topic), modalities (e.g., virtual, in-person), and features (e.g., coaching, role play) of these trainings may contribute to improved teacher outcomes and enhanced preparedness to support autistic students.

Methods: This review employs a systematic-narrative hybrid literature review methodology (Turnbull et al., 2023) to address the present aims. An electronic search was completed in January 2024 using the search concepts “teacher,” “training,” and “autism” to generate search term combinations. To be included, studies had to discuss a training on an autism-related topic; include a training audience of in-service general or special educators (PreK through 12th grade); and discuss training content and modality and at least one post-training teacher outcome. 640 articles were screened by title and abstract, resulting in 134 articles screened via full text to determine a final sample of included articles. An overview of the complete search strategy is shown in Figure 1.

Results: 33 articles were eligible for inclusion and were synthesized by training content, modality, features, and teacher outcomes. Student and feasibility outcomes were also included where reported. Findings across 16 countries and five continents (Figure 2) indicated that nearly 80% of studies reported improvement in one or more teacher outcomes following training. The most common content area covered was interventions/evidence-based practices, with results suggesting that effectiveness of training topic varied based on host country. Improved teacher outcomes were most common among studies employing hybrid training modalities, suggesting that a delivery format combining virtual and in-person components may be ideal for teachers who face competing demands for their time and/or accessibility barriers to obtaining PD. Trainings which allowed teachers opportunities to practice their skills and receive feedback or coaching appeared to positively impact teacher outcomes. Teacher improvements were often associated with improved student outcomes (when reported), suggesting that teacher improvements led to student improvements. Feasibility outcomes indicated that teachers generally perceived ASD trainings to be beneficial.

Conclusions: This review highlights the promising potential benefits of ASD PD when teachers are provided with access and opportunities to obtain training. Strengths of this review include representation of countries underrepresented in ASD research and breadth in content, modality, features, and outcomes among included trainings. Future recommendations include larger study sample sizes, expansion of training content to consider students of varying developmental levels and support needs, and incorporating input from autistic self-advocates, families, and teachers in the development of future trainings.

406.324 Family Support Needs Following an Autism Spectrum Disorder (ASD) Diagnosis

G. Engel^{1,2}, R. Eloy³, A. Furey³, S. Griswell⁴ and A. J. Schwartz⁵, (1)Emory University, Atlanta, GA, (2)Rollins School of Public Health, Emory University, Atlanta, GA, (3)College of Arts and Sciences, Emory University, Atlanta, GA, (4)Division of Women, Children, & Nursing Services, Department of Public Health, Atlanta, GA, (5)Department of Psychiatry & Behavioral Sciences, Emory University School of Medicine, Decatur, GA

Background: While early identification has been recognized as critical for children with autism spectrum disorder (ASD), the immediate period following an ASD diagnosis is also a crucial time for establishing interventions and early support. Research indicates that specific ASD resources provided during early childhood can significantly improve developmental outcomes. Guardians and caregivers play an integral role in post-diagnosis stages, as they provide support, facilitate communication, and deliver essential care for children with ASD. Guardians of children with ASD experience high levels of stress both before and after diagnosis. Further, elevated rates of anxiety and depression are seen among guardians of children with ASD, notably higher than those observed in guardians of children with other developmental or physical disabilities. While the impacts of an ASD diagnosis on guardians have been studied, our understanding of the unmet needs of families of young children recently diagnosed with ASD remains limited.

Objectives: This study was part of a larger contract between a university and state health department. The study aimed to increase ASD diagnostic opportunities through a telehealth assessment pilot for children enrolled in Early Intervention (EI) services who scored as high-risk on an autism screener. Following low attendance at post-diagnosis webinars offered for guardians, this study aimed to identify specific gaps in the service delivery of the pilot and assess post-diagnostic needs of families, as experienced by both guardians and EI service providers.

Methods: Through qualitative data collection, EI providers and guardians of young children recently diagnosed with ASD were surveyed. Guardians and EI providers were asked about outstanding questions, desired post-diagnosis support, barriers to obtaining care, and services already received. Qualitative data was analyzed through thematic coding using MAXQDA-v24 software.

Results: In total, 16 families and 8 EI providers participated in the study; the majority (N=15) of families were from rural areas. Thematic analysis revealed five key themes surrounding family needs: (1) uncertainty about next steps post-diagnosis, (2) barriers such as cost and insurance complications, (3) the need for clearer and timelier referrals, (4) the desire for ongoing intervention support, and (5) the importance of emotional and social support for caregivers. Notably, both caregivers and EI providers identified similar unmet needs, with some differences appearing in the types of referrals and social support the two groups highlighted. Findings also revealed guardians' desire for further contact from the diagnostic team, with 69% of respondents stating that additional contact post-diagnosis would have been beneficial.

Conclusions: Caregivers and EI providers have clear and consistent perspectives of shared challenges during this critical period for families of young children recently diagnosed with ASD. These challenges indicate a need for specific connections to community-based referrals and interventions and help navigating barriers. All participants highlighted the need for structured guidance, including professional and peer reassurance and support. These findings can help inform and guide the development of targeted interventions in low-resource communities to improve service delivery systems for families of young children recently diagnosed with ASD.

406.325 Fidelity Measures of Job Coaching Interventions That Support Autistic Youth and Adults in Obtaining and/or Maintaining Paid Employment: A Narrative Review

S. Selvakumaran^{1,2}, I. O'Connor^{1,3}, V. Thusyanthan^{1,2}, M. Freeman², K. Varathan^{1,2} and B. Di Rezze^{1,2}, (1)McMaster University, Hamilton, ON, Canada, (2)CanChild Centre for Childhood Disability Research, McMaster University, Hamilton, ON, Canada, (3)McMaster University-Offord Centre, Dundas, ON, Canada

Background:

High unemployment rates among autistic adults are reported globally. Supported employment, including job matching, training, and ongoing support like job coaching (JC), can address this challenge, increasing retention in paid employment. JC assists autistic adults by providing various supports to address personal and work-related barriers (e.g., accessing job accommodations, modifying tasks, developing compensatory strategies, delivering behavioural interventions, skills training). The effectiveness of JC is best determined by evaluating implementation quality, specifically through assessing fidelity—how well the intervention is delivered as intended. Standardized fidelity evaluation, such as using a fidelity measure, ensures consistent, high-quality coaching, aiding the broader reproduction of successful programs. Limited understanding exists of how to evaluate JC fidelity. Examining how JC is measured in literature is the first step in establishing best practices for supported employment in autism.

Objectives:

This narrative review examines JC fidelity measures used in employment programs supporting autistic individuals in obtaining or maintaining competitive employment over the last decade.

Methods:

A comprehensive secondary analysis is being conducted using data from an ongoing review that aims to describe the published literature on job coaching for autistic youth and adults. From this pool of studies, research that specifically evaluates job coaching using fidelity measures is being selected concurrently for this secondary analysis. Fidelity tools are being sought from authors if not provided in the selected papers. The search spans CINAHL, Medline, PsycInfo, Embase, Emcare, and Business Source Premier databases. The process involved title and abstract screening, followed by full-text screening to identify studies using JC fidelity measures. Inclusion criteria: (1) participants diagnosed with autism, (2) aged 15 years or older, and (3) receipt of JC. Eligible studies supported participants in obtaining or maintaining paid employment, used a fidelity tool, and were published from 2014 onward. Studies were excluded if participants were in sheltered workshops or if the paper was a review.

Results:

The original search identified 69 studies, 15 of which met most of the inclusion criteria for this analysis. At this stage, these studies either mentioned a fidelity tool or indicated some form of fidelity assessment, though the precise number of studies utilizing formal fidelity measures is still being determined. Further examination of the selected studies will confirm whether a specific measure was employed. The next steps involve collecting fidelity measures (from the articles or directly from authors) and extracting fidelity-related data (e.g., observer, in vivo assessment, frequency) as well as components of the measures (e.g., JC instructions, supports, prompts, pacing). The studies will also be categorized using the National Institutes of Health Behavior Change Consortium's Treatment Fidelity framework, which includes dimensions such as design, training, delivery, receipt, and enactment to assess comprehensive fidelity.

Conclusions:

This review will identify existing JC fidelity measures in employment programs for autistic individuals. The findings will describe specific characteristics of fidelity published in the literature. Findings from this work will outline best practices in fidelity evaluations and what to consider moving forward to improve JC implementation and outcomes for autistic youth and adults.

406.326 Filipino American Help-Seeking of Autism Treatment Moderated By Religious Support

E. A. S. del Rosario¹, H. Onovbiona², P. Moreno³, E. Shah⁴, S. Menon¹ and L. B. Quetsch¹, (1)University of Arkansas, Fayetteville, AR, (2)University of Arkansas - Fayetteville, AR, Fayetteville, AR, (3)University of Arkansas, 72701, AR, (4)The University of Arkansas, Fayetteville, AR

Background: With the apparent lack of representation in the literature, not much is known about the effects and impressions that parents of Filipino American communities have on autism diagnoses and treatments. A major issue experienced by immigrant families in the US with an autistic child or a child with a developmental disability diagnosis is not receiving adequate care (Lin et al., 2012). Despite the appalling disparities, these families were also more reluctant than non-immigrant families to report delayed/forgone care for their child. With nearly 79.5% percent of Filipinos identifying as Roman Catholic (Philippine Statistics Authority, 2017), religious roots run deep and help shape their cultural values and beliefs (Agbayani-Siewert, 1994). One aspect of the Catholic religion integral in the Filipino culture is the tradition of bringing fictive relatives (i.e., godparents) into the family network through the *compadre* (co-parent) system (Agbayani-Siewert, 1994). While research indicates low rates of mental health help-seeking among Asian Americans (Abe-Kim et al., 2007; Han and Pong, 2015), Filipino Americans seek mental health services at an even lower rate than average reports (Gong et al., 2003). Gong et al. found that nearly 75% of their sample of 2,285 Filipino Americans from the Filipino American Community Epidemiological Study (FACES; a strata-cluster study conducted from 1998-1999 in San Francisco and Honolulu) had never utilized any type of mental health service (2003). Additionally, the most frequently used source of care came from the lay system (e.g., family and friends), along with a moderate level of folk system utilization (e.g., priests, herbalists; Abe-Kim et al., 2004). While past research has indicated that rates of mental health-seeking behaviors are generally low for Filipino Americans (Tuazon et al., 2019), Abe-Kim et al. found that rates of help-seeking behaviors were similar for those reaching out to mental health specialists (2.9%) and religious clergy members (2.5%) for all respondents (2004). With the apparent barriers, Filipino-Americans may experience a range of cultural pulls when deciding how to care for their autistic child.

Objectives: The present study explored if the relationship between concern of autism and likelihood of seeking out treatment is moderated by parent religious support.

Methods: To analyze the relationship, Filipino Americans read a vignette portraying an autistic child and were asked how much of a concern they felt about the portrayed child and whether they would seek out treatment for the child. Additionally, participants filled out the Brief Multidimensional Measure of Religiousness/Spirituality (BMMRS; Fetzer Institute/ National Institute on Aging Working Group Report, 1999) to determine the importance that religious support plays in their lives.

Results: The relationship between participant concern of autism and likelihood for seeking treatment is significantly moderated by perceived support by their religious community, ($B = .422$, $SE = .115$, $t = 3.664$, $p < .001$).

Conclusions: These results show that perceived support within a religious community can affect help-seeking behavior for autism diagnosis and treatment on top of concern of autism symptoms. Overall, this shows the importance that support networks play in Filipino Americans' likelihood of seeking services for autism.

406.327 Findings from a Psychoeducational Intervention for Black Families Raising Autistic Youth

J. Pearson, *Teacher Education and Learning Sciences, North Carolina State University, Raleigh, NC*

Background: Given the increased diagnostic prevalence of autism among Black children (Maenner et al., 2023), Black caregivers raising autistic youth experience barriers to accessing autism-related services. The barriers experienced by Black families are unique and more nuanced than those experienced by non-Black families. Increasing Black caregiver advocacy may help reduce these diagnostic and service disparities. FACES (Fostering Advocacy, Communication, Empowerment, and Support) is a caregiver advocacy program designed to empower Black families to combat autism service disparities and to help strengthen equitable and inclusive access to autism supports (Pearson & Meadan, 2021). Previous findings indicate that FACES strengthens advocacy and service utilization (Pearson et al., 2022). Findings also suggest that training community-based parent educators to deliver FACES could facilitate program sustainability while making FACES more widely available to Black families.

Objectives: The purpose of this mixed methods study was to examine the impact of a train-the-trainer approach to prepare community-based providers to implement FACES. We assessed the training efficacy using a multiple-baseline, single-case experimental design across participants and we implemented a qualitative interview design to assess the training feasibility. Our research questions were: Is there a functional relation between the FACES Facilitator Training and community-based FACES Facilitators' fidelity of implementation of the FACES intervention? To what extent do parent educators perceive the FACES Facilitator Training as (a) feasible, (b) usable, and (c) likely to improve parent and child outcomes?

Methods: Phase one of this mixed method design included a multiple-baseline, single-case design across participants. Three community-based facilitators completed the 16-hour hybrid FACES Facilitator Training (FFT), which included 12 hours of online asynchronous training and 4-hours of in-person training. Following the FFT, participants implemented FACES across three sites with 15 Black caregivers. FACES was offered weekly, in person for three hours per session. To assess parent educators' fidelity to the intervention we conducted visual analyses of behavioral characteristics such as: (a) consistency of changes in level, trend, and variability within and across each phase and tier; (b) consistency of data and presence of overlap across phases and tiers; (c) projected patterns of the data; and (d) anomalies within the data (Kratonchwill, 2013). In phase two of the mixed method design, we conducted a series of semi-structured interviews with the FACES facilitators (before the training, after the training, and after their implementation of FACES). To analyze the qualitative data, we employed a constant comparative method (Corbin & Strauss, 2015). **Results:** Findings offer emergent evidence of the feasibility of the FACES train-the-trainer approach. Our findings also support the need for ongoing scaling and implementation of the FACES intervention. Preliminary qualitative data analysis indicates that the FACES Facilitator Training was feasible and acceptable. Data analysis is ongoing at the time of this submission, however, we will discuss the final results in detail, following our rigorous data analysis process.

Conclusions: The findings from this study will inform ongoing development of the FACES intervention and the FACES Facilitator training to better support Black autistic children across the lifespan and their families through a community-embedded psychoeducational intervention.

406.328 First-Hand Accounts of Autistic Students' Experiences in Work-Integrated Learning

E. Birmingham¹, M. Waite², G. Iarocci³, E. White³, S. Sharma⁴, N. Modzelik⁵ and E. Carrier⁶, (1)Faculty of Education, Simon Fraser University, Burnaby, BC, Canada, (2)Psychology, Simon Fraser University, Burnaby, BC, Canada, (3)University of Edinburgh, Edinburgh, United Kingdom, (4)Simon Fraser University, Burnaby, BC, Canada, (5)Skills to Play, Aldergrove, BC, Canada, (6)Self employed, Vancouver, BC, Canada

Background: Autistic adults in Canada face substantially higher rates of unemployment compared to the general population (Statistics Canada, 2017). Autistic adults are increasingly pursuing postsecondary education to benefit their employment outcomes (Cheriyen et al., 2021). Yet, they report that the services currently available in postsecondary institutions are insufficient and ill-fitting (Lucas et al., 2022; Wolpe, 2024). Work-integrated learning (WIL) programs provide experiential learning opportunities for postsecondary students, leading to numerous beneficial employment outcomes and offering an important opportunity for students to gain skills and work experience within a supported environment (Jackson et al., 2023). However, autistic postsecondary students are less likely to access WIL programs than students without disabilities and students from other disability groups (McLeod et al., 2019). Autistic students face several barriers in WIL programs, including a lack of autism-specific supports (Sullivan, 2023; Pesonen et al., 2021). While WIL programs have the potential to improve employment outcomes for autistic students (May, 2018; Janice et al., 2021), the lack of research and resources dedicated to making these programs accessible means they are not adequately supporting this population.

Objectives: This study aims to explore the perspectives of autistic students on the barriers and facilitators within Canadian WIL programs that impact their successful engagement.

Methods: Autistic postsecondary students currently enrolled in or who recently completed a WIL program are being recruited to participate in this study. Participants will complete a demographics form, two measures of employment readiness (Work Readiness Inventory (Brady, 2010) and Ansell-Casey Life Skills Assessment (Wittevrongel et al. 2022), and a semi-structured interview. The interview questions, created in collaboration with autistic researchers and community members, focus on the barriers and facilitators encountered in WIL programs, as well as suggestions for improving accessibility. Thematic analysis will be used to identify patterns across participant responses (Braun & Clarke, 2013).

Results: Data collection from 25 autistic participants will begin shortly, following thorough consultation with various stakeholders and a review of the literature. The study design and materials were created collaboratively by our team of autistic and non-autistic researchers and in consultation with various stakeholders. This participatory approach is expected to lead to meaningful results that not only accurately reflect the voices of those with lived experience but also provide concrete suggestions for improving the accessibility of WIL programs. Further, these results will contribute to a larger research project that examines the perspectives of different stakeholder groups in the WIL ecosystem (students, WIL Practitioners, and employers), ultimately informing the development of a publicly available, evidence-based online resource toolkit.

Conclusions: To address the gap in research examining autistic students' experiences in WIL programs, this qualitative community-engaged study seeks to capture and explore their perspectives and recommendations. By prioritizing the voices of students, this design allows for rich, nuanced insights that can inform future WIL practices. Our aim is to generate actionable suggestions that contribute to the development of an evidence-based resource toolkit.

406.329 Gender-Sensitive Approaches to Autism Identification: Addressing Policy Gaps in U.S. Public Schools

A. Watson-Grace¹ and J. E. Crasta², (1)*The Ohio State University, Columbus, OH,* (2)*Physical Medicine and Rehabilitation, The Ohio State University, Baltimore, MD*

Background: Autism identification relies on subjective judgment of behaviors thought to reflect core autism traits. Historical and ongoing exclusion of autistic females from research determining core autism traits suggests a male bias in conceptualization that puts autistic females at high risk for underidentification both clinically and educationally. Even when females are clinically diagnosed, they are much less likely than their male counterparts to receive special education services under autism eligibility. State-level variability in applying Individuals with Disabilities Education Act (IDEA) criteria may influence the overall prevalence of students served under autism eligibility, and this variability may be of particular concern for autistic females. However, no studies have examined the potential disproportionate impact of state-level practices on autism educational identification for males vs females.

Objectives: To investigate sex-related disparities in students served under autism eligibility within U.S. schools by analyzing state-level special education policies in relation to autism prevalence by sex.

Methods: Using state education agency (SEA) and legislative websites, we extracted special education policy information related to autism definition, assessment requirements, and team member mandates for all 50 states and Washington D.C. (hereafter referred to as states). We used U.S. Department of Education IDEA Section 618 State Part B Child Count Data and National Center for Education Statistics Tables 203.20 and 204.70 to calculate autism prevalence ratios for each of the 51 states overall and by sex. We will use multiple regression to analyze the relationship between coded policy variables, demographic variables (per pupil expenditure, number of students receiving free or reduced lunch), and autism prevalence overall and by sex.

Results: Preliminary results suggest a mismatch between state-level definitions (what autism is) and assessment mandates (how autism is identified). For instance, 49/51 states (96%) include some variation of "unusual responses to sensory experiences" in their autism definition for special education eligibility. Yet fewer than 20% of states require that a sensory processing assessment be conducted when evaluating to determine qualification for special education services under autism eligibility.

Conclusions: Autistic females report higher lifetime sensory symptoms, and research suggests that sensory processing assessment may discriminate between autistic and typically developing children with higher accuracy for females (89%) than males (75%). Thus, failure to mandate assessment of sensory processing for autism special education eligibility may contribute to disproportionate underidentification of autistic females in U.S. public schools. Overall, this research makes a crucial contribution by addressing systemic barriers to female autism identification, emphasizing the need for gender-sensitive policies and assessment practices. Our final results will have the potential to inform a new gold standard that improves the accuracy and equity of autism identification in educational settings.

406.330 Impact of Parent Education and Case Management on Access to ABA Therapy Services and Parent Satisfaction in an Early Intervention ABA Program

M. A. Minjarez¹ and J. Sigismund², (1)*Department of Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA,* (2)*Seattle Children's Hospital, Seattle, WA*

Background: Children with autism spectrum disorder (ASD) receive recommendations for a range of services, accessed through different systems. Applied Behavior Analysis (ABA) therapy is often recommended and availability of parent education about how to obtain services is inconsistent. Wait times for ABA may exceed 1-2 years, often because families lack knowledge to navigate service systems. In an effort to potentially reduce wait times, the ABA Early Intervention (ABA EI) Program at Seattle Children's Autism Center provides intensive parent education and case management in the context of a short-term (3 months), center-based ABA treatment program, including a focus on how to access ongoing ABA following program discharge.

Objectives: The objective of this study is to highlight the parent support package included in the ABA EI Program, and to explore its effects on access to ongoing care and parent satisfaction from baseline to post-treatment. Access to care findings for ABA EI patients are compared to a population of children with ASD served in an outpatient clinic in order to examine how many children accessed ABA therapy across groups.

Methods: Participants thus far include 74 children with ASD, ages 18 months-6 years, and their parents. Children were selected from two groups: ABA EI participants (N = 42) or general outpatients (N = 32). To compare access to care across groups, an independent chart review was completed to determine if patients with referrals for ABA therapy were receiving it. Percent of children receiving ABA in each group was then calculated as the primary outcome measure. Secondary outcomes were evaluated using the ABA EI Parent Satisfaction Survey, collected at post-treatment.

Results: Data collection is ongoing. Preliminary primary outcome measure results indicate that 62% (N = 42) of children in the ABA EI program successfully accessed ongoing ABA therapy, compared to 18% (N = 32) of outpatients. Data are available on 137 additional ABA EI participants, and data collection is ongoing for both groups. Preliminary results from the ABA EI Satisfaction Survey include an overall mean satisfaction score of 4.95 (SD = 0.22; N = 20) on a scale of 1-5 (1 = unsatisfactory; 5 = very satisfactory). The Parent Self-Assessment of Knowledge and Confidence scores increased from M = 2.47 (SD = 1.44; N = 21) at baseline to M = 4.52 (SD = 0.51; N = 21) at post-treatment and M = 2.48 (SD = 1.43; N = 21) at baseline to M = 4.8 (SD = 0.44; N = 21) at post-treatment respectively.

Conclusions: Families receiving parent education and case management in the context of a brief ABA early intervention program successfully accessed ongoing ABA therapy services at a much higher rate than children receiving less intensive outpatient services. Parents reported high satisfaction with the ABA EI program and increases in self-assessed knowledge and confidence. These pilot findings suggest a focus on increased family support may be important for insuring families are able to navigate the complex service systems involved in caring for children with ASD.

406.331 Implementation Climate and Characteristics of Community-Based Agencies Serving Young Autistic Children in the U.S.: Preliminary Results

S. Dufek¹, M. R. Martin Loya², A. M. Iosif³ and A. C. Stahmer⁴, (1)Psychiatry and Behavioral Sciences, UC Davis Health, MIND Institute, Sacramento, CA, (2)Department of Psychiatry & Behavioral Sciences, UC Davis MIND Institute, Sacramento, CA, (3)Public Health Sciences, University of California Davis, Davis, CA, (4)UC Davis MIND Institute, University of California at Davis MIND Institute, Sacramento, CA

Background: The rising number of young children being identified as autistic has led to exponential growth in for-profit community-based agencies (CBAs) that serve them. CBA providers often use highly structured approaches that may not be developmentally appropriate for young children which may limit the use of learned skills across settings and time. Naturalistic Developmental Behavior Interventions (NDBIs) integrate theory and strategies from applied behavior analysis and developmental science and are considered best practice for young autistic children. While NDBIs are a promising option for CBAs to better serve young autistic children, organizational change and adopting new practices is challenging. Examining implementation climate is an important first step to change, as a strong implementation climate is associated with successful adoption of new practices.

Objectives: This presentation will showcase a preliminary look at the implementation climate in CBAs nationally. These data were collected as part of a larger hybrid type 1 randomized controlled trial designed to examine NDBI effectiveness (specifically the Early Start Denver Model [ESDM]) in the community and to gather data on implementation determinants. This first look will provide a snapshot of the implementation climate in CBAs, informing understanding of implementation readiness.

Methods: CBAs across the United States that (a) accept public funding (e.g., Medicaid), (b) serve at least ten autistic children under age five from English- or Spanish-speaking homes, and (c) have not previously received training in ESDM participated in this study. All participating CBA providers completed the Implementation Climate Scale (ICS), a measure of climate for the implementation of evidence-based practices (EBPs) with strong internal consistency and construct-based validity in mental health populations. The ICS yields scores on six dimensions reflecting organization priorities and values related to the successful implementation of EBP: focus on EBP, (2) educational support for EBP, (3) recognition for EBP, (4) rewards for EBP, (5) selection for EBP, and (6) selection for openness. All scores range from 0 to 4, with higher scores indicating participants perceive their workplace to have excellent implementation climate.

Results: To date, 29 CBA providers across 4 agencies and 7 states have completed the survey, and data collection is ongoing. Providers identify as mostly female (n=26), not Hispanic or Latino (n=19), and White (n=20). The implementation climate at CBAs is low overall (M=2.5, SD=0.5), similar to previous literature examining school and mental health settings. The highest scoring dimension was Focus (M=3.7, SD=0.4) and the lowest scoring subscale was Rewards (M=0.7, SD=0.8).

Conclusions: This is the first study of its kind to examine implementation climate in CBAs across the United States. Preliminary results show low ICS scores across CBAs, which highlights the need to identify methods to improve implementation climate to support CBAs' abilities to provide accessible and effective best practices for young autistic children and their families.

406.332 Improved Appointment Completion at an Autism Specialty Clinic Following Intake Simplification and Introduction of Community Health Worker Support: Results from a Quality Improvement Project

C. Ravichandran¹, A. James², Y. J. Howe³, M. Y. Parra^{4,5}, N. Y. Baez⁵, S. Fleishman¹, H. Patel⁶, C. Canales¹, S. Kessler¹, E. Roth¹, G. Erhabor¹, M. Plagge⁷, F. Patino⁸, S. DeStefano⁸, L. Nowinski¹, A. Arauz Boudreau² and A. M. Neumeyer^{9,10}, (1)Lurie Center for Autism, Massachusetts General Hospital, Lexington, MA, (2)Pediatrics, Mass General for Children, Boston, MA, (3)Cortica, Burlington, MA, (4)MGH Equity and Community Health, Chelsea, MA, (5)MGH Chelsea HealthCare Center, Chelsea, MA, (6)UMass Chan Medical School, Worcester, MA, (7)Beth Israel Lahey Health, Cambridge, MA, (8)Office of the Chief Medical Officer, Health Equity, Mass General Brigham, Boston, MA, (9)Pediatrics and Neurology, Massachusetts General Hospital, Boston, MA, (10)Lurie Center for Autism Massachusetts General Hospital, Lexington, MA

Background: Children from marginalized racial and ethnic groups and children whose families speak a language other than English encounter barriers to autism evaluation and care. An internal review confirmed that, within a large academic hospital system in the northeast, fewer than half of pediatric patients newly referred from its Community Health Centers (CHCs), which serve a racially, ethnically, and linguistically diverse patient population, were completing initial autism evaluation and specialist appointments at its multidisciplinary autism clinic.

Objectives: We designed and implemented a process improvement quality project to improve access to autism evaluations and specialty care for patients from the CHCs. Our objective was to increase the new pediatric patient appointment completion from below 40% to at least 70% for patients from two CHCs.

Methods: Using root cause analysis we determined two aims: 1) simplify the intake process at the autism clinic, ultimately allowing CHC physicians to submit a direct referral with brief clinical information without requiring the patient's family to complete a lengthy intake form 2) develop a community health worker role specializing in autism spectrum disorders (ASD-CHW) to assist families in navigating the health system. Pediatricians at the CHCs could refer their patients for ASD-CHW support at any time during the process of obtaining an appointment. Progress toward appointment completion was tracked for new patient referrals placed by primary care pediatricians at the two CHCs to the autism clinic between July 1, 2019, and June 30, 2024. An extrapolated appointment completion rate was calculated pre-project and for each six-month project period based on percent intakes received, percent received intakes with scheduled appointments, and percent scheduled appointments completed.

Results: We tracked outcomes for 312 referrals for 301 children from the two CHCs. Mean (SD) age at referral was 4.4 (3.1) years, 202 (65%) of referrals were for the autism diagnostic clinic (children <6yo), and 110 (35%) referrals were for diagnostic evaluation of older patients or specialty care. Patients with race (76%) and ethnicity (84%) identified in their medical records were most commonly identified as other race (38%), White race (38%), Black race (17%), and Hispanic ethnicity (59%). Of 300 with preferred language identified 165 (55%) preferred English, 106 (35%) preferred Spanish, and 29 (10%) preferred another language. Number of referrals increased on average over the course of the project, and more than half of new referrals were referred concurrently for ASD-CHW support by the third year (Figure). The project met its 70% appointment completion rate target for five of six six-month project periods. Appointment completion rate with ASD-CHW support was greater or equal to rate without ASD-CHW support for all six-month project periods (Figure).

Conclusions: A simplified referral process and community health worker support improved access to autism evaluation and multidisciplinary care for a diverse pediatric patient population. Referrals from the CHCs to the autism clinic increased during the project, and appointment completion rate exceeded the target of 70% for the majority of the project.

406.333 The Cascades Program: A School-Clinic Partnership Addressing Barriers to Autism Assessment Among Underserved Youth
T. P. Nguyen¹, D. X. Hu², F. Orlich³ and G. Gerardi⁴, (1)University of Washington, WA INCLUDE & Seattle Children's Autism Center, Seattle, WA, (2)Department of Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (3)University of Washington & Seattle Children's Hospital, Autism Center, Seattle, WA, (4)Snoqualmie Valley School District, Snoqualmie, WA

Background: Autism spectrum disorder (ASD) is a high-incidence neurodevelopmental condition that affects 1 in 36 school-aged youth in the United States. For youth of color and those from low-income and/or immigrant family backgrounds (hereinafter referred to as “underserved youth”), disparity in timely identification and diagnosis of ASD is evident compared to non-Latine/non-Hispanic White youth and those from higher socioeconomic status background. Barriers to a medical diagnostic evaluation for underserved youth suspected of ASD include: a) limited access to community clinicians due to low rate of Medicaid reimbursement, b) barriers to get to the hospital or clinic for in-person appointments, and c) prolonged wait time for a diagnostic evaluation appointment with little support available for families to effectively self-advocate and navigate the complex medical system. Altogether, these barriers underscore the need for alternative and equitable pathways for underserved youth to access ASD diagnostic evaluation.

Objectives: The Collaborative Autism School Assessment and Development Efforts (CASCADES) program addresses these disparities by creating a school-clinic collaborative model for ASD diagnostic evaluation. The goals of the CASCADES program are: 1) to enhance community capacity to provide comprehensive ASD diagnostic evaluations within schools; 2) to provide an alternative pathway for underserved youth to access comprehensive diagnostic evaluation and medical diagnosis of ASD, as appropriate; and 3) to promote a sustainable collaborative school-clinic model of care for underserved youth suspected of ASD in their local community.

Methods: The CASCADES program was implemented across four local education administrations (LEAs) in the Pacific Northwest between the 2022 and 2024 academic year. Clinical psychologists from a pediatric hospital partnered with school-based providers (e.g., school psychologists, speech language pathologists) to provide comprehensive evidence-based diagnostic evaluation for underserved youth suspected of ASD. Using data obtained across a two-year span, this proof-of-concept study evaluated the acceptability, engagement, and initial outcome of the CASCADES program.

Results: Evidence of the successful rollout of the CASCADES program include the training of 35 school-based providers, with a 71% retention rate by the end of the 2023-2024 academic year. Discontinuation among 10 providers was attributed to retirement, job relocation, and shifting district priorities toward intervention services. Additionally, 116 underserved youth completed comprehensive ASD evaluation, with a 73% increase in evaluations from Year 1 (n=49 in 2022-2023) to Year 2 (n=67 in 2023-2024). Projections indicate an approximately 61% increase in evaluation capacity with fully trained school teams, based on an estimated case rate of 4 to 6 evaluations per month. With regards to the acceptability and sustainability of the CASCADES program, all four LEAs independently introduced incentives to encourage school-based provider participation, such as protected time for team meetings and evaluations, and FTE allocations for ASD evaluations and team collaborations.

Conclusions: The CASCADES program demonstrates that school-clinic collaboration can address disparities in ASD diagnostic access for underserved youth. The program's success, evidenced by increased productivity, high retention, and independent adoption of incentives by LEAs, highlights its potential as a sustainable and scalable model. Future research will explore long-term outcomes and refine the program for broader implementation.

406.334 The Intersection of Autism and Gender Diversity in the Canadian Clinical Context: Characterizing a Sample of Adults Referred to Canada's Largest Publicly-Funded Adult Gender-Care Service

M. I. Pascoe^{1,2}, **J. Vincent**^{3,4}, **M. C. Lai**⁵, **P. Desarkar**^{6,7}, **N. Vitopoulos**⁸, **Y. Lunskey**⁶ and **J. S. H. Lam**^{7,8}, (1)Psychology, University of Toronto, Toronto, ON, Canada, (2)Margaret and Wallace McCain Centre for Child, Youth & Family Mental Health, Campbell Family Mental Health Research Institute, Centre for Addiction and Mental Health, Toronto, ON, Canada, (3)General Adult Psychiatry Division, Centre for Addiction and Mental Health, Toronto, ON, Canada, (4)Department of Psychiatry, Women's College Hospital, Toronto, ON, Canada, (5)Campbell Family Mental Health Research Institute, Centre for Addiction and Mental Health, Toronto, ON, Canada, (6)Azrieli Adult Neurodevelopmental Centre, Centre for Addiction and Mental Health, Toronto, ON, Canada, (7)Department of Psychiatry, University of Toronto, Toronto, ON, Canada, (8)Centre for Addiction and Mental Health, Toronto, ON, Canada

Background: Recent research shows high rates of co-occurrence of transgender and gender-diverse (TGD) identities and autism. Autism and TGD identities are each associated with increased rates of mental health difficulties. Adults with intersecting autism-TGD identities can have unique mental health needs exacerbated by multiple minority stress, and experience substantial barriers to accessing mental health services. Few studies have focused on this intersection in the Canadian context, and no studies thus far have focused on individuals seeking clinical care in Canada. This study investigates the characteristics of a sample of adults referred to gender-related clinical care services at the Centre for Addiction and Mental Health (CAMH), a large, tertiary mental health hospital in Toronto, Canada.

Objectives: To characterize the clinical profile of adults referred to the Adult Gender Identity Clinic (GIC) at CAMH, especially regarding the prevalence rates of autism and clinical characteristics between those with and without an autism diagnosis.

Methods: Demographic and clinical characteristics were extracted from the electronic medical records of 1195 adults (aged 18+) referred to the GIC between January 2020 and March 2023. Descriptive statistics were calculated. An independent samples *t*-test examined differences in age between autism and comparison groups. A chi-square test identified differences in sex-assigned-at-birth frequency between groups. A chi-square test assessed differences in gender dysphoria diagnosis frequency between groups. Months of intake were split into three-month intervals, and cross-tabulation and chi-square tests identified differences in frequency of adults with autism diagnoses referred to the clinic at each time-interval. **Results:** See Table 1 for demographic information. Frequency calculations indicated that 3.8% of individuals in the sample had received a clinical diagnosis of autism. The comparison group was significantly older than the autistic group, $t(55.6)=3.37, p=0.001$. There was no difference between the autistic and comparison groups in sex-assigned-at-birth, $\chi^2(3, N=1191)=0.01, p=0.988$. There was no difference in the prevalence of gender dysphoria diagnosis between the autistic and comparison groups, $\chi^2(1, N=1191)=1.07, p=0.300$. Cross-tabulation for autism diagnosis prevalence within each of the three-month windows is shown in Table 2. Results of the three-month test revealed overall significant differences in prevalence rates between the time-windows, $\chi^2(12, N=1195)=25.12, p=0.01$.

Conclusions: This study provides a starting point in characterizing autism and gender-diversity in adults in Canadian clinical contexts. The higher rate of autism diagnoses in this referred sample (3.8%) compared with the general Canadian population rate (~1%) emphasizes the importance of neuroaffirmative approaches to gender-related clinical care. Measuring autism solely based on categorical diagnoses prior to entering the gender-care clinic was a limitation, as it did not account for potential underdiagnosis of minoritized groups and those who received a diagnosis following being seen by the GIC. With disparities in accessing care experienced by autistic TGD people in mind, better characterizing those who currently have access to gender-related clinical care versus those without can inform future research and service quality improvement on reducing care barriers.

**406.335** Court and Tribunal Proceedings Involving Autistic Adults in England and Wales: Autistic Community and Justice System Professionals' Perspectives

R. Bagnall¹, **L. Crane**², **M. Mattison**³ and **K. L. Maras**⁴, (1)Psychology, Centre for Applied Autism Research, University of Bath, Bath, United Kingdom, (2)University of Birmingham, Birmingham, Birmingham, United Kingdom, (3)University of Chester, Chester, Cheshire, United Kingdom, (4)university of bath, bath, United Kingdom

Background: There is little empirical research on autistic individuals' experience of participating in court and tribunal proceedings in the Justice System. Even less is known about the impact and effectiveness of 'Special Measures' (a series of provisions in England and Wales that help vulnerable witnesses give their best evidence in court and help to relieve some of the stress associated with giving evidence) and other reasonable adjustments for autistic individuals in court and tribunal settings.

Objectives: 1. To explore the experiences of autistic people, those who support them (e.g., family, friends, carers) and justice system professionals in relation to participating in court and tribunal settings. 2. To examine how the presence (and absence) of Special Measures and other adaptations contribute to autistic people's experience of giving evidence in these justice settings.

Methods: Using qualitative surveys and semi-structured interviews, we examined the perspectives of autistic community members and justice system professionals regarding court and tribunal proceedings involving autistic adults. We recruited a total of 113 participants: (i) 67 autistic adults who participated in court and/or tribunal proceedings; (ii) 11 family members, friends, and/or carers who supported an autistic person through these processes and (iii) 35 justice system professionals who have worked with autistic people in these settings. Analysis of qualitative survey and interview data was conducted using reflexive thematic analysis.

Results: Many of the autistic people who took part in the study experienced significant challenges when participating in court and/or tribunal proceedings. Such proceedings were often described as highly emotionally demanding, prior to, during, and after court and tribunal hearings. The physical and social environments of justice system settings, as well as giving evidence, were frequently described as overwhelming; intersecting issues including sensory sensitivity, social-cognition, and communication. Participants described the disadvantage of unfamiliarity with justice system processes, language, and environments - heightened in cases where an autistic individual has no or limited legal representation and/or support. Participants (across groups) who had experience with Special Measures and other adaptations broadly believed these to be beneficial for many autistic people. For example, adaptations to the phrasing of questions, giving evidence remotely (or via live link) or using pre-recorded evidence were viewed as crucial enablers to giving evidence. However, the application of such adaptations can be impacted by a range of factors, from autism disclosure to practical implementation (such as technical difficulties). In criminal courts, some participants also expressed concerns about the potential distancing effects upon jurors when a witness/complainant is giving evidence remotely or pre-recorded evidence is used. There was broad agreement amongst participants that greater understanding of autism in the justice system is needed, as well effective autism training for professionals working within it.

Conclusions: Our findings indicate that many autistic people would benefit from support and/or adaptations prior to, during, and after court and tribunal proceedings. Given that participating in court and tribunal proceedings present often profound emotional, social-cognitive, communication and sensory challenges, many autistic people may be at risk of disadvantage when such support is absent.

406.336 Autism in Court: Simulated Criminal Court Proceedings with Autistic Adults, Justice Professionals and Mock Jurors.

R. Bagnall¹, L. Crane², M. Mattison³ and K. L. Maras⁴, (1)Psychology, Centre for Applied Autism Research, University of Bath, Bath, United Kingdom, (2)University of Birmingham, Birmingham, Birmingham, United Kingdom, (3)University of Chester, Chester, Cheshire, United Kingdom, (4)university of bath, bath, United Kingdom

Background: Little is known about autistic peoples' experiences of giving evidence in criminal courts, and even less so how 'Special Measures' (SMs) impact these experiences. SMs are a series of provisions aimed at supporting vulnerable people to give evidence in court proceedings in England and Wales, including adaptations such as a witness being able to give their evidence remotely via video link and the use of a registered intermediary (forensic communication specialist) to facilitate communication during questioning.

Objectives: The objectives of this study were to gain insight into autistic people's experience of providing evidence as mock witnesses in simulated criminal court proceedings; the impact of the presence (and absence) of SMs; and how autistic mock witnesses are perceived during such proceedings. We examined these issues from a range of perspectives: autistic mock witnesses; barristers; judges; intermediaries; and mock jurors.

Methods: We simulated the experience of giving witness evidence in a criminal case, in a realistic replica criminal court. Across a series of eight mock hearings, autistic adult mock witness participants (n = 8; 1 in each trial) provided evidence about a previous, live mock crime under examination by real-life, qualified, and experienced barristers (n = 7; seven barristers each participated in one trial and one barrister completed two trials). Proceedings were overseen by a retired judge (n = 3; two judges each completed two trials, and one judge completed four trials), observed by separate cohorts of mock juror participants (n = 99; average 12 jurors per trial). Half of the autistic mock witnesses (n = 4) gave evidence with the assistance of SMs (such as giving evidence remotely via video link) alongside individually tailored recommendations from intermediaries (n = 3; two intermediaries participated in one trial, and one intermediary in two trials). The remaining four autistic mock witnesses gave evidence without SMs. Qualitative data was collected from all participant groups in each trial using a range of written feedback, interview and focus group methods

Results: Autistic mock witnesses, barristers, judges, and intermediaries took part in researcher-led semi-structured interviews immediately after their mock hearing. To elicit further reflections on their experience, autistic mock witnesses also took part in later follow up video-elicitation interviews, where they viewed audio-video footage of when they gave evidence and reflected on their experiences. During and after the mock hearings, jurors completed written feedback forms (about their perceptions of the witness) and then participated in juror cohort focus groups. Reflexive thematic analysis of the dataset is currently being conducted by the research team. Findings will be ready by December and presented at INSAR 2025.

Conclusions: Participating in the Criminal Justice System presents a complex set of emotional, social-cognitive, communication and sensory demands for many autistic people, with adaptations potentially required for when they give evidence. From a range of key perspectives, this study will provide unique insights into how autistic people experience giving evidence in realistic mock criminal court hearings, the impact of SMs, and how they are perceived by jurors and legal professionals.

Poster Session

408 - Adult Outcome: Medical, Cognitive, Behavioral I

May 1st, 2025, 5:30 PM - 6:30 PM - Hall 4A

408.001 Perceptual Experiences of Autistic People with an Intellectual Disability and People with Williams Syndrome

A. Remington¹, C. Hamilton², E. Milne³, G. Scerif⁴, J. Brinkert⁵, **B. Irvine⁶**, F. Elise⁷ and E. Farran⁸, (1)UCL Centre for Research in Autism and Education, London, UNITED KINGDOM, (2)UCL Institute of Education, London, London, United Kingdom, (3)The University of Sheffield, Sheffield, United Kingdom, (4)Experimental Psychology, University of Oxford, Oxford, Oxfordshire, United Kingdom, (5)Centre for Research in Autism and Education, UCL Centre for Research in Autism and Education (CRAE), London, United Kingdom, (6)Centre for Research in Autism and Education, Centre for Research in Autism and Education (CRAE), UCL Institute of Education, University College L, London, United Kingdom, (7)Centre for Research in Autism and Education, CRAE, London, United Kingdom, (8)DevElop, University of Surrey, Guildford, United Kingdom

Background: Autistic people without intellectual disabilities have increased perceptual capacity: they can process more information at any given time compared to non-autistic people (Remington et al., 2009, 2012). Having an increased perceptual capacity can explain both positive and negative aspects of the autistic experience. For example, better performance on visual search tasks (e.g. Joseph et al 2009) yet increased distractibility and sensory overwhelm (Lewis & Stevens, 2023). Although, there is evidence for increased perceptual capacity in autism from both qualitative (Irvine et al., 2023) and quantitative studies (Remington et al., 2012), to this date studies have been limited to cognitively-able participants. Here, we examined first-hand accounts of perceptual experiences of a group of autistic people with intellectual disabilities, and a group of people with Williams Syndrome (WS). WS is a rare chromosomal disorder due to a deletion on chromosome 7. Like many autistic people, those with WS often experience sensory processing differences and an intolerance of uncertainty (Glod et al., 2019).

Objectives: We aimed to establish whether increased perceptual capacity is universal across the autistic spectrum (i.e. for autistic people both with and without intellectual disabilities) and whether it is specific to autism, or also experienced by people with Williams Syndrome (WS).

Methods: We adopted a participatory approach to investigate this issue: via advisors with intellectual impairment (both autistic and those with WS) and a neurodiverse research team. Five autistic adults with intellectual disabilities and five adults with WS (mean age of 30.8 years) took part in accessible, qualitative interviews together with a Trusted Adult. Prior to taking part all participants completed a research passport that assessed likes, dislikes, and daily routines. We conducted interviews using personalised questions based on answers provided in the research passport. All interviews were transcribed and analysed using reflexive thematic analysis (Braun & Clarke, 2022).

Results: Both groups expressed enjoyment of focussed attention, with autistic participants preferring multiple simultaneous inputs. Responses suggested increased perceptual capacity for autistic participants only. The sensory environment was reported to be anxiety-inducing for both groups and participants shared ways in which they actively managed the sensory environment.

Conclusions: This study gives preliminary evidence that increased perceptual capacity may be universal across the autistic spectrum, and specific to autism. Understanding differences in capacity offers more targeted suggestions to support sensory challenges. This is crucial to support flourishing in schools and workplaces. This research project also uniquely enabled the voices of autistic people with intellectual disabilities and people with WS. People with intellectual disabilities are currently often marginalised and excluded from research, and without studies like this we risk neglecting a vulnerable subsection of the neurodivergent community

408.002 Self-Reported Strengths and Talents of Autistic Adults

L. A. Lampinen¹, J. Singer¹, X. Wang¹, B. VanHook² and V. H. Bal³, (1)Rutgers University, New Brunswick, NJ, (2)Organization for Autism Research, Arlington, VA, (3)Graduate School of Applied and Professional Psychology, Rutgers University - New Brunswick, Piscataway, NJ

Background: Many adults express dissatisfaction with the diagnostic assessment process (Jones et al., 2014), and concerns have been cited regarding the lack of neurodiversity-affirming assessment methods (Harman et al., 2023). In part, this is due to instruments framing behaviors as symptoms causing impairment, overlooking the potential benefits that many autistic adults report associated with autistic features (e.g., DePape & Lindsay, 2016; Kapp et al., 2019; H. Lee et al., 2024; Russell et al., 2019). Systematically measuring autistic adults' strengths and talents during diagnostic assessment may improve satisfaction with the assessment process and inform diagnosis in a more neurodiversity-affirming manner. Historically, research has relied on caregiver-reported strengths (e.g., Howlin et al., 2009; Sabapathy et al., 2017; Warren et al., 2021; Wilkinson et al., 2022); more information on self-reported strengths is needed to inform instrument development and best assessment practices.

Objectives: To assess autistic adults' self-reported strengths and talents and examine overlap with questionnaires designed to evaluate strengths.

Methods: Participants included 127 legally-independent autistic adults recruited through SPARK Research Match (*Age*=35years, *SD*=10years; 51% female; 65% White; 50% diagnosed with autism in adulthood). Participants completed open-ended questions regarding strengths, along with questionnaires designed to capture various domains of strengths and difficulties (Table 1). Qualitative content analysis identified themes from the open-ended questionnaire. Differences in self-reported qualitative and quantitative strengths were examined by age of diagnosis (under 21 vs. over 21) and gender (male, female, and non-binary). Autistic team members collaborated on qualitative coding and data interpretation.

Results: Common themes emerging from the qualitative responses included cognitive/executive functioning (61%), character strengths (55%), creativity/artistic (52%), academic (33%), and interpersonal strengths (30%). Quantitative measures reflected strengths across categories related to creative achievement, character, self-determination, and autism-related strengths (Table 1). The number of qualitatively reported strengths did not differ by gender or age of diagnosis. Females and non-binary individuals reported more external recognition of talents in Visual Arts compared to males ($p=.0009$; Table 2). Non-binary individuals also reported greater recognition in Dance and Film compared to females and males ($p<.04$; Table 2).

Conclusions: Qualitative and quantitative data revealed a range of strengths and talents reported by autistic adults. Results from this study provide initial information on domains of strengths to examine in autistic adults, which will inform future research aimed at developing measures of strengths in this population. Notably, a range of strengths were reported that have not been highlighted in the extant literature, including advocacy, specific creative achievements, and interpersonal skills. Certain strengths endorsed by autistic adults may map onto DSM-5 diagnostic criteria for autism; for example, strengths related to communication and interpersonal skills may relate to DSM-5 A criteria, while sensory awareness, attention to detail, and repetitive work may be associated with DSM-5 B criteria. Given that autistic adults report both benefits and difficulties associated with autistic features (e.g., H. Lee et al., 2024), evaluating strengths associated with DSM-5 criteria, in addition to challenges, may inform diagnosis in a more neurodiversity-affirming manner. Gaps in existing measures and opportunities for measure development will be discussed.

408.003 Supports and Accommodations for Autistic College Students: A Self-Reported Study

A. Gladfelter¹ and **L. Abbott²**, (1)*Speech-Language Pathology, Northern Illinois University, DeKalb, IL*, (2)*Speech-language Pathology, Northern Illinois University, DeKalb, IL*

Background: Approximately 1 in 36 people are diagnosed with autism spectrum disorder (ASD) (CDC, 2023), but only 30 to 40 percent of autistic individuals have a co-occurring intellectual disability (Maenner et al., 2023). Given the majority of autistic individuals with average intelligence and the continuous increase in prevalence rates of autism, there are more autistic students entering higher education. Of those who decide to attend higher education, only about 38% graduate (Sanford et al., 2011). There is a significant lack of research on the autistic college student experience, specifically from the perspective of the autistic students.

Objectives: The purpose of this study is to gain insight from autistic college students about their college experience, by asking them directly, to identify challenges autistic students face in higher education, and to identify the supports and accommodations that are beneficial to autistic college students' success. The long-term goal is to further research on how to promote success in neurodivergent students in higher education.

Methods: Twenty-five autistic college students completed an eighteen-question Qualtrics survey that asked questions related to academic/social supports, accommodations, campus environment, self-advocacy, social participation, executive functioning, and sensory processing. Participants were 18 years or older, currently enrolled in a higher education institution, and had a formal diagnosis or self-diagnosis of autism spectrum disorder. Self-diagnosis was allowed, as many autistic college students have historically missed getting a diagnosis younger because of age-appropriate language and intellectual abilities, and autistic adult diagnosis is difficult/expensive to access. Participants were recruited through social media platforms (e.g., Facebook, Reddit), organization websites, and autism-specific college programs. Data was collected using Qualtrics, an online survey platform, and analyzed using descriptive statistics, as well as qualitative methods to analyze open-ended questions.

Results: The majority of autistic students rated the following accommodations as "helpful" or "very helpful": extended time on tests, video/audio recordings of lectures, notetaker, housing accommodations, flexibility for absences. They rated the following supports as "helpful" or "very helpful": professors, parents, friends, academic advisors, disability support services. Students identified the following challenges: completing assignments on time, staying organized, planning assignments, handling heavy coursework, understanding class expectations. A majority of participants felt they had to make a choice between being successful academically or being social, felt lonely, and felt their school could be doing more to make autistic students feel included on campus. Additionally, a majority of participants did not feel comfortable disclosing their autism diagnosis to their peers and did not feel like their peers understood autism.

Conclusions: There are several identified supports and accommodations that help autistic students through college, but also many barriers and challenges that prevent autistic students from being successful. More self-reported studies need to be conducted to continue to learn about how higher education institutions can help support their neurodiverse students both academically and socially.

408.004 Cognitive Abilities of Autistic Adults and Intellectual Disability in Relation to Age: Accelerated Development, Stable Progression, or Continued Age-Related Trajectories?

M. Melamed^{1,2}, **M. Zemach³**, **D. Haham⁴**, **D. A. Zachor⁵**, **E. Ben-Itzhak⁶**, **S. Shnitzer Meirovich³** and **H. Lifshitz⁴**, (1)*The Autism Center, ALUT-Israeli organization for children & adults with ASD, Givataym, Israel*, (2)*The Bruckner Autism Research Center, Ariel University, Ariel, Israel*, (3)*The Academic College Levinsky-Wingate, Tel-Aviv, Israel*, (4)*Education Faculty, Bar Ilan University, Ramat Gan, Israel*, (5)*ALUT The Israeli Society for autistic children, Tel-Aviv, Israel*, (6)*Bruckner Center for Autism Research, Department of Communication Disorders, Ariel University, Ariel, Israel*

Background: Research on long-term cognitive trajectories in autistic adults with intellectual disability (ID) remains limited, and their specific aging patterns are not well understood. This cross-sectional study examines cognitive changes from young to late adulthood, drawing on three neurocognitive disorder models: Accelerated Aging, Stable, and Continuous Trajectories. While cognitive stability is typical in the general population until decline begins at ages 50-60, individuals with ID tend to show continuous improvement in both verbal and non-verbal abilities until middle age (40-50), followed by stability, in line with the Compensation Age Theory. This study explores whether similar or distinct patterns emerge in autistic adults with ID.

Objectives: To assess age-related trajectories of nonverbal cognitive ability, receptive and expressive language, and adaptive behavior in three age cohorts of autistic adults with ID, in relation to the above three models of cognitive change with age.

Methods: Seventy-eight participants (24 females), aged 25.9 to 63.3 years ($M=41.95/SD=9.91$), previously diagnosed with autism based on their medical records, and currently residing and working in sheltered environments for autistic adults with high support needs, were enrolled in the study. All participants were assessed for adaptive skills using the Vineland Adaptive Behavior Scales (VABS) and for autism trait intensity with the Social Responsiveness Scale. They were divided into three age groups (25-35, 35-45, and 45+), which were equivalent in autism trait intensity. Nonverbal reasoning ability was evaluated using the Test of Nonverbal Intelligence (TONI), while verbal intelligence was assessed through the SHEMESH naming skills test and the Peabody Picture Vocabulary Test for language comprehension.

Results: Since the distribution of test scores deviated significantly from normality, non-parametric analyses were conducted. Kruskal-Wallis tests revealed significant differences between age groups for TONI ($p < .001$), PPVT ($p = .045$), and VABS ($p = .023$) scores, but not for SHEMESH scores ($p = .074$). Additional Mann-Whitney tests examining differences between the two groups indicated that TONI scores were significantly higher in the 35-45 cohort compared to the 25-35 cohort ($p < .001$) and remained stable in the 45+ cohort ($p = .498$). The 45+ cohort scored significantly lower on the PPVT compared to the 35-45 cohort ($p = .016$). Although SHEMESH scores did not differ overall, significant declines were observed in the 45+ cohort compared to the 35-45 cohort ($p = .036$). VABS scores also declined significantly in the 45+ cohort compared to the 35-45 cohort ($p = .009$).

Conclusions: The cognitive profile of participants revealed divergent age-related patterns: verbal test scores declined in late adulthood, while nonverbal test scores improved in young adulthood and remained stable in late adulthood. These findings suggest a decline in verbal abilities and an increase followed by stability in nonverbal abilities in late adulthood, consistent with the Continuous Trajectory Model for verbal decline and the Compensation Age Theory for nonverbal improvement. However, since only the TONI assessed nonverbal ability, these findings should be interpreted with caution. The overall findings suggest distinct cognitive aging trajectories, which could be crucial for developing targeted interventions aimed at enhancing functioning in older adults.

408.005 Psychological Needs, Autonomous Work Motivation, and Job Satisfaction: A Moderated Mediation Analysis in Autistic and Non-Autistic Employees

Y. Goldfarb^{1,2}, E. Gal¹, L. Teveje¹ and O. Golan³, (1)Department of Occupational Therapy, University of Haifa, Haifa, Israel, (2)Faculty of Business Administration, College of Law and Business, Ramat-Gan, Israel, (3)Department of Psychology, Bar-Ilan University, Department of Psychology, Ramat-Gan, ISRAEL

Background: Self-Determination Theory (SDT) of motivation has been widely substantiated as a useful framework for understanding and promoting employment integration of adults in the general population. SDT theorizes that: (a) all employees share the aspiration to satisfy three work-related psychological needs: autonomy, social-relatedness and competence. Satisfaction of these needs promotes Autonomous Work Motivation (AWM) and its positive outcomes (b) AWM which is driven by choice leads to positive employment outcomes such as job satisfaction (Gagné & Deci, 2005). Recent research supported SDT's utility in addressing both personal and environmental factors affecting work motivation in autistic adults (Goldfarb et al., 2022, 2023).

Objectives: (1.) To examine an SDT-based theoretical model in autistic (AUT) vs. Non-Autistic (NA) employees, hypothesizing that satisfaction of the work-related psychological needs will lead to higher AWM, which will in turn lead to increased job satisfaction. (2.) To examine if this model is moderated by diagnosis, i.e. if the effects differ between autistic and non-autistic employees (Figure 1).

Methods: Data was collected from a sample of 44 autistic (6 females, aged 19-53), and 45 NA (11 females, aged 18-54) employees who completed a cross-sectional survey. Self-reports included the Basic Psychological Need Satisfaction-Work domain; the Multidimensional-Work-Motivation Scale (Relative Autonomy Index); and the Minnesota Job Satisfaction Questionnaire. A moderated mediation analysis using PROCESS for SPSS (Model 8) was computed, predicting job satisfaction by each of the three work-related psychological needs, with AWM as the mediator, and group (Autistic/NA) as the moderator, controlling for age.

Results: The predictive model for *relatedness* explained 42.4% of the variance in job satisfaction ($R = 0.65$, $F(5, 83) = 12.21$, $p < 0.001$). The direct effect was significant in both groups, but stronger for the NA group. The mediation effect was moderated by group and significant only for the autistic group. For *autonomy*, the model explained 33.2% of the variance ($R = 0.58$, $F(5, 83) = 8.25$, $p < 0.001$). A direct effect was significant in both groups, but stronger for the NA group. No significant indirect effects were found. For *competence*, the model explained 26.1% of the variance ($R = 0.51$, $F(5, 83) = 5.87$, $p < 0.001$). The direct effect was moderated by group, and significant only for the NA group. The mediation effect was moderated by group and significant only for the autistic group. Results are presented in Table 1.

Conclusions: Findings confirm that the satisfaction of work-related psychological needs is essential for job satisfaction, with notable differences between autistic and non-autistic employees. Non-autistic employees showed stronger direct effects, while autistic employees exhibited significant indirect effects via autonomous work motivation, particularly for relatedness and competence. These results suggest that understanding and promoting AWM may be especially beneficial for autistic employees, highlighting the importance of personalized approaches to workplace motivation and satisfaction for neurodiverse populations.

408.006 A Home That Meets the Needs of Autistic Adults: What Factors in the Living Environment Should be Considered?

A. M. Nader¹, E. St-Jean², M. Giroux³, L. Guerrero³, B. Forgeot d'Arc³, V. Lasalle⁴, I. Courcy⁵ and R. Godbout¹, (1)Psychology, Université de Montréal, Montréal, QC, Canada, (2)Psychiatry, Université de Montréal, Montréal, QC, Canada, (3)Aut'Créatifs, Montréal, QC, Canada, (4)Faculty of Design, Université de Montréal, Montréal, QC, Canada, (5)Sociology, Université de Montréal, Montreal, QC, Canada

Background: Housing has been identified as a priority by autistic people in Canada and elsewhere in the world. The challenge is considerable, given the lack of available environments adapted to the needs of autistic adults and the lack of knowledge that takes into account the plurality of needs of this population. So far, studies have focused on the built environment and mainly in the context of group homes, with limited understanding of the needs of autistic adults living independently. Most studies have relied on questionnaires and have treated built and social environments separately, without considering the intersection of all environmental factors.

Objectives: This study aims to capture first-person perspectives of autistic adults on: 1) what constitutes an optimal living environment, including both the built and the social environment aspects; 2) how these aspects intersect together. Grounded in a transdisciplinary perspective, this project involves researchers with complementary expertise (architecture, design, social sciences, medical sciences) alongside autistic collaborators.

Methods: Interviews were conducted with 42 verbal autistic adults (21-60 years; 58% woman, 35% men, 7% other gender identity) from diverse living situations, to seek their views on what constitutes a home that would meet their needs. The inclusive interview process allowed for various communication methods, pre-sent questions, visual aids, and opportunities to provide additional input up to 7 days after the interview. Interviews focussed on 5 main domains: 1) appreciation of the current living environment, 2) the ideal home, 3) challenges and obstacles, 4) individual strengths and facilitators and 5) neighborhood. A thematic qualitative content analysis was conducted using a person-environment fit model. Coding was performed using NVivo software by two members of the research team and discrepancies were resolved by mutual agreement.

Results: The intersection of individual factors (eg. sensory perception) with the built and social environments led to 3 key themes encompassing 10 components for designing homes adapted to the needs of autistic adults: 1) access to adapted living spaces (a. sensory comfort, b. diverse communication options, c. places that are easy to understand and find one's way around, d. access to support and professional services, e. proximity to nature and green spaces); 2) the possibility of making choices (a. increased power to act, b. access to a greater diversity of housing models, c. access to safe, salubrious and affordable housing); 3) sense of community belonging (a. supportive social environment, b. opportunities to meet others).

Conclusions: This study highlights what autistic adults consider to be important for their wellbeing in the context of housing, showing how physical and social components intersect together. It underlines the importance of conceiving housing options and supports that foster self-determination and social inclusion. It is possible as well as imperative to consider autistic individuals' views and experiences for designing home *with* and *for* autistic adults. The findings provide decision-makers with solutions for creating living spaces where each autistic individual can feel safe and flourish.

408.007 A Longitudinal Study of Aggression in People with Autism and Other Neurodevelopmental Disabilities

D. Gohari¹, H. K. Schiltz² and C. Lord³, (1)Semel Institute for Neuroscience and Human Behavior, Los Angeles, CA, (2)University of Washington, Los Angeles, CA, (3)UCLA Semel Institute for Neuroscience and Human Behavior, Los Angeles, CA

Background:

Aggression is prevalent in autism spectrum disorder (ASD) and other neurodevelopmental disabilities (NDDs), yet longitudinal research tracking aggression over time is lacking. Most existing studies on aggression focus on childhood and use parent-reported, cross-sectional data, underscoring the need for multi-method assessments of aggression beyond childhood. Certain factors are known to correlate with aggression, including fewer adaptive skills, sensory difficulties, self-injury, ADHD symptomatology, and restricted and repetitive behaviors (RRBs).

Objectives:

(1) to characterize rates of aggression at various developmental time points (toddlerhood: age 2; school-age: age 9; and emerging adulthood: age 18) using a composite score based on clinician observation, clinical interview, and parent-reported questionnaire; (2) determine patterns of changes in aggression over time; (3) identify factors related to various trajectories of aggression over time; and (4) examine whether the presence of early aggression is predictive of aggression later in life.

Methods:

This study leverages data from 254 participants, recruited from North Carolina, Illinois, and Michigan. Participants with a range of cognitive abilities are included: 39.9% were classified as more-cognitively-abled (MCA; IQ ≥ 70) and 60.1% were classified as less-cognitively-abled (LCA; IQ < 70). Scores on the E2 code of the Autism Diagnostic Observation Schedule (ADOS), items 81 and 82 on the Autism Diagnostic Interview—Revised (ADI-R), and the Aggression Subscale on the Child Behavior Checklist (CBCL), generated a binary *Aggression Composite* score for each time point (age 2, 9, and 18). One-way ANOVAs examined factors related to aggression, both within and across time points (Table 1). Logistic regression analyses determined the extent to which early aggression predicted later aggression, controlling for cognitive ability and autism symptoms severity.

Results:

Fifty-four percent, 69%, and 42% of the full sample showed aggression in toddlerhood, school age, and emerging adulthood, respectively. LCA individuals had higher rates of aggression in school age (80%) and emerging adulthood (58%) compared to MCA individuals (48% and 22%, respectively).

Longitudinal aggression profiles, derived from *Aggression Composite* scores, provide insight about aggression prevalence, change in aggression over time, and early aggression predicting later aggression. A total of six profiles emerged: *Absent*, *Late Decreasing*, *Early Decreasing*, *Persistent*, *Increasing*, and *Transient* (Table 1).

Across ages 2, 9, and 18, distinct patterns of change were found: 31% displayed persistent aggression, 25% increased, 23% decreased, and 13% never displayed aggression. Higher autism symptoms, lower verbal IQ (VIQ), nonverbal IQ (NVIQ), and fewer adaptive skills correlated with more aggression cross-sectionally. Nonverbal IQ and RRBs related to aggression longitudinally, such that people in *Decreasing* or *Absent* profiles had higher NVIQ and fewer RRBs than those with *Persistent* or *Increasing* profiles. Finally, participants with aggression at 9 were almost four times likelier to exhibit aggression at 18.

Conclusions:

Aggression is common in autism and NDDs, peaking around age 9, and declining in emerging adulthood. Patterns of change varied widely in our sample, with evidence that higher NVIQ and fewer RRBs may be protective. Findings have implications for clinical practices, highlighting important developmental periods and high-risk subgroups.

408.008 Leadership Perception and Development in Autistic Individuals**Z. Myszko, J. Bragger and L. Lakusta, Psychology, Montclair State University, Montclair, NJ**

Background: Unemployment and underemployment rates within the autistic population are high, even though many have attained education and have characteristics that qualify them for advanced positions (Lorenz & Heinitz, 2014; Chen et al., 2015). While there are negative stereotypes about autistic individuals in the workplace and assumptions that they would not make good leaders (Praslova, 2021), there are currently autistic individuals in leadership roles (Williams et al., 2024), and little research has investigated how they understand leadership and what kind of leaders they are. Further, research has shown that servant leadership (SL) may be an effective leadership style (Banks et al., 2018; Hoch et al., 2018), leading to the inclusion of SL principals and developmental experiences in some training programs. However, no research has investigated what leadership styles autistic leaders practice and whether SL will benefit autistic leaders within their organizations. If common leadership training programs focus on developing a certain type of leader based on neurotypical strengths, this training may not be useful to – and may even be detrimental for – the autistic population.

Objectives: Determining whether autistic individuals can discern leadership behaviors and the types of leadership behaviors they are likely to practice will be instrumental in promoting inclusivity in the workplace, creating training programs that adapt to the needs of this population, and enabling upward mobility within organizations. These goals led to the questions: (1) How do autistic adults currently in leadership roles understand leadership? (2) Do autistic adults currently in leadership roles tend to identify as a certain type of leader? and (3) Does scoring higher with regard to particular characteristics on the Autism Spectrum Quotient (AQ) relate to the leadership styles of autistic leaders?

Methods: In this exploratory study, 34 autistic adults in leadership positions (11 women, 32.4%) completed an online survey that included a Match-to-Sample (MTS) task and two self-report questionnaires to assess leadership understanding, and eight leadership style self-report questionnaires.

Results: Using a one-sample t-test it was determined that participants were able to identify SL behaviors above and beyond chance on the MTS task, $t(32) = 8.19, p < .001$. Descriptives revealed that participants most often self-identified as servant leaders on the leadership style measures (Please see Table 1 for a complete list of descriptives). SL was negatively associated with difficulty imagining and positively correlated with attention to detail, difficulty with social skills, difficulty with switching attention, and overall AQ scores.

Conclusions: The results indicate that autistic leaders understand leadership implicitly and they may prefer to practice and develop as servant leaders. These findings are an important contribution to the leadership field and suggest that more autistic people should be in leadership positions. Autistic leaders are employed worldwide, and it is necessary to understand their perspectives on leadership in order to create a more accepting and accommodating workplace, as well as to facilitate their growth. Understanding more about how autistic leaders view leadership and their own leadership behaviors is the first step towards realizing these goals.

**408.009 A Qualitative Study and Evocative Auto-Ethnography of Intersectional Concordance in Research: Perspectives of Black Autistic Adults****A. Tolliver¹ and A. M. Davis², (1)Johns Hopkins University, Baltimore, MD, (2)Disability Health Research Center, Johns Hopkins School of Nursing, Baltimore, MD**

Background:

The field is nascent in understanding how intersectional concordance (i.e., Black and autistic) has an impact on the autistic person. Because minimal literature exists on this topic and multiply marginalized autistic adults are less involved in research it is important to better understand concordance bidirectionally.

Objectives:

This evocative auto-ethnography + qualitative analysis will expose the bidirectional viewpoints on interviewer/researcher- research participant concordance in the context of a qualitative interview on structural racism, structural ableism and intersectionality in Black autistic youth and young adults (n=10).

Methods:

Ten autistic adults, ages 18 to 35 took part in a qualitative interview focused on exploring experiences for Black autistic adults (e.g., healthcare, housing, education). These participants were interviewed by a Black autistic research assistant who disclosed at the start of the interview her intersectional identities. Participants could opt in to completing a follow-up concordance survey through Qualtrics and compensated with a \$10 e-gift card.

The open ended responses were based on the following inquiries:

1. Were there aspects of this interview resonated with you the most? Please describe.
2. How was the experience for you knowing that the interviewer was also someone on the autism spectrum?
3. How was the experience for you knowing that the interviewer was Black and also autistic?
4. What are your thoughts on having someone autistic be an interviewer of you in the future? How about Black and autistic (a researcher engaging you who has these identities)?
5. On a related topic, how would you feel about having a therapist or doctor who is also autistic?

Data will be analyzed through open coding, refining of codes, theme development and finalization iteratively to ensure final themes best reflect the participants' responses.

Results:

Results are forthcoming. All data collection will conclude by early December 2024 and analysis of data will conclude by March 2025. All findings will be prepared and ready for presenting at INSAR 2025. Results will be based on Evocative Autoethnography whereas the researcher reflecting on their own experiences, emotions, and personal narratives related to the research topic. The evocative aspect of autoethnography emphasizes personal storytelling, inviting the reader to engage emotionally. Cultural contextualization will also ensue, as while the focus is on the self, the researcher connects their personal stories to broader cultural, social, or political contexts. Combining evocative autoethnography with qualitative open-ended responses will offer a rich, dynamic approach to research that deepens both personal insight and collective understanding. Further through triangulation, the researcher's evocative autoethnography will provide a deep, personal lens, while qualitative open-ended responses from participants offer external validation or contrast. By comparing and contrasting the researcher's narrative with participant responses, the study becomes more robust and reflective of multiple viewpoints.

Conclusions:

This research will feature the perspectives of Black autistic adults who were interviewed by a Black autistic researcher along with an autoethnographic sharing of a Black autistic researcher. These findings will provide insights into the research experience of autistic people with concordant identities in a dynamic and insightful manner.

408.010 A Qualitative Study of the Experiences of Autistic Adults Taking Part in a Co-Produced Randomized Controlled Trial of Sertraline Vs. Placebo for Anxiety

J. E. Norris¹, A. X. Realpe², A. Lorenc³, L. Cotton¹, D. Rai³ and N. Mills³, (1)Centre for Applied Autism Research, University of Bath, Bath, United Kingdom, (2)University of Bristol, Bristol, United Kingdom, (3)Population Health Sciences, Bristol Medical School, University of Bristol, Bristol, United Kingdom, (4)Bristol Trials Centre, University of Bristol, Bristol, Bristol, United Kingdom

Background:

Randomized controlled trials (RCTs) provide gold-standard evidence for effective treatments. Study integrity and statistical power to answer the research question depends on participants not only agreeing to take part, but continuing until the end of the study. Poor participant experience can also lead to drop-out, contributing to mistrust in science, of particular importance within the autism community. Autism-specific factors such as difficulties processing uncertainty (a key feature of trials, e.g., blinding and randomization) mean that recruitment and retention issues are anticipated with this population. The STRATA RCT aimed to assess whether sertraline is an effective treatment for anxiety in autistic adults (placebo-controlled; blinded). The study was co-produced with an Autistic Advisory Group. Qualitative research in the form of 1:1 interviews was carried out to explore the decision making process of participants, and their experiences of the study and the intervention.

Objectives: To understand participants' motivations for i) deciding to take part, ii) continuing participation throughout the study, and iii) feedback on their experiences of trial communication and processes, including experiences of taking the study medication.

Methods:

Data from 63 interviews with STRATA study participants from all UK study sites were thematically analyzed. Participants and interviewers were blinded to treatment allocation.

Results:

Interviewees' average age was 36.35 years (range=19-70), with the majority being of White ethnicity (N=7 other). Findings showed that most reported altruistic motivations for participation, such as helping with autism and mental health research, as well as personal reasons, including receiving support with their own anxiety. Participants wished to complete 12 months in the study as they felt they had made a commitment to do so, and valued the importance of completeness of data collection to successful research. Placebo-control and blinding processes were well accepted, and some participants experienced benefits in terms of improvements to their own mental health whilst in the study. Feedback about trial processes and communication was largely positive, including praise for the communicative approach and care shown by the study teams, and an appreciation for flexibility (e.g., appointment times and meeting methods, as well as judgement-free rescheduling in case of missed appointments). However, some challenges were also noted, including experiences of medication side effects, and a few participants finding aspects of the standardized questionnaires difficult (e.g., responding about symptom frequency). However, some noted that the combination of the questionnaires with a study appointment helped them to provide context to how they were feeling.

Conclusions: Findings show that autistic adults wish to contribute to the evidence base regarding treatments for their mental health, and may be motivated to continue in the study to honor that commitment, as well as for reasons of scientific/personal curiosity. Concerns about blinding tended to be outweighed by these motivations. The results highlight that co-produced study design, including a focus on person-centered care can help to build a strong professional relationship between research staff and participants, contributing to successful recruitment and retention in RCTs with autistic people.

408.011 A Retrospective Chart Review of Late-Diagnosed Autistic People: Demographic and Clinical Variables

A. Porthukaran¹, A. Tafler¹, A. Li¹, K. Jackson¹, P. Desarkar², N. Fernandes³, H. Y. Lin¹, L. Man¹, A. Palikucin¹, A. Thakur¹ and Y. Lunskey¹, (1)Centre for Addiction and Mental Health, Toronto, ON, Canada, (2)Department of Psychiatry, University of Toronto, Toronto, ON, Canada, (3)Centre for Addiction and Mental Health, Toronto, ON, Canada, (4)Azrieli Adult Neurodevelopmental Centre, Centre for Addiction and Mental Health, Toronto, ON, Canada

Background: While autism is typically diagnosed in childhood, many people are not identified during this time and are instead diagnosed in adulthood. Some studies have reported increased mental and physical health challenges in those diagnosed in adulthood (see Huang et al., 2020 for a review), but this population is not well understood. Late diagnosis can follow misdiagnosis, and often indicates that proper accommodations are not provided in the developmental period. Additionally, late diagnosis is more prevalent among certain groups including women, gender diverse people, those of low socioeconomic status, and ethnically diverse peoples (Rutherford et al., 2016; Brugha et al, 2011).

Objectives: We present data from a retrospective chart review from the Adult Neurodevelopmental Services at the Centre for Addiction and Mental Health in Toronto, Canada. This clinic offers a publicly funded autism diagnostic service for any adult living in Ontario. The aim of this project is to characterize those given a diagnosis of autism in adulthood. We examine variables including sex and gender, employment status, previously diagnosed mental health conditions, co-occurring physical health conditions, and medication usage.

Methods: This chart review examined all adults diagnosed with autism at the hospital as part of the outpatient service in 2023 (n = 183). These assessments did not include those with intellectual disability. As this was a retrospective review, data was gathered by reviewing consultation notes in medical charts of assessments completed by psychiatrists and psychologists at the clinic. Information was also gathered from a self-reported health equity questionnaire completed at intake used by the hospital.

Results: Half of the autistic adults were between the ages of 18-29, while the next largest segment was the 30-39 group (28%). Sixty-two percent of the autistic adults were assigned female at birth, and 48% identified as a woman, 3% as genderfluid, 6% as transgender, and 14% as non-binary. Only 57% were in full-time employment or enrolled in a post-secondary program. Most (81%) had at least one co-occurring mental health condition and 58% had co-occurring medical conditions. Sixty-four percent were taking at least one medication.

Conclusions: Unlike samples of children diagnosed with autism, the autistic group in this sample were predominantly female (sex assigned at birth) and nearly one quarter were gender diverse. Compared with the population at large, the autistic people in this review had significantly higher rates of mental and physical health conditions. Other unique aspects of this population will be explored. This study highlights specific variables that may be linked with missed diagnosis in childhood (e.g., gender, diagnostic overshadowing, other demographic variables). Implications for the assessment, diagnosis, and outcomes of late-diagnosed autistic people will be discussed.

408.013 A Self-Directed Behavioral Executive Skills Program for Autistic Youth and Young Adults

D. A. Samelson¹, L. Sneed² and B. Pfingston³, (1)Clinical Excellence, Catalight Foundation, Walnut Creek, CA, (2)Research Institute, Catalight, Walnut Creek, CA, (3)Research Institute, Catalight, Walnut Creek, CA

Background: Challenges with executive functioning (EF) skills are a barrier to wellbeing for autistic youth and adults (Wong et al., 2022). EF skills are a set of mental skills including mental manipulation of ideas, planning, preceptive taking, cognitive inhibition, and flexibility (Diamond, 2013). Wellbeing is the measure of a person's overall happiness, satisfaction, and positive outlook on life (Thompson-Hodgetts). Compass-Behavioral is a "coaching" program that utilizes behavioral principles to teach EF skills to autistic youth and adults (ages 12+) with the goal of improving wellbeing. Autistic individuals work directly with their Compass-Behavioral coach to set personal goals around FE skills that are important to their wellbeing.

Objectives: We conducted two studies to understand how a behavioral intervention that emphasizes self-determination in a person-centered framework could improve EF skills and wellbeing in autistic youth and young adults. Study 1 evaluated the effectiveness of Compass-Behavioral at improving wellbeing by improving specific EF skills (e.g., perspective taking). Study 2 compared the effectiveness of Compass-Behavioral to typically delivered tiered applied behavioral analysis (ABA) at improving wellbeing in autistic youth.

Methods: In Study 1, 376 autistic individuals (age range 11 to 26; mean age 16.08 years; 45.5% = female, 55% = male) participated in Compass-Behavioral. EF skills were measured pre-and post-participation with self-report measures for each EF skill (e.g., perception taking) plus sleep. Wellbeing was measured by the Catalight Youth or Adult Wellbeing Scales. To gather qualitative information, a post-program survey was completed. Study 2 compared wellbeing, goal attainment, and length of stay (LOS) in a sample of 60 autistic youth. Thirty youth ($M_{age} = 16$ years) received Compass-Behavioral, and 30 youth ($M_{age} = 14$ years) received ABA. Groups were matched on baseline adaptive abilities.

Results: In study 1, we found sleep and all EF skills (self-observation, self-advocacy, communicating socially, preceptive taking, self-management, understanding vulnerabilities) improved significantly. Wellbeing significantly improved ($p < .001$) Average personal goal attainment was 83%. Qualitative comments indicated high level of satisfaction ("Would highly recommend.") and usefulness of EF skills ("I understand my behaviors and other people's behaviors better.") Negative comments were uncommon and tended to focus on when to use skills ("I might use [skills] later but not now") or which EF skills to pick ("hard for me to tell which elements I should pick.") Dropout rate was low.

Study 2: Wellbeing scores increased in Compass-Behavioral participants but not for ABA participants. Compass-Behavioral participants achieved significantly more goals than ABA participants. Length of stay was significantly lower in the Compass-Behavioral group.

Conclusions: EF skills are a barrier to wellbeing for autistic youth and adults. Compass-Behavioral resulted in an improvement in EF skills, sleep and wellbeing for autistic youth and adults. Compared to ABA, Compass-Behavioral was more effective in improving wellbeing and goal attainment over a shorter length of time. Participants in Compass-Behavioral reported the program was effective and enjoyable. While additional research is needed to examine long-term benefits, Compass-Behavioral may be an option for autistic youth and adults seeking to improve EF and wellbeing.

408.014 Acceptability and Feasibility of a Primary Care Health Check for Autistic Adults in England: Evaluation Findings from Questionnaires and Interviews

H. Merrick¹, H. Taylor², C. Wilson², C. Scarlett³, S. Moss⁴, C. Buckley⁵, T. Finch⁶, S. Al-Ashmori⁷, S. A. Cooper⁸, C. Fernandez-Garcia⁷, T. Robinson², S. Haining⁹, R. F. Lees¹⁰, N. G. Lennox¹¹, T. Nicholls¹², M. R. Osborne¹³, C. Nicolaidis¹⁴, D. M. Raymaker¹⁴, A. Urbanowicz^{15,16}, J. M. Wason⁷, B. Ingham¹⁷ and J. R. Parr², (1)Population Health Sciences Institute, Newcastle University, Newcastle upon Tyne, Tyne and Wear, United Kingdom, (2)Population Health Sciences Institute, Newcastle University, Newcastle upon Tyne, United Kingdom, (3)North Tyneside CCG, Newcastle-upon-Tyne, United Kingdom, (4)Northumberland CCG, Newcastle upon Tyne, United Kingdom, (5)The Royal College of General Practitioners UK, London, United Kingdom of Great Britain and Northern Ireland, (6)Nursing, Midwifery and Health, Faculty of Health and Life Sciences, Northumbria University, Newcastle upon Tyne, United Kingdom, (7)Population Health Sciences Institute, Newcastle University, Newcastle upon Tyne, Tyne and Wear, United Kingdom, (8)School of Health and Wellbeing, University of Glasgow, Glasgow, Glasgow, United Kingdom, (9)North East England Commissioning Support, Newcastle upon Tyne, Tyne and Wear, United Kingdom, (10)Newcastle University, Newcastle upon Tyne, United Kingdom, (11)MRI/UQ, The University of Queensland, Brisbane, QLD, Australia, (12)National Autistic Society, London, Greater London, United Kingdom, (13)South Tyneside's Kids And Young Adults Klub - Special needs support group (KAYAKS), South Shields, United Kingdom, (14)School of Social Work, Portland State University, Portland, OR, (15)School of Health and Social Development, Deakin University, Burwood, VIC, Australia, (16)School of Global, Urban and Social Studies, RMIT University, Melbourne, VIC, Australia, (17)Cumbria, Northumberland, Tyne & Wear NHS FT, Newcastle upon Tyne, Tyne and Wear

Background: Autistic people commonly have physical and mental health conditions and frequently experience barriers to accessing healthcare, contributing to problems identifying and treating health conditions. These factors may lead to increased and earlier morbidity, and lower average life expectancy. Health checks specifically designed for autistic people, incorporating a pre-appointment questionnaire and adjustments to healthcare, may help overcome these barriers and reduce health inequalities.

Objectives: This study reports the acceptability and feasibility of a primary care health check for autistic adults living in England, delivered as part of a Randomised Controlled Trial (RCT).

Methods: Practices were randomly allocated to deliver health checks, or treatment as usual; the RCT primary outcome is unmet health needs identified and met. Autistic adults, carers/supporters, and primary care clinicians who received or participated in health checks completed evaluation questionnaires for each health check. A purposive sample was selected for semi-structured interviews to gain deeper insights into their experiences. Non-clinical primary care staff were also invited for interview. Questionnaire data was analysed using descriptive statistics and Fisher's exact tests to explore subgroup differences. Thematic analysis was undertaken with interview transcripts.

Results: 95 health checks were completed. Evaluation questionnaires were received from 81 autistic adults, 11 carers/supporters, and 71 questionnaires from 18 clinicians delivering the health check. Most autistic adults found the health check pre-appointment questionnaire acceptable to use and helpful preparation for the appointment. Reasonable adjustments for the appointment were requested by 32% of autistic people; nearly all found them beneficial. Twenty-five (31%) autistic adults reported they took a carer/supporter to the appointment. Carers/supporters helped with overcoming barriers (e.g. supporting communication, reducing anxiety). Clinicians' responses indicated the health check process was feasible to deliver, with most (85%) creating a Health Action Plan during the appointment to summarise the identified needs and subsequent actions. For autistic adults, comparative analysis showed no significant differences across all subgroups (e.g. age, number of health conditions). Participants with more health conditions were more likely to prefer annual health checks, while those with fewer conditions were more likely to prefer less frequent checks ($p=0.037$).

Interviews with 24 autistic adults, 5 carers/supporters, 11 clinicians and 4 non-clinical primary care staff revealed overarching themes around the practicality of delivering health checks, facilitators and barriers to delivery (individual characteristics, setting, role of carers/supporters), health check outcomes (intervention, advice, support, and reassurance) and barriers to future implementation (capacity, funding). Primary care staff emphasised the value of health checks in identifying support needed by autistic adults, although some noted challenges for future implementation, including appropriate funding, patient engagement, and current primary care capacity pressures. Some autistic people and clinicians noted the health check had identified new health and/or care needs.

The results of the RCT will be available in 2025 and presented, including the clinical and cost effectiveness of the health check.

Conclusions: Primary care health checks for autistic adults are acceptable and feasible for use in health care. Both autistic adults and healthcare professionals recognised the potential value of these checks in improving healthcare access and outcomes.

408.015 The Influence of Income, Disability, and Employment on Quality of Life and Health Outcomes in Older Autistic and Non-Autistic Adults

S. Bittner¹, L. G. Klinger², D. V. Chan³ and C. Harrop⁴, (1)Department of Allied Sciences, University of North Carolina at Chapel Hill, Chapel Hill, NC, (2)TEACCH Autism Program; Psychiatry, UNC TEACCH Autism Program, Chapel Hill, NC, (3)Allied Health Sciences, University of North Carolina at Chapel Hill, Chapel Hill, NC, (4)Department of Allied Health Sciences, University of North Carolina - Chapel Hill, Chapel Hill, NC

Background: Autistic individuals frequently encounter barriers to securing and maintaining employment, which is crucial for health and well-being. Employment provides financial stability, yet most research on autistic individuals focuses on younger populations. Studies including older autistic adults often skew toward younger or middle-aged participants, with only about 1% aged 66 or older. Few autistic adults receive long-term services, compromising their economic stability and decreasing quality of life. However, a recent study found no significant link between employment and subjective quality of life in older adults, emphasizing the need to investigate this relationship further as autistic adults reach retirement age.

Objectives: In older autistic and non-autistic adults: (1) Identify disparities in income, public assistance, and health outcomes. (2) Explore how employment-related income, disability support, and learning disabilities correlate with quality of life (QoL) and overall health. (3) Characterize the relationship between overall health and quality of life.

Methods: The study included 29 older adults: 15 autistic ($M = 63.40$ years, $SD = 5.67$) and 14 non-autistic ($M = 62.50$ years, $SD = 4.32$), with a history of mental health concerns. Participants completed self-report measures of disability status (WHODAS), QoL (AASPIRE Adaptation of Single Item Global Quality of Life) income, psychiatric and learning disorder diagnoses and overall health. Adults also completed the WASI-II 2-subtest version (autistic mean $IQ = 106.47$, $SD = 15.05$; non-autistic mean $IQ = 108.55$, $SD = 17.00$). Independent samples t-tests identified group differences, and Pearson correlations examined relationships between variables.

Results: Older autistic adults reported that a smaller percentage of their income came from employment ($n = 15$, $M = .40$, $SD = .51$) compared to non-autistic adults ($n = 14$, $M = .77$, $SD = .43$) and were more likely to receive public assistance ($t(26) = -1.74$, $p < .001$). Self-reported total general disability scores on the WHODAS negatively correlated with overall quality of life ($r(19) = .57$, $p = .009$) and overall health ($r(18) = -.82$, $p < .001$). Self-reported sufficient income associated with higher quality of life ($r(19) = .44$, $p = .022$), whereas reliance on public assistance for income negatively associated with overall health ($r(27) = -.46$, $p = .014$). No relationship was found between employment status and quality of life or overall health. Furthermore, autistic individuals had significantly higher rates of learning disabilities ($t(28) = -2.18$, $p < .001$). Learning disabilities was positively correlated with public assistance for income ($r(28) = .52$, $p = .005$) and negatively correlated with work income ($r = -.47$, $p = .011$).

Conclusions: Our preliminary findings align with existing literature that employment income and disability status significantly influence the quality of life and overall health of older autistic adults, who face greater employment challenges and higher dependence on public assistance. Our findings add to growing literature on older autistic adults, suggesting the need for targeted supports. Future directions include increasing our autistic sample by Spring 2025 (target $N = 45$), exploring impacts of retirement, unemployment, and the COVID-19 pandemic on employment trends in this population.

408.016 Agency in Defining Autism: A Hierarchical Regression Analysis

K. Zhou¹, S. Park² and S. Qin², (1)University of North Texas, Denton, TX, (2)University of Wisconsin-Madison, Madison, WI

Background: Societal changes shape how autistic young adults define autism, influencing their identity development and psychosocial adaptation. The pathological model of autism appears to significantly conflict with the lived experiences of autistic individuals. Due to the inconsistency between societal definition of autism and personal experiences, autistic individuals may take different actions to address this incongruence. They may actively redefine the meaning of autism based on their personal experiences (agency) or passively define autism and conform to social norms (passivity). Agency has been identified as a significant predictor of well-being and other psychosocial outcomes. However, its role in the psychosocial adaptation process is rarely explored in autism literature.

Objectives: The study primarily aims to explore the role of agency and its effect on psychosocial outcomes (i.e., self-efficacy, quality of life (QOL)) among autistic young adults. Additionally, it also examines the effects of demographic covariates (i.e., gender, age, age of diagnosis) and self-acceptance in the psychosocial adaptation process of this population. The goal is to expand the understanding of human agency within autism literature and inform the development of effective services and programs.

Methods: 204 autistic youths aged 18 to 26 recruited from Prolific and Amazon Mechanical Turk (MTurk) completed an online survey consisting of instruments measuring target variables. To assess the strengths of the adjusted associations, hierarchical regression analyses (HRA) were performed between the covariates (i.e., three dichotomized gender variables for female, non-binary, and prefer to self-disclose with male as the reference group, age, age at diagnosis, self-acceptance), primary independent variables (i.e., agency and passivity), and the two dependent variables (i.e., self-efficacy, QOL).

Results: Findings indicated that gender and self-acceptance emerged as significant predictors of self-efficacy and QOL. Specifically, autistic young adults identifying as non-binary reported significantly lower self-efficacy and QOL compared to males. Also, higher levels of self-acceptance were significantly associated with improved self-efficacy and QOL. Additionally, agency in defining autism, where autistic young adults actively redefine their autism, significantly and positively affected both self-efficacy and QOL, even after controlling demographic covariates and self-acceptance.

Conclusions: Autistic young adults undergo a complex yet valuable journey in understanding and defining autism. Achieving positive psychosocial outcomes requires them to fully grasp their role in the relationship between self and autism. This study emphasizes the importance of agency in fostering self-efficacy and quality of life. Future research should delve deeper into how agency influences identity development and psychosocial adaptation. The findings of this study offer implications for service delivery to autistic young adults with multiple minority identities. Healthcare providers should receive training that equips them with the necessary knowledge about the experiences of autistic and gender minority individuals. Acceptance-based programs should move beyond encouraging passive acceptance of reality and society's definition of autism. Rather, they should incorporate components that empower autistic young adults to recognize their agency and active role in shaping their own lives, supporting them to develop their unique definition of autism that resonates with their personal experiences.

408.017 Aging and Life Stories of Brazilian Autistic Individuals: Results of a Pilot Interview

V. R. D. Gomes, L. B. A. Moura and G. S. Tavares, University of Brasilia, Brasilia, Federal District, Brazil

Background: In Brazil, there is a shortage of qualitative studies on the experiences of autistic adults and older persons. Considering the rapid aging of the population in several countries around the world, it is essential to understand the reality experienced by autistic individuals to guide public policies aimed at healthy ageing. This work is part of the preliminary results of an ongoing master's research project at the University of Brasilia (UnB).

Objectives: The objective is to understand and analyze the needs of autistic adults over 45-year-old and autistic older persons in the aging process in Brazil's capital, Brasilia.

Methods: This is an exploratory qualitative study that was approved by the UnB Human Sciences Ethics Committee (CAAE 76855423.0.0000.5540). The chosen method is cartography. It focuses on life stories and uses photographs to help the participants' narratives. A 47-year-old autistic woman was recruited by convenience sampling (snowball) to validate the methodology and the semi-structured interview script. Three meetings were held in August 2023. The first meeting presented the research objectives. The second was the interview, which lasted 1 hour and 42 minutes and provided a space for listening and recording stories empathetically. The third meeting was the participant's feedback on the whole process. The interview was transcribed and analyzed using the thematic analysis method with the help of Atlas.ti software.

Results: Three important categories emerged from thematic analysis: (1) autism throughout life, (2) meaningful activities and (3) aging. In the first category, the participant reported a late diagnosis at the age of 45, after the autism diagnosis of two of her children. Her childhood shyness concealed social and communication difficulties, among other things that she didn't understand and couldn't cope with. The masking of feelings, socialization, and communication difficulties is a thread that runs through many of her experiences (see Figure 1). The masking mechanism is widely cited in scientific studies, and one of the strengths identified is that autistic women and girls compensate for the difficulties of autism with better cognitive flexibility. In the second category: the activity of writing, especially poems, is reported from a very young age as one of the ways of expressing the feeling of inadequacy experienced and little verbalized to the world (see figure 2). In the third category: the participant expressed concerns about the end of her life and caring for her children, should something happen to her. There was also a desire to fulfill dreams and develop personal projects (see figure 2).

Conclusions: The use of photographs contributed significantly to the participant's narrative and memory when telling her life story. The thematic categories revealed important perspectives for understanding some of the needs of autistic individuals. The pilot interview was essential for validating the methodology and refining the interview script. Thus, the master's research will move on to the next phase, seeking to map other stories of autistic individuals in an accessible way, using a script with simple language and ethical care, to respect individualities and different ways of being.

408.018 Alzheimer's Disease Genetic Risk Dosage in Autistic Individuals

S. A. Harker¹, I. S. Piras², M. J. Huentelman³, F. Taguinod², C. R. Lewis² and B. B. Braden¹, (1)School of Life Sciences and College of Health Solutions, Arizona State University, Tempe, AZ, (2)Translational Genomics Research Institute, Phoenix, AZ, (3)College of Health Solutions, Arizona State University, Tempe, AZ

Background: Middle-aged and older autistic adults are 2.6 times more likely to be diagnosed with early onset Alzheimer's disease (AD) compared to non-autistic adults, however understanding cognitive and brain aging heterogeneity with autism is lacking. Genetics explain substantial variance in cognitive aging outcomes and incidence of neurodegenerative disease, but there are no genetically-informed studies of aging with autism. Polygenic risk scores (PRS) are an effective tool to measure an individual's genetic liability to complex traits, including predicting AD development. Lastly, due to historical malpractices concerning autism and genetics, we intend to use genomics to empower aging autistic adults by helping them better understand how aging may affect them.

Objectives: To explain heterogeneity cognitive and brain aging outcomes of autistic adults through genetic approaches, we aim to 1) Determine whether autistic individuals carry a higher cumulative genetic risk for AD compared to non-autistic individuals and 2) Determine if AD-PRS differentially moderates memory performance in autistic vs. non-autistic adults

Methods: One hundred and forty-seven (91 male) participants included 65 non-autistic and 82 autistic adults ages 18-70 (38.62 ± 16.75). Sex was defined as assigned at birth (concordant with all participants' gender identities). Participants scored >70 on the Kaufman Brief Intelligence Test-2, >25 on the Mini Mental State Exam, and autistic participants met criteria on the Autism Diagnostic Observation Schedule-2 and DSM-5. DNA was extracted from saliva using Oragene's DNA purification protocol and genotyped on the Illumina Global Diversity Array with an additional 180K neurodegenerative disease markers, then imputed for whole genome coverage through the TOPMed server. AD-PRS was generated from a Genome Wide Association Study (GWAS) of 71,880 AD and 383,378 controls using the PRSice-2 software. The Rey Auditory Verbal Learning Test and raw scores from the long-term delayed recall (A7; long-term memory) were used for analyses since this measure is sensitive to mild cognitive impairment that precedes AD. We performed an ANCOVA to test a diagnostic group difference in AD-PRS, controlling for sex, and the interaction between group and sex. Additionally, ANCOVA was used to test a diagnostic group difference in long-term memory (AVLT A7), controlling for sex, age, AD-PRS, and the interaction between group, sex, and AD-PRS.

Results: The autism group had a significantly larger AD-PRS ($p=0.035$), and significantly worse long-term memory scores ($p=0.017$) than non-autistic controls. The interaction between autism diagnosis and AD-PRS was significant and driven by a steeper negative slope in the autism group, indicating that cognitive function in autistic individuals is impacted more by AD-PRS than non-autistic individuals. Sex was not a significant predictor or moderator for AD-PRS or long-term memory scores.

Conclusions: This study was the first to investigate cumulative genetic risk for AD in autistic adults and found that autistic adults have a greater genetic risk in comparison to non-autistic adults. Synoptically, we found that the Alzheimer's PRS has a greater impact on cognitive function in autistic individuals compared to non-autistic individuals.

408.019 Knowledge, Perceptions, and Use of Psychedelics Among Autistic Adults: An Online Survey

S. Afsharnia¹, V. Liang¹, Y. Lunskey¹, A. Orsini², A. Tint³ and H. Y. Lin¹, (1)Azrieli Adult Neurodevelopmental Centre, Centre for Addiction and Mental Health, Toronto, ON, Canada, (2)Autistic Psychedelic Community, Los Angeles, CA, (3)Psychology, University of Calgary, Calgary, AB, Canada

Background: Psychedelics have shown promise in treating mental health conditions (such as depression and post-traumatic stress disorder) in neurotypical populations. However, psychedelic therapeutic potential for individuals with autism spectrum condition (ASC) remains under-explored. Autistic individuals frequently experience co-occurring mental health challenges, yet are often excluded from clinical trials, creating a gap in understanding effective treatments for this population.

Objectives: This study aimed to explore the knowledge, perceptions, and experiences of autistic adults regarding psychedelics as a treatment option.

Methods: A cross-sectional online survey was conducted with English-speaking autistic adults. The survey assessed participants' knowledge of psychedelics, their willingness to use them for mental health treatment, and past experiences with psychedelic substances. Data were analyzed using descriptive statistics and chi-square tests to assess group differences.

Results: A total of 424 participants began the survey, with 262 completing it. Participants (45.6% residing in Canada) generally had positive perceptions of psychedelics, with 77.8% expressing a willingness to try them in the future. 69.7% of participants reported prior psychedelic use, with psilocybin mushrooms being the most commonly used substance. Higher doses and highly meaningful experiences were significantly associated with longer-lasting mental health improvements. Barriers to psychedelic use included legal concerns, health risks, and logistical challenges. Participants with prior psychedelic experience reported greater perceived knowledge and lower perceived risks associated with use. Demographic factors (e.g., sex/gender, nationality, or diagnostic methods) did not influence the reported outcomes.

Conclusions: This study highlights a strong interest and positive perceptions among autistic adults in exploring psychedelics as a potential treatment for their mental health challenges, despite significant barriers to participation. This suggests a pressing need for education, policy reform, and inclusive research practices to improve access to psychedelic therapies/studies for autistic people. Future trials are needed to optimize dosing strategies and explore the long-term benefits of psychedelics in autistic people.

408.020 Are Anxiety and Depression Linked to Independence in Autistic People? - a Cross Cultural Study

P. Bhattacharya¹, E. Bastan², M. Banerjee³, M. C. V. Teixeira⁴, R. Osu⁵, M. South⁶, A. K. Platner⁷, S. Sengupta⁸, K. A. Woodcock⁹ and A. Surtees¹⁰, (1)School of Psychology, University of Birmingham, Birmingham, West Midlands, United Kingdom, (2)Psychology, Karadeniz Technical University, Trabzon, Trabzon, Turkey, (3)Psychology, Techno India University, Kolkata, West Bengal, India, (4)Human Developmental Sciences Graduate Program, Mackenzie Presbyterian University, sao paulo, SP, Brazil, (5)Waseda University, Tokyo, Tokyo, Japan, (6)Psychology & Neuroscience, Emory Autism Center, Decatur, GA, (7)Franciscan Children's, Brighton, MA, (8)My Life Learning Center, Ellicott City, MD, (9)University of Birmingham, Birmingham, West Midlands, United Kingdom, (10)Psychology, University of Birmingham, Birmingham, West Midlands, United Kingdom

Background: Co-occurring mental health conditions are highly prevalent in autistic people. Independent functioning is frequently more negatively impacted by poor mental health than by autism symptoms alone (Howlin, 2021). However, there is limited understanding of how these co-occurring conditions influence independent functioning, particularly across different cultural contexts. This study aims to explore the relationship between anxiety, depression, and independence in autistic adults across various countries.

Objectives: This quantitative study aims to assess the impact of co-occurring mental health conditions (specifically, anxiety and depression) on the independence of autistic people. This study furthers our understanding of the cross-cultural relationship between mental health co-occurring conditions and independence in autistic people across different countries by conducting a comparative analysis.

Methods: This research adopts a cross-cultural quasi-experimental design to explore differences between autistic and neurotypical participants from economically developed (US, UK, Japan) and developing countries (India, Brazil, Turkey). The study will recruit 240 to 300 participants, including 40-50 autistic adults from each of the participating countries. Participants are being recruited through local support groups, research databases, and collaborating institutions. The study involves the administration of standardized assessments to examine the relationships between anxiety, depression, and independence across these groups. The primary assessments include the Autism Quotient screening tool, Depression Anxiety Stress Scales, and a Visual Analogue Scale of Independence. Data are being collected either online or in person, depending on participant preferences. Multiple regression analyses will be employed to assess the relationship between mental health symptoms and independence, with cultural comparisons using chi-square and t-tests.

Results: As this is a work in progress, data collection is ongoing. Initial findings are expected to shed light on the extent to which anxiety and depression impact the levels of independence in autistic people across different countries. Findings are expected to shed light on the cultural factors that may play a significant role in moderating the relationship between mental health symptoms and independent functioning.

Conclusions: This study aims to contribute to a more nuanced understanding of how co-occurring mental health conditions, particularly anxiety and depression, affect the independence of autistic adults across different cultural contexts. By exploring these relationships, the study hopes to inform culturally sensitive interventions that promote independence and improve the quality of life for autistic people. Ultimately, the findings will advocate for inclusive policies and support systems that account for both autism and mental health needs globally.

NOTE: The data collection has begun, and we are expecting to finish the data collection by April 2025.

408.021 Atypical Postural Control Persists through Adulthood in Autism Spectrum Disorder (ASD): Static and Dynamic Postural Control Deviations in Autistic Adults Ages 30-73

H. Qu^{1,2}, J. Wang^{1,2}, D. J. Shirley^{1,2}, H. Gemmell^{1,2}, D. Christensen^{1,2}, A. M. Orlando^{3,4,5}, R. A. A. Romero^{4,5}, B. A. Zielinski⁶ and Z. Wang^{1,2},
(1)Neurocognitive and Behavioral Development Laboratory, University of Florida, Gainesville, FL, (2)Applied Physiology and Kinesiology, University of Florida, Gainesville, FL, (3)Center for Autism and Related Disabilities (CARD), University of Florida, Gainesville, FL, (4)UF Health Center for Autism and Neurodevelopment (UF Health CAN), University of Florida, Gainesville, FL, (5)Psychiatry, University of Florida, Gainesville, FL, (6)Pediatrics, Neurology, and Neuroscience, University of Florida, Gainesville, FL

Background: Postural control deficits are well-documented in autistic children and adolescents, significantly impacting clinical manifestations and interfering with daily activities. Research on postural control in autistic adults, particularly in older age, remains limited. Given the elevated prevalence of neurodegenerative comorbidities (e.g., Parkinsonism) in middle-aged autistic adults, precise quantification of postural variability and coordination may offer critical insights into age-related neuromotor deviations in autistic adults.

Objectives: This study aims to 1) quantify postural sway variability and coordination during static and dynamic stance in autistic adults, and 2) examine age-related deviations in key postural control variables that differentiate autistic adults from neurotypical controls.

Methods: This cross-sectional study involved 47 autistic adults (22F) ages 30-73 years and 48 age-, sex-, and IQ-matched neurotypical controls (26F). Participants completed three 45-second trials on a Qualisys force platform for each of the three conditions: static stance and dynamic anterior-posterior (AP), and mediolateral (ML) postural sways. Center of pressure (COP) metrics were extracted following the standard approach, including standard deviation (COP_{SD}), trajectory length (COP_{TL}), dimensionless squared jerk (COP_{DSJP}) for all conditions, and postural sway frequency (COP_{Freq}), range of motion (ROM_{avg}), and range of motion variability (ROM_{cv}) in the target direction for dynamic stance. Group differences were assessed using repeated-measures ANOVAs with Bonferroni adjustment, while age and group-by-age effects were examined using multi-linear regressions. Spearman's correlations were utilized to explore relationships between key postural control measures and clinical assessments, including the Autism Diagnostic Observation Schedule-2 (ADOS-2) and Repetitive Behavior Scale-Revised (RBS-R). The false discovery rate (FDR) method was applied to minimize Type 1 error for correlation analyses. All statistical significances were interpreted at the level of $p < 0.05$.

Results: Autistic adults showed greater COP_{SD} in both AP and ML directions during static stance, but reduced COP_{SD-AP} during dynamic AP sways compared to neurotypical controls. Autistic adults also exhibited greater COP_{TL} during static stance. COP_{DSJP} quantifies the smoothness of individuals' postural sway, where autistic adults showed COP_{DSJP} reductions during static stance but increases during dynamic sways relative to controls. During AP sways, autistic adults demonstrated reduced COP_{SD} and ROM_{avg}, but increased ROM_{cv} in the target direction compared to controls. No between-group differences were identified for dynamic ML sways. During static stance, neurotypical controls exhibited increased COP_{SD-AP} while autistic adults showed COP_{SD-AP} reductions in old age. No significant correlations were found between postural control measures and ADOS-2 or RBS-R total raw scores after FDR correction.

Conclusions: Our study is the first to examine postural control deviations in autistic adults ages 30-73 during static and dynamic stance. Atypical postural control is reflected as increased sway variability during static stance, while reduced postural coordination (i.e., less smooth COP trajectories) during dynamic stance in autistic adults. Old age differentially affects postural sway variability (COP_{SD-AP}) in autistic adults and controls during static stance. Together, we demonstrate that postural control deviations persist through adulthood in ASD. The extent to which changes in COP variables are associated with the onset and progression of neurodegenerative conditions, such as Parkinsonism, in autistic adults warrants further examination.

408.022 Autigender, Neuroqueer: A Mixed Methods Exploration of the Use Intersectional Labels to Describe Sexual Orientation and Gender Identity Among Autistic Adults

M. R. Maroney¹, R. Shinnick², E. Coombs³, T. Eggers², K. Sliz², L. Jamin-Lynn¹, D. Hagerty⁴ and J. Desruisseaux⁵,
(1)Counseling and School Psychology, University of Massachusetts Boston, Boston, MA, (2)University of Massachusetts Boston, Boston, MA, (3)Counselling Psychology, University of Alberta, Calgary, AB, Canada, (4)University of Alberta, Edmonton, AB, Canada, (5)The Lurie Center, Lexington, MA, (6)Research Volunteer, Boston, MA

Background:

Previous research has shown that Autistic people are more likely to identify as LGBTQ+ (see Hillier et al., 2019; George & Stokes, 2018). Within autistic community spaces, intersectional labels (e.g., autisexual, autigender) have become popularized as a label that captures the inability to separate an autistic identity from sexual orientation and gender identity (Valvano & Shelton, 2021). Emerging research suggests the use of such terms can help with distancing Autistic people from more deficit-based identity labels and help with communicating the relationship between autism and SOGI label (Toft, 2024), yet little is known about the use of intersectional labels.

Objectives:

The purpose of this study is to explore how Autistic adults understand and use intersectional Autistic SOGI labels (e.g., neuroqueer, autigender, autisexual).

Methods:

As of October 2024, a total of thirty three participants shared their perspectives on intersectional labels. Participants ranged in their ages from 18-53 ($M = 31.25$, $SD = 9.54$), were largely European American/Canadian (75%), transgender/nonbinary/genderqueer (66.6%), and reported labels of bisexual, pansexual, or queer to describe their sexual orientation (69.4%). Nineteen participants endorsed using neuroqueer to describe their sexuality, ten used autigender to describe their gender identity, while others reported the use of other intersectional terms that were informed by an Autistic lens (e.g., autiqueer, genderfluid). We utilized a reflexive thematic analysis (Braun & Clarke, 2021) to analyze open-ended qualitative responses. We analyzed descriptive statistics to explore perceptions and disclosure of intersectional labels.

Results:

Qualitative results are presented as three themes. Theme 1: Exposure to Labels: Participants reported first learning about intersectional labels in a variety of ways including online spaces (e.g., Facebook, Tumblr), authors (e.g., Dr. Nick Walker), neurodivergent queer community, university LGBTQ center, and this study. Theme 2: Defining Labels: Participants spoke about the ways their neurodivergence informed their understanding of their intersectional labels, noting that it's "impossible to separate" from one another, and that they influence one another. Theme 3: Knowing it Fits: Participants reported feeling "happy and seen and heard" and reflected on the powerful resonance of finding a label that fit, noting "suddenly I had a word."

Descriptive quantitative results revealed that most participants reported they felt they were unable to separate their sexual orientation (66.6%) and gender identity (75%) from their Autistic identity. Regarding use of intersectional labels, participants felt that the use was received positively or very positively (60%) by the Autistic community, neutral or positively (45%) by the non-Autistic LGBTQ+ community, and neutral or somewhat negatively (54%) by the non-Autistic (i.e., neurotypical) people.

Conclusions:

As LGBTQ+ Autistic people increasingly use intersectional labels, it is critical that researchers understand how they are used and the relationships with on identity development, disclosure, and mental health. Many participants in this sample learned about intersectional labels through connection to community, which has been found to be a buffer against stigma events. Additional planned analyses will explore the relationship between use of intersectional labels and stigma, mental health, and community connectedness.

408.023 Autism Spectrum Disorder and Adults Diagnosis: A Study Based on the Brazilian Reality

E. A. Guerreiro¹, A. A. Cardoso Rodrigues², C. S. A. de Oliveira³, E. Castro³, F. Vieira⁴, R. B. da Silva³, W. C. Tirelli³, V. R. D. Gomes⁴ and A. C. Steinkopf³. (1)Instituto Steinkopf, Brasilia, Federal District, Brazil, (2)Universidade Federal de Minas Gerais, Belo Horizonte, Brazil, (3)Steinkopf Institute, Brasilia, Federal District, Brazil, (4)University of Brasilia, Brasilia, Federal District, Brazil

Background: The number of autism diagnoses has increased not only among children but also adults. Although there is no consensus among scientists about the cause of this phenomenon, it is known that the evolution of diagnostic methods, dissemination of information about the topic and better qualification of professionals have contributed. The Mapa Autismo Brazil - MAB (Autism Map Brazil) seeks to collect information about the profile of autistic population in Brazil to support quality public policies for both diagnosis and treatment.

Objectives: To outline the sociodemographic profile of autistic individuals who responded to the Mapa Autismo Brazil survey, correlating age of diagnosis with the therapies they underwent in childhood and adulthood.

Methods: MAB is a pilot and exploratory study developed by a non-governmental organization. The study was approved by the Ethics Committee of the University of Brasilia, according to opinion CAAE: 70226623.9.00005540. Two online questionnaires were conducted using the SurveyMonkey platform between July-September 2023. One questionnaire was directed at autistic individuals over 18 years old with autonomy to respond; the other to those responsible for autistic individuals without autonomy to respond.

Results: This study considered 297 responses who answered the questionnaire for autistic individuals. The profile of the autistic individuals who responded to the survey is mostly white (62.29%), female (51.85%), in the age group of 20-24 years old (19.27%), with support level 1 being the most predominant (85.19%).

Verbal people account for 78.45%. The hypothesis of the diagnosis was raised by health professionals and by the autistic individuals themselves in the same percentage (35.55%). The main signs and symptoms indicated as the cause for suspicion of ASD diagnosis were restricted interests (84.85%) and little social reciprocity (73.06%). The highest number of diagnoses occurred between 20 and 24 years old (17.17%). Only 12.79% received the diagnosis before 18 years old; 10.63% at an age over 45 years. The average age of these individuals was 30 years, thus characterizing a late diagnosis. The data indicate that, even without a diagnosis in childhood and adolescence, some individuals had access to psychotherapy (37.37%), speech therapy (15.82%), and psychopedagogy (10.44%). In adulthood, 58.59% engage in some type of therapy, with psychotherapy being the most frequent (93.68%), followed by nutrition (16.09%) and occupational therapy (8.62%).

Conclusions: The research points to late diagnosis as a predominant characteristic among autistic adults, with the average age of diagnosis being 30 years. This fact highlights the historical difficulty of early detection of ASD, which limits intervention in critical phases of development. Psychotherapy is the most common intervention among participants. Even without formal diagnosis, many individuals participated in therapies, which reflects the need for therapeutic support in childhood. The Mapa Autismo Brazil reinforces the need for public policies focused on the early detection of autism and the expansion of multidisciplinary therapeutic approaches, seeking to promote better quality of life and inclusion for people on the spectrum.

408.024 Autism and Quality of Life: Insights from Self-Identified, Diagnosed, and Nationally Representative Samples

F. Leung¹, L. D. Hargitai², O. Layinka³ and P. Shah². (1)Department of Psychology, University of Bath, Bath, Somerset, United Kingdom, (2)Department of Psychology, University of Bath, Bath, United Kingdom, (3)University of Bath, Bath, Somerset, United Kingdom

Background:

Quality of life (QoL) is often reported to be lower in clinically diagnosed autistic people than the general population. Despite a growing number of people self-identifying as autistic, the differences in QoL across these diverse populations have not been systematically examined. Expanding research to include this subgroup is crucial, considering many self-identified autistic individuals may not have access to support for their unique difficulties. Additionally, recent studies have indicated that autistic traits, particularly those related to social cognition (e.g., mentalising), are predictive of QoL in clinically diagnosed autistic people, yet their role among self-identified autistic people remains unknown.

Objectives:

Addressing these research gaps, this study examines whether: (i) QoL differs across self-identified autistic, clinically diagnosed autistic, and the general population, and (ii) the impact of mentalising on QoL varies between these groups, while accounting for sociodemographic and individual characteristics.

Methods:

Self-identified autistic adults (SI; $n = 999$), clinically diagnosed autistic adults (CD; $n = 458$), and a nationally representative group of adults from the general population (NR; $n = 1500$) completed an online survey, which comprised self-report measures of mentalising ability (FIMI) and autistic traits (AQ), a measure of cognitive ability (ICAR-16), as well as a range of demographic and health-related questions. Participants also reported their QoL across physical, psychological, social, and environmental domains (WHOQOL-BREF).

Results:

A one-way ANOVA revealed the CD group, followed by the SI group, scored significantly lower than the NR group in mentalising ability. Several covariates, including autistic traits, cognitive ability, and mental health conditions, also significantly differed between groups. After accounting for these covariates, a MANCOVA revealed a significant group effect on combined QoL scores, as well as individual domain scores, particularly in the psychological and social domains, with the SI group reporting the lowest QoL (Figure 1). Lower mentalising ability was also associated with lower combined and individual QoL domain scores. Interestingly, the group $\times$ mentalising ability interaction was only significant when examining the QoL domains individually. The relationship between mentalising ability and QoL was strongest in the NR group, particularly for physical, psychological, and environmental QoL (Figure 2). Other factors, such as relationship status, household income, and the presence of mental health conditions, also significantly influenced QoL.

Conclusions:

Adults who self-identify as autistic generally experience lower QoL compared to, not only the general population, but also those with a formal autism diagnosis. Notably, the influence of mentalising on QoL was less pronounced in both autistic groups than in the general population, suggesting that autistic individuals may rely less on social cognitive skills to navigate their life experiences. Rather, factors like mental health may play a more central role in shaping the lives of autistic people. Our findings highlight the importance of directing attention towards adults who self-identify as autistic—a group that has been historically overlooked in both research and clinical practice—to better conceptualise and support the experiences of those who are on the borderline of diagnostic criteria or undergoing the diagnostic process.

408.025 Autistic Identity Dimensions and Profiles Are Associated with Daily Living and Mental Wellness Among Autistic Adults

S. R. Terroso¹, K. O. Gotham¹ and T. A. M. McDonald², (1)Psychology, Rowan University, Glassboro, NJ, (2)Sleep Disorders Division, Department of Neurology, Vanderbilt University Medical Center, Nashville, TN

Background: Variation in how autistic individuals identify with autism may play a key role in their well-being, daily life, and relationships. As autistic people generally report poorer well-being and quality of life compared to the general population (Croen et al., 2015; Hollocks et al., 2019; Mason et al., 2018), autistic identity may present a promising avenue for developing effective, neurodiversity-affirming approaches for supporting well-being. While research on autistic identity is increasing (Botha & Gillespie-Lynch, 2022; K. Cooper et al., 2017; Davies et al., 2024), few studies explore the elements that define this identity.

Objectives: This study examines the association between autistic identity, characterized by the Autism Spectrum Identity Scale (ASIS) dimensions of Positive Difference and Changeability, and well-being, as well as daily life and relationships (DLR) of autistic adults. In addition to dimensional analyses, post hoc profile analyses were used to identify variations among participant profiles across measures of well-being and DLR.

Methods: Participants ($N=1,139$) in this online study included formally diagnosed ($n=893$) and self-diagnosed ($n=246$) autistic adults. Surveys measured autistic identity (ASIS; McDonald, 2016), quality of life (AAQoL; Brod et al., 2006), self-esteem (RSE; Rosenberg, 1965), stigma (SS; King et al., 2007), and questions about loneliness and self-care. We used multivariate general linear models to examine the relationships between Positive Difference and Changeability dimensions and well-being and DLR domains. In post hoc analyses, we imposed categories based on these identity dimensions and examined relationships between identity profiles and well-being and DLR domains.

Results: Dimensional analyses demonstrate that, controlling for Changeability, greater endorsement of autism as a Positive Difference was associated with greater psychological health as measured by the AAQoL ($F(3,1040)=26.37, p<2.2e-16$), self-esteem ($F(3,1071)=128.2, p<2.2e-16$; see Figure 1), and lower fear of disclosure ($F(3, 826)=58.01, p<2.2e-16$). When controlling for Positive Difference, greater endorsement of Changeability (i.e., viewing autistic traits as changeable or malleable) was associated with greater life productivity ($F(3, 1015)=27.09, p<2.2e-16$), relationship satisfaction ($F(3, 1040)=25.49, p=6.484e-16$), and self-care ($F(3, 1070)=18.07, p<1.929e-11$). Post hoc results showed that endorsing both Positive Difference and Changeability was linked to the greatest well-being, while Positive Difference was more associated with mental well-being and Changeability was more strongly related to DLR domains (see Figure 2).

Conclusions: Autistic adults who viewed autism as making a positive difference in their lives and as malleable reported the highest levels of well-being and DLR, while those who were least likely to endorse these identity dimensions had the lowest levels. Post hoc analyses highlighted distinct identity profiles, revealing individual and synergistic roles of positive difference and changeability on well-being and DLR. These findings emphasize the need to support diverse experiences and perspectives within the autistic community, and inform peer support programs and therapeutic approaches aimed at improving the quality of life and mental health of autistic adults.

408.026 Autistic Individual's Transition to Higher Education: Accessibility and Acceptability of College Support Services

T. D. Marsh¹, M. M. Corcoran², C. B. Klein³, M. L. Cook⁴, E. M. Lamarche⁵, L. Varblow², L. G. Klinger⁵ and B. Tomaszewski², (1)TEACCH Autism Program, TEACCH Autism Program, UNC Chapel Hill, Chapel Hill, NC, (2)UNC TEACCH, Carrboro, NC, (3)TEACCH Autism Program; Psychology & Neuroscience, TEACCH Autism Program, UNC Chapel Hill, Chapel Hill, NC, (4)TEACCH Autism Program, UNC Chapel Hill, Carrboro, NC, (5)TEACCH Autism Program; Psychiatry, UNC TEACCH Autism Program, Chapel Hill, NC

Background: Autistic individuals are entering college at growing rates and report significant challenges in college (Shaw et al, 2023). Accessing disability/accessibility services and supports (DAS) is a known factor to facilitating success in college for autistic individuals (Cai & Richdale, 2016). The UNC TEACCH School Transition to Employment and Post-Secondary Education (T-STEP) Program is a transition to adulthood program that includes a 12-week transition to college course and 12 hours of counseling on higher education, career exploration, and self-advocacy. Taking place either virtually or in-person at a local community college campus, the counseling sessions include education about and visits with colleges' offices of DAS, the career center, the writing center, and the tutoring center.

Objectives: Are transition counseling sessions effective in improving access and/or satisfaction of these services? How do individuals assigned female at birth (AFAB) compare to those assigned male at birth (AMAB) in their rates of access and satisfaction with DAS and other college support center?

Methods: Participants were 94 autistic young adults that formerly completed the T-STEP Program and attended college. T-STEP participants from two RCTs were included in this study with 1 RCT using a waitlist control design and 1 RCT using a comparative efficacy study with some students receiving the comprehensive T-STEP and some receiving the counseling without the class. All participants completed the counseling sessions. Participants completed a brief online survey about their higher education experiences after the T-STEP at 3-4 months after completing the program and again 1-5 years later.

Results: Of the 94 students completing the T-STEP who had graduated from high school, 55 (56%) had attended or were attending college. Notably, 83% of students attended a 2-year college. Most students are accessing disability services (67%) and rating them good (49%), great (32%), or excellent (11%). AFAB individuals were more likely than AMAB individuals to access disability/accessibility services ($\chi^2(1, N = 53) = 6.2, p = .02$). However, AFAB and AMAB individuals did not differ in their satisfaction ratings ($t(34) = -1.1, p = .277$). Of those accessing DAS, (35.29%) were accessing at least 1 other support service through their colleges.

Conclusions: Similar to past reports, the majority of autistic high school graduates in this study elected to attend a community college instead of or before attending a university (Roux et al., 2015). Participants in this study appear to be accessing DAS more often than other autistic college students (Newman et al., 2011; Petcu et al., 2021) supporting the efficacy of the T-STEP counseling program. These results support the importance of educating transition aged autistic students on the supports available at college to increasing the likelihood of autistic college students advocating for themselves by accessing these services. Future research is needed to identify which students benefit the most from this type of low intensity (12 hours) higher education counseling program and which students benefit from more intensive transition support services (e.g., the full 60-hour T-STEP program).

408.027 Autistic Physicians: A Hidden, Unaddressed, Physician Health and Wellness Issue

V. Bowen¹, D. B. Nicholas² and L. Zwaigenbaum³, (1)Paediatrics, University of Alberta, Edmonton, AB, Canada, (2)University of Calgary, Edmonton, AB, Canada, (3)University of Alberta, Edmonton, AB, Canada

Background: Understanding the needs of autistic people within specific disciplines is important in fostering greater understanding and integrating needed supports. The public has shown interest in media accounts of autistic doctors in part reflected in popular television medical dramas. A 2017 Scientific American article asked 'Could someone with autism be a superstar surgeon?' Dr. Darold Treffert concluded 'Yes, it's definitely plausible' but could find no examples. In 2020 Dr. Nina Purvis wrote 'Autistic doctors – we're not exactly as portrayed on TV'. As exemplified in these accounts, there is need for disciplinary understanding, in this case, in medicine, related to autism. The literature contains information indicating that autistic doctors do exist but very little is known about them and the medical profession has done little to embrace neurodiversity.

Objectives: The research question was 'What has been written about autistic physicians?' with sub-questions 'Does autism interfere with their ability to practice medicine?' and 'Does autism affect their health and wellness?'

Methods: A narrative literature review was completed on the subject of autistic physicians, synthesising results of computerised database searches, authoritative text searches and hand searches. Peer reviewed and lay press material was included, using multiple medical, psychological and general databases. Searches used keywords including 'autism', 'autistic', 'physician', 'doctor', 'Asperger's' and 'savant' and combinations. Boolean operators, adjacency techniques and stopping rules were utilized and the bibliographies of retrieved literature were also searched. Inclusion and exclusion criteria were set. Descriptive analyses evaluated publication type, number of cases, physician specialty, mental health and ability to practice. Qualitative analysis sought out common themes.

Results: Forty-five documents were identified on the subject of autistic physicians, including peer-reviewed papers, editorials, commentaries, letters to the editor, book chapters, a newspaper story, and 'fitness to work proceedings'. Reports emerged in three phases and were sparse prior to increased publication starting in 2019.

Phase 1: Anecdotal cases: These identified the existence of real life autistic doctors in patient contact specialties, and identified experiences of feeling stigmatised, masking their existence, struggling with life, in career difficulties, calling for help and with no confidence in provided support services.

Phase 2: Commentaries, editorials and opinions: Common themes included that autistic people are drawn to medicine and have traits, which make them good practitioners. Most function well but get into difficulties if demands (especially administrative), exceed ability. Interpersonal misunderstandings, sensory reactivity, and mental exhaustion could precipitate problems.

Phase 3: Original research studies: Only five studies were found. A survey indicated 1% of doctors are autistic. Studies confirmed that most are functioning well, mostly in general practice and psychiatry, although high rate of psychiatric conditions and suicide risk was reported.

Conclusions: Very little is known about autistic doctors, including their professional experiences. Limited data suggests they are practicing satisfactorily but masking, with fear of stigmatisation. They report sensory overload, and interpersonal communication problems that evoke stress and career difficulties, as well as high rates of mental health conditions. Further understanding, supports and research are needed.

408.028 Autistic, Socially Anxious, and Neurotypical Adults Use Similar Profiles of Emotion-Regulation Strategies Based on Momentary Mood

T. I. King¹, J. A. Nielsen², R. Y. Cai³, M. South⁴ and T. P. Gabrielsen⁵, (1)Psychology, Brigham Young University, Provo, UT, (2)Brigham Young University, Provo, UT, (3)Aspect Research Centre for Autism Practice, Autism Spectrum Australia, Sydney, NSW, Australia, (4)Psychology & Neuroscience, Emory Autism Center, Decatur, GA, (5)Counseling Psychology and Special Education, Brigham Young University, Provo, UT

Background: Difficulties regulating emotions effectively may contribute to negative mental health outcomes in adults diagnosed with autism and social anxiety. Traditional research on emotion-regulation of autistic and socially anxious adults often relies on self-reports littered with memory bias and lab-controlled environments that fail to capture the emotional experiences these populations experience day-to-day. Ecological momentary assessment (EMA) mitigates these challenges by using real-time data collection, offering ecologically valid interpretations of the variables being studied. As emotion-regulation research shifts toward EMA methods as the preferred approach for gathering emotion-regulation data, understanding how emotion-regulation strategies vary in response to momentary mood affect can inform specific suggestions to improve emotion-regulation across different emotional contexts.

Objectives: This exploratory study analyzed data from a 9-month EMA of mental health behaviors in adults. We examined possible changes in profiles of emotion-regulation strategies according to type of affect experience (positive or negative) across three groups of adults: an autistic group, a socially anxious group, and a neurotypical comparison group.

Methods: Seventy-nine participants, including individuals diagnosed with autism (AUT; n = 27), individuals diagnosed with social anxiety (SA; n = 27), and a neurotypical comparison group (NT; n = 25), completed daily surveys related to their experience of both positive and negative emotions over the past 24 hours, and also how often they used each of six emotion-regulation strategies: savoring, acceptance, reappraisal, suppression, self-blame, and dampening. Multilevel logistic regression models examined within-person associations between mood affect and strategy use as well as interactions between group status and within-person mood affect. Results were adjusted using the Benjamin-Hochberg procedure to control the false discovery rate.

Results: There were no group differences in the pairing of negative affect and adaptive regulation strategies. All groups reported that negative affect was associated with a decrease in the odds of using savoring and acceptance strategies, with no change in the odds of using reappraisal. For all groups, greater negative affect increased the odds of using maladaptive suppression, self-blame, and dampening strategies. Additionally, the experience of positive affect increased the likelihood of use for savoring and acceptance and decreased use in self-blame with no change in the odds for suppression or dampening use across all groups.

Conclusions: In all cases, self-reported use of emotion-regulation strategies in response to both positive and negative affect was similar for all three comparison groups, which contrasts with previous research that suggests that autistic and socially anxious adults typically show different emotion-regulation patterns than neurotypical groups. These findings raise questions about the contexts in which these strategies are used or the accuracy of self-report measures in capturing real-time emotion-regulation. However, the small sample size and limited geographic scope caution against broader generalizations. Future EMA studies should utilize higher temporal resolution or incorporate physiological measures to gather more contextual data that better links emotion-regulation strategy use to more specific emotional experiences. These insights could enhance interventions aimed at improving emotion-regulating abilities in adulthood, particularly for autistic adults.

**408.029** Behavioral Health & Service Utilization Among Autistic Adults in the All of Us Research Program

S. Sivathanan¹, A. G. Hartman², J. B. Northrup³, E. D. G. Williams⁴, A. Saunders⁵, C. Gu⁶ and S. P. Martin⁵, (1)Counseling, Developmental, and Educational Psychology, Boston College, Chestnut Hill, MA, (2)University of Pittsburgh, Pittsburgh, PA, (3)Department of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, PA, (4)Social Work, University of Michigan, Ann Arbor, MI, (5)Boston College, Chestnut Hill, MA

Background: Often, autism research registries involve participants who identify in dominant groups in society (e.g., White, heterosexual, and socioeconomically-advantaged), making it difficult to generalize findings unto marginalized groups. In an effort to rectify this, the goal of the current research study is to examine the currently available behavioral health data among people who identify as autistic within the All of Us (AoU) Research Program.

The AoU Research Program is an NIH-funded effort to recruit populations that have been historically underrepresented in biomedical research (e.g., racial/ethnic minorities, LGBTQ+, individuals with disabilities); it has currently enrolled >500,000 US participants. As such, comprehensive analysis of AoU data, utilizing an open-science framework, will allow us to examine the extent to which disparities exist between our typical research samples and those from underrepresented communities.

Objectives: Broadly, we are focused on 3 main objectives using the AoU database:

1. To characterize the autistic sample based on key sociodemographic variables,
2. To evaluate reported behavioral health problems and service use, and
3. To explore whether specific social determinants of health (SDoH) are associated with behavioral health outcomes among autistic people.

Methods: We are currently using descriptive analyses to characterize the sociodemographic make-up and basic behavioral health and service utilization patterns within an identified cohort of autistic individuals. As of October 2024, N=1231 adults were identified as having 'autism spectrum disorder' (0.67%).

Results: At the time of completing the surveys, 66% of the autism cohort were between the ages of 18-44 years, 23% were between 45-64 years, and 11% were 65+ years. Fifty-nine percent of participants indicated their assigned sex at birth as female, and 38% as male. In terms of gender, 33% identified as 'male' (as indicated on the survey), 42% as 'female,' and 12% identified with a different gender identity. There is additional variability regarding when participants learned of their autism diagnosis; ~38% of participants reported that they learned of their diagnosis in childhood, compared with 60% in adulthood (18-64 years), and around 3% after the age of 65. Despite ~45% of the AoU database being represented by racial/ethnic minorities, most autistic participants identified as White (82%) and Not Hispanic/Latino (88%).

AoU-generated Initial descriptive analyses identify the "top 10 conditions" (physical and mental) experienced in a selected cohort. Of note, the top three conditions reported were anxiety disorder (19%) and major depression, single episode (17%), followed by chronic pain (14%). Additionally, ~24% of the cohort reported currently being prescribed medication and/or are receiving services related to autism.

Conclusions: There is a wealth of data on autistic people and their families in the AoU Research Program, available for collaborative scientific inquiry. Additional planned analyses will examine in further detail sociodemographic, behavioral health, service utilization, and SDoH, to identify initial indicators related to health and wellbeing among a diverse representation autistic people. Future research may contrast findings with other large autistic and/or comparison samples, ultimately with significant potential for meaningful clinical, research, and policy implications.

408.030 Being Confused with Choice? Choice Architecture Interventions to Reduce the Choice Confusion of People with Autism
N. Rogge, Faculty of Economics and Business, KU Leuven, Brussels, Belgium

Background: Autobiographical reports and empirical findings of survey studies suggest that people with autism experience choice-making to be difficult, confusing and stressful. The notion is that people with autism may be especially susceptible to adverse effects of increasing choice freedom in society. Given the central role of choice-making in daily lives, it is important to examine the impact of autism on choice-making in order to support people with autism in a targeted way.

Objectives: This paper explores (1) whether individuals with autism experience more confusion in choice-making compared to neurotypical individuals and (2) interventions in the choice architecture to reduce choice confusion for individuals with autism. The paper consists of three studies. In Study 1, the general tendency to be confused in choice-making is measured by the Consumer Confusion Proneness scale (CCP) of Walsh et al. (2007) which provides measures for choice similarity confusion, choice overload confusion and choice ambiguity confusion. In Study 2, the subjective experiences of choice confusion are measured across a series of choice tasks that differ in choice product and size of choice assortment (Fig.1). In

study 3, three interventions in the choice architecture to reduce the choice confusion of autistic consumers are examined (ordering choice options on a key attribute, categorizing choice options with informative category labels, sequential presentation of choice options).

Methods: Participants with autism were invited via organizations in Flanders and the Netherlands to participate in the online survey. Neurotypical participants were contacted by social media. In Study 1, the CCP-scale data of autistic and matched neurotypical participants were analyzed by a multi-group CFA (MGCFA). In Study 2, a multi-level modeling (MLM) analysis is applied to study the subjective experiences of choice confusion among autistic and neurotypical participants across a series of choice tasks. In study 3, a MLM analysis is used to examine the impact of interventions in the choice architecture in reducing the experience of choice confusion among autistic and neurotypical participants.

Results: The MGCFA-outcomes (Fig.2) show that the proneness for choice similarity confusion, choice overload confusion, and choice ambiguity confusion was significantly higher among participants with autism (differences in latent means of .931, .812 and .662 (all $p < .001$). The MLM estimations (Study 2) show that participants with autism experience more choice confusion than neurotypicals (Figure 3). In Study 3, the MLM demonstrates that ordering and categorizing choice options are two effective interventions in the choice architecture to reduce choice confusion among autistic individuals (and neurotypical individuals). The opposite holds for the sequential presentation of choice options (Figure 5).

Conclusions: The findings demonstrate that (1) individuals with autism have a higher general tendency to be confused in choice-making compared to neurotypicals (Study 1), (2) the subjective experiences of choice confusion observed among autistic

individuals did not differ significantly across the examined choice settings (Study 2), and (3) the ordering and the categorization of choice options are two effective interventions in the choice architecture to reduce choice confusion among autistic individuals

408.031 Understanding How Emotional States and Friendships Relate to Community Participation in Autistic Young Adults: A Mixed-Methods Study

Y. Kim, D. Gunasekar and G. I. Orsmond, Department of Occupational Therapy, Boston University, Boston, MA

Background: Community participation (CP) is essential for health and well-being. During the transition to adulthood, CP provides a context for key developmental tasks of adulthood, such as developing autonomy, identity, and social relationships. However, autistic young adults often report a decline in and poor satisfaction with CP after high school. Prior research has identified that depressive and anxious feelings, and friendship, are related to CP in autistic people. However, little is known about how different aspects of emotion and friendship are related to CP, particularly in young adulthood. Moreover, the relationships between emotion, friendship, and CP experiences, including both objective (frequency) and subjective (importance), are understudied. Understanding these relationships is crucial for developing effective strategies to support CP in autistic young adults.

Objectives: We conducted a convergent mixed-method study to answer these questions:

1. Which emotional states and aspects of friendship are associated with CP?
2. How do autistic young adults describe their emotional states and friendships in the context of CP?

Methods: Thirty-five autistic young adults without intellectual disability (ID; ages 18-29) completed online measures, including the Depression Anxiety Stress Scale (DASS), friendship items from the Adult Self-Report (ASR), and the Temple University Community Participation (TUCP) measure. Most participants were White (73.5%), and 48.6% were Female. Follow-up interviews were conducted with 14 participants. We conducted correlations between DASS anxiety, depression, and stress subscales, ASR friendship items (number of close friends, self-reported friendship quality) and TUCP outcomes (frequency, importance, diversity, breadth, and sufficiency; see Table 1). Qualitative interviews queried why community activities were important and what made it easy or hard for participants to engage in CP. Interviews were transcribed, coded, and analyzed using thematic analysis. Themes were identified based on the coded data and case summaries.

Results: Key findings of the quantitative and qualitative data are presented in a joint display (Table 2). Quantitatively, higher levels of anxiety were associated with fewer important community activities and a lower degree of engagement in those important activities (breadth). Higher friendship quality was associated with greater frequency, diversity, breadth, and sufficiency of CP. Qualitative interviews revealed the following themes: (1) aspects of social situations influenced how young adults engaged in community activities, (2) young adults recognized the positive influence of CP on their mood, (3) young adults engaged in community activities to build friendships, and (4) accompanying friends boosted satisfaction with CP and motivated young adults to try new activities.

Conclusions: Quantitative findings showed that anxiety states were linked to subjective experience of CP; friendship quality was related to both objective and subjective experience in autistic young adults. Qualitative findings provided further insight into the reasons for these associations; friendships facilitated and provided benefits to CP. Programs supporting young adults to manage anxiety in social situations may improve their CP experience. Interventions targeting both CP and close friendships might be effective in supporting CP and mental health. Future steps include understanding CP in young adults with different support needs (e.g., individuals with ID) and diverse racial and ethnic backgrounds.

408.032 Brain Network Activity in Autistic and Non-Autistic Adults Thinking about Preferred Interests

D. J. Su¹, A. Johnston², K. O. Gotham³, C. A. Mazefsky⁴ and G. J. Siegle⁵, (1)University of Pittsburgh Medical Center, Pittsburgh, PA, (2)Psychiatry, University of Pittsburgh Medical Center, Pittsburgh, PA, (3)Psychology, Rowan University, Glassboro, NJ, (4)Department of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, PA, (5)University of Pittsburgh, Pittsburgh, PA

Background: Preferred interests are common, intense, and idiosyncratic among autistic people. Autistic people commonly use preferred interests as an emotion regulation strategy, particularly to reduce anxiety. Among general samples, “savoring” (thinking about) positive topics increases positive affect and emotions, and reduces anxiety. The extent to which thinking about preferred interests resembles or differs from savoring, neurally, is unclear. Given the clinical implications of preferred interests, autistic and non-autistic adults may have different levels of brain network activity when thinking about preferred interests and positive topics.

Objectives: 1) To contrast how brain activity differs between autistic and non-autistic adults when thinking about preferred interests and savoring. 2) To examine how differences in brain network activity correlate with emotion dysregulation.

Methods: Participants (n=79) included 59 study-diagnosed autistic and 20 verified non-autistic adults (mean age=32.62, range = 18-60 years). Gender demographics comprised of 22 male (12 autistic), 33 female (23 autistic), 11 nonbinary (10 autistic), 13 other gender (12 autistic). Racial demographics included 57 white (47 autistic), 11 Black (6 autistic), 4 Asian (2 autistic), and 8 other (5 autistic). All participants completed a 5-minute task consisting of cognitive and emotional operations during functional MRI assessment. The task included conditions that required participants to think about positive (savor) and interesting (interest) topics for 10 seconds at a time, each for two blocks. Prior to the scan, participants generated personally relevant topics in each category and completed the Emotion Dysregulation Inventory questionnaire (EDI-SR). We compared neural activity in 12 theoretically identified, a priori, meta-analytically (Neurosynth) derived brain networks (task, social, sensation, self, salience, pain, motor, memory, interoceptive, executive, emotion, default, attention, arousal) during interest, savor, and rest conditions. We examined group differences in means and distributions. Across groups, differences in neural reactivity was correlated with the EDI-SR Dysphoria and Reactivity Indices.

Results: There were no significant differences between groups when comparing interest, savor, and rest conditions (see Figure 1). Between the two groups, we found distribution differences in the executive, memory, salience, and task networks for the interest minus rest condition, and in the memory network for the interest minus savor condition. Overall, we found lower network reactivity in the autistic group than the non-autistic group. We also found significant correlations between several brain networks and both reactivity and dysphoria for the interest minus rest and interest minus savor conditions (see Table 1). The savor minus rest condition did not yield any significant correlations.

Conclusions: Surprisingly, autistic and non-autistic adults showed no differences in commonly examined brain networks implicated in perception, emotion, and cognition when thinking about preferred interests and savoring positive topics. Moreover, adults who are more emotionally reactive or dysphoric engage less with their preferred interests neurologically, possibly because emotion dysregulation consumes cognitive resources. However, future studies should investigate relationships between neuroimaging and behavioral/observational data to inform our understanding of preferred interests in autistic adults.

408.033 Camouflage, Self-Esteem, and Mental Well-Being in Autistic Adults in Japan*M. Sunagawa, Clinical Psychology, Ochanomizu University, Bunkyo, Tokyo, Japan*

Background: Camouflage is a set of strategies that autistic people use in social situations to hide aspects of their autistic characters and try to fit in with others (Hull et al., 2020). Although camouflage has the adaptive aspect, it also affects self-esteem and increases the risk of mental health deterioration (Hull et al., 2021). The association between camouflage and mental health has also been suggested to differ by country, with over- or under-camouflage being associated with worse mental health in Japanese autistic individuals (Oshima et al., 2024). However, research findings are scarce, and the actual state of camouflage among Japanese autistic individuals is not clear.

Objectives: This study aimed to examine the relationship between camouflage, self-esteem and mental health among Japanese autistic adults.

Methods: Japanese version of the following measurement scales were used: the Camouflaging Autistic Traits Questionnaire (CAT-Q), the Rosenberg Self-Esteem Scale (RSES), and the World Health Organization-Five Well-Being Index (WHO-5). This study included 118 Japanese autistic adults (97 women, 17 men, and four others; mean age 37.0 years) who self-reported formal diagnosis of autism related condition.

Results: Results suggest that camouflaging autistic traits using assimilation is associated with an increased risk of experiencing thwarted self-esteem and mental well-being, but no association was found between either compensations or masking and RSES or WHO-5 scores. The characteristics of the combination of camouflage strategies showed a significant association between masking and self-esteem when compensation scores were high, but no association was found when compensation was low or average.

Conclusions: Among the camouflage strategies, assimilation was associated with lower scores on self-esteem and mental health in Japanese autistic individuals. However, the results suggest that the effects may differ depending on the combination of camouflage strategies. These findings indicate that assimilation may have a stronger negative impact on self-esteem and mental health than other camouflage strategies, possibly due to assimilation being a way of playing a different character from one's true self, which is considered to be more deeply related to one's self-identity. Therefore, compared to compensation and masking, the effects on self-esteem and mental health were considered more significant. This highlights the need to carefully consider the psychological costs of encouraging such strategies in social communication support and underscores the importance of refraining from approaches that encourage assimilation. Additionally, there is potential for effectively using compensation and masking as an adaptive strategy for conscious and short-term purposes. Further study is needed to understand the influence of socio-cultural factors on camouflage in non-Western countries, as well as the diversity of camouflage styles.

408.034 Camouflaging and Anticipation of Social Rejection Are Associated with Elevated Physical Health Symptoms in an Autistic Adult Sample*R. Baliga¹, A. Senanayake¹, R. H. Himelstein² and K. O. Gotham², (1)Rowan University, Glassboro, NJ, (2)Psychology, Rowan University, Glassboro, NJ***Background:**

Minority stress may contribute to poorer physical health outcomes across various minority groups: Discrimination correlates with reduced access to medical treatment among LGBTQ+ individuals, increasing risk for breast cancer, asthma, and HIV/AIDS (Lick et al., 2013). Black individuals face healthcare-related discrimination (e.g., not being given pain medications; Dhaem et al., 2020); discrimination correlates with nausea, stomachaches, and breast cancer (Yazdiha et al., 2022).

Ableism (i.e., discrimination against individuals with physical and/or mental disabilities) may similarly correlate with adverse physical health outcomes; however, research on ableism and physical health is sparse. Croen et al. (2015) found that autistic individuals who may experience autistic-identity-based ableism were more likely than non-autistic individuals to experience health problems, including gastrointestinal and sleep problems. Overall, research on the effects of minority stress among autistic individuals is needed.

Objectives:

To examine the association between autistic camouflaging and anticipation of social rejection – psychosocial processes that potentially reflect experiencing ableism – and physical health symptoms in autistic adults.

We anticipate greater self-reported camouflaging, or masking of autistic traits, and greater anticipation of identity-based social rejection will be associated with greater likelihood of endorsing stomachache, nausea/vomiting, headache, dizziness, and sleep difficulties.

Methods:

N=303 autistic adults participated in a three-timepoint survey study of well-being through the SPARK online autism registry (Feliciano et al., 2018). The current study focused on cross-sectional analyses of Timepoint 1 data.

We used the Camouflaging Autistic Traits Questionnaire (CAT-Q; Hull et al., 2019) to measure autism-specific masking; Expectations of Rejection Scale (Botha, 2020) to measure anticipation of identity-based social rejection; and Adult Somatic Symptom Questionnaire (Williams, n.d.) to measure bothersomeness of physical symptoms.

Assumptions held for separate binary logistic regression models predicting each physical symptom, covarying for chronological age and gender.

Results:

Holding age and gender constant, for each one-point increase in camouflaging, odds of reporting stomachache increased by 2.16% (95% CI [.011, .033]); nausea/vomiting by 1.87% (95% CI [.008, .03]); headache by 1.54% (95% CI [.003, .028]); dizziness by 3.08% (95% CI [.019, .043]); and sleep difficulties by 2.24% (95% CI [.009, .036]) (see Table 2).

Similarly, controlling for age and gender, for each one-point increase in anticipation of social rejection, the odds of reporting stomachache increased by 4.02% (95% CI [.006, .076]); nausea/vomiting by 5.7% (95% CI [.024, .092]); dizziness by 5.64% (95% CI [.022, .094]); and sleep difficulties by 5.51% (95% CI [.013, .101]) (headaches n.s.; see Table 2).

Women, non-binary, or other gender respondents were more likely to endorse nausea/vomiting than men (95% CI [1.061, 2.967]).

Conclusions:

Our study suggests that autistic adults who engage in camouflaging and anticipate social rejection have a significantly greater likelihood of reporting stomachaches, nausea/vomiting, dizziness, and sleep difficulties; camouflaging was also related to greater endorsement of headaches. These findings represent preliminary evidence that minority stress may be associated with adverse physical health outcomes among autistic adults, indicating the need for future study of the harmful effects of ableism.

408.035 Caregivers' Mental Health and Well-Being in Supporting Autistic Individuals' Transition to Adulthood

X. Jiang¹, S. R. Cohen¹, S. M. Zeedyk² and H. Brown³, (1)University of California - San Diego, La Jolla, CA, (2)California State University, Fullerton, Fullerton, CA, (3)University of Oregon, Eugene, OR

Background: As autistic individuals transition to adulthood, they often experience a reduction in available support services (Wolpe et al., 2023). This leads to a significant burden and heightened levels of stress and anxiety among their caregivers (Herrema et al., 2017). Caregivers frequently express concerns about their autistic adults' ability to live independently and the financial pressures associated with limited employment opportunities and low wages (Dillenburg & McKerr, 2011).

Objectives: This study aimed to explore caregivers' perceptions of mental health services and supports available as they assist their autistic adults' through the transition to adulthood. Additionally, the study sought to gather advice caregivers might offer to others currently navigating this transition period.

Methods: We conducted semi-structured interviews with 17 caregivers of autistic adults (aged between 19 and 33) who participated in an eight-week STEM internship at a university in the western United States in 2021. The sample included 10 mothers, 1 father, 1 great-aunt, 1 caregiver who selected "Other", and 3 participants who did not disclose demographic information. Each interview was conducted via Zoom, lasting approximately 45 minutes. Interviews were audio-recorded, transcribed verbatim, and analyzed using a thematic coding approach. A codebook, including all the code names, definitions, and representative examples, was developed to ensure consistent coding. Data were analyzed using the Dedoose software program.

Results: Three major themes emerged from the interview data: (1) caregiver's mental health experiences during their autistic adults' transition to adulthood, (2) the types of support caregivers have received or wish to receive, and (3) practical advice for other caregivers undergoing a similar transition period. Caregivers frequently reported feelings of emotional, physical, and financial exhaustion due to the demands of supporting their autistic children. Many highlighted the difficulty of finding appropriate services and resources. In terms of advice, caregivers recommended seeking out support groups, engaging in self-care, and employing positive reinforcement strategies to help manage stress and maintain a positive outlook.

Conclusions: The study underscores the urgent need for targeted mental health support and resources that are specifically designed for caregivers of autistic adults. Recommendations for improving caregiver well-being will be discussed, with an emphasis on accessible services and community-based supports that help reduce caregiver burden and enhance their ability to cope with the demands of this life stage.

408.036 Childhood Traumas, Mental Health Conditions, and Suicide-Related Behaviours Among Autistic Adults

T. A. Chikaura¹, E. M. Weir², S. Griffiths³, T. L. Procyshyn⁴, M. Pelton⁵, C. Allison⁶, S. White⁷, T. Ford⁸ and S. Baron-Cohen⁹, (1)Psychiatry, Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, Cambridgeshire, United Kingdom, (2)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, Cambridgeshire, United Kingdom, (3)University of Cambridge, Cambridge, United Kingdom, (4)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, NA, United Kingdom, (5)University of Cambridge, Cambridge, Cambridgeshire, United Kingdom, (6)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, Cambridgeshire, United Kingdom, (7)Psychiatry, University of Cambridge, Cambridge, Cambridgeshire, United Kingdom

Background: Autistic people have a higher risk of mental health conditions, suicide, self-harm, and suicidal thoughts compared to others. In the general population, childhood trauma increases the likelihood of suicide, particularly among individuals who experience emotional or physical abuse. However, there is a lack of research examining this relationship in autistic adults.

Objectives: To determine whether specific childhood traumas are associated with suicidality and poor mental health in autistic adults.

Methods: Data from an existing, anonymized, self-report survey (the Vulnerability Experiences Quotient [VEQ]) was used to catalogue the frequency of childhood traumatic experiences among autistic and non-autistic people. The VEQ was developed through a participatory framework and includes nine childhood traumas that were investigated individually. The final sample included n=769 participants (including 424 autistic adults). Three iterative models of unadjusted and adjusted binomial logistic regression models were utilized (accounting for age, education-level, country of residence, and childhood traumas). A multiple comparison correction was applied to reduce Type I errors using the Benjamini-Hochberg method.

Results: Autistic adults were more likely to experience poor mental health and suicide-related behaviours than others. After accounting for demographic differences and childhood traumas, autistic people were 3 times more likely to self-harm, 2.2 times more likely to make suicide plans, 2.8 times more likely to attempt suicide, and 4 times more likely to have a mental health condition that affects their daily life than others. However, being autistic was not a significant factor in substance abuse (OR: 1.01, 95% CI: 0.70, 1.44, p-value: 0.97). In the overall sample, rumours being spread by other children and sexual abuse by an adult were associated with suicide attempts. These were the only types of childhood traumas significantly associated with suicide attempts in this study. Sexual abuse by an adult was significantly linked to self-harm and substance abuse. Additionally, being physically hurt by other children was significantly associated with experiencing daily mental health conditions. Strikingly, our findings showed a downward shift in the effect size of an autism diagnosis for all three suicide-related behaviours and experiencing a daily mental health condition after childhood trauma is factored in. For example, autistic people are 5 times more likely to engage in self-harm compared to non-autistic people without accounting for childhood trauma, which decreased to 3 times more likely after accounting for trauma. Full results are reported in Table 1.

Conclusions: Even after accounting for demographics and childhood trauma, autistic people have increased risk of suicidality. This provides preliminary evidence that autism may be an independent risk factor for suicide. These findings provide evidence of complex relationships between autism, trauma, and risk of suicide-related behaviours and daily mental health conditions. Our findings suggest that sexual abuse is a risk factor for suicide among autistic people, aligning with trends in the general population. Clinicians must take childhood trauma histories and provide needs-based care for autistic people. Additionally, early interventions and safeguarding strategies that target childhood traumas should be implemented in childhood to curb the effects of these traumas during the transition into adulthood.

408.037 Clinical and Demographic Characteristics of Autistic Individuals Diagnosed in Middle Age or Later Adulthood: A Clinic Sample from 2012-2022

J. L. Vanderburg¹, A. K. Izuno-Garcia², A. F. Pagà³, K. R. Hughes² and K. A. Loveland³, (1)Developmental Behavioral Pediatrics, University of Oklahoma Health Sciences Center, Oklahoma City, OK, (2)University of Texas Health Science Center, Houston, TX, (3)Louis A Faillace, MD, Department of Psychiatry and Behavioral Sciences, McGovern Medical School, University of Texas McGovern Medical School, Houston, TX

Background:

As public understanding and awareness of autism spectrum disorder (ASD) has increased, a greater number of individuals have begun to seek first-time evaluations and diagnoses of ASD in adulthood. However, as most research focuses on autistic adults diagnosed in childhood, little is known about the clinical and demographic characteristics of older adults seeking diagnostic clarification later in life.

Objectives:

The purpose of this study was to explore the clinical and demographic characteristics of adults receiving a first-time diagnosis of ASD in later adulthood (ages 40 and above).

Methods:

This study involved a retrospective record review from an outpatient clinic specializing in the diagnosis of ASD in adulthood over a 10-year period (2012 to 2022). Participants ($n = 76$) were drawn from an outpatient clinic specializing in the diagnosis of ASD in adults. Variables of interest included measures of ASD (i.e., scores from the ADOS-2, SRS-2, AQ, and EQ) and demographic characteristics (i.e., sex, education, relationship status, employment status, living situation, and co-occurring conditions). SPSS was used to generate descriptive statistics and frequencies for variables of interest. Correlations between variables were calculated as well.

Results:

Most participants in this sample were employed full time, married or in committed relationships, and lived independently. Nearly half of the sample had obtained a graduate degree. Participants, despite meeting criteria for ASD, on average, did not exceed the cutoff score for autism on the Autism Diagnostic Observation Schedule, Second Edition, Module 4 (ADOS-2; Lord et al., 2012). However, scores on self- and informant-report measures revealed clinically significant difficulties associated with core and associated features of ASD.

Conclusions:

Overall, the results of this study suggest that individuals who receive a diagnosis of autism for the first time at the age of 40 or above may have met typical societal expectations for adulthood (e.g., full-time employment, long-term relationships, etc.), while still evidencing clinically significant autistic traits. In addition, this study substantiates evidence on the importance of supplementing the ADOS-2 with self- and informant-report measures with a full developmental history when making diagnostic decisions for older adults who are suspected of being on the autism spectrum. This study provides an important first step in understanding how individuals first evaluated in older adulthood perform on self- and informant-measures of autism symptoms and their demographic characteristics. Future work should continue to explore not only the critical variables that impact success for children diagnosed with autism, but those that impact functioning for older autistic adults diagnosed in adulthood.

408.038 Co-Production of Complex RCTs with Autistic People: Reflections of the Autistic Advisory Group of the Strata RCT

J. Welch¹, S. Douglas², P. Hale³, S. O'Brien⁴, A. Walker¹, **J. E. Norris⁵**, L. Cotton⁶, A. X. Realpe⁷ and D. Rai⁸, (1)Autistic contributor, London, London, United Kingdom, (2)Autistic contributor, Bristol, UK, (3)Autistic contributor, Bristol, Bristol, United Kingdom, (4)King's College London, London, United Kingdom, (5)Centre for Applied Autism Research, University of Bath, Bath, United Kingdom, (6)Bristol Trials Centre, University of Bristol, Bristol, Bristol, United Kingdom, (7)University of Bristol, Bristol, United Kingdom, (8)Population Health Sciences, Bristol Medical School, University of Bristol, Bristol, United Kingdom

Background:

The benefits of co-production and involvement of autistic people are increasingly recognized in autism research. However, randomized controlled trials (RCTs) with autistic adults are relatively rare, and even rarer are accounts of RCTs that integrate the voices and expertise of autistic people throughout the research process. In June 2018, an autistic advisory group was formed to advise on a grant/funding application for what would eventually become the STRATA placebo-controlled RCT of sertraline for anxiety in autistic adults. For over 6-years, the group have continuously been closely involved in all stages of this large, complex international medication RCT.

Objectives:

This presentation, led by an autistic member of the STRATA advisory group, will provide a detailed account of:

- how co-production was implemented in this complex study and the challenges and opportunities towards meaningful contributions
- the impact of the autistic advisory group's contributions in shaping the study's aims, methodology, participant recruitment and retention, and planned dissemination.
- how being a part of this study impacted on the advisory group members
- lessons for future RCTs in co-producing meaningful research with and for autistic people.

Methods: STRATA was a multicenter, pragmatic, double-blind RCT aiming to assess the effectiveness of sertraline versus placebo in reducing anxiety in autistic adults, and to understand its adverse effects. The trial was conceived in 2018 with the autistic advisory group providing input on the acceptability of the design and measures ahead of the funding application. The trial was funded and set up during the Covid-19 pandemic and closed to recruitment in 2023, having surpassed the enrolment target (n=318). The 12-month follow-up phase is nearing completion in October 2024. The advisory group met regularly throughout the life-cycle of this trial. Oral histories and written reflections of members of the autistic advisory group collected for the period between 2018 to early 2025 will be synthesized and presented.

Results:

The advisory group provided input into all stages of the trial. Co-production included helping shape the funding application, test and time outcome measures, shaping the study protocol and the participant facing processes, advising on ethical concerns, representation at the ethics (IRB) committee, trial management groups and staff recruitment panels, staff training including videos that helped new researchers understand the trial process and communication with autistic people, reviewing participant materials for accessibility, ensuring safety and adverse effect information was effectively communicated whilst proactively anticipating participant concerns, contributing to planning of the statistical analysis and dissemination to different stakeholders. There were tangible benefits of the involvement of the advisory group in relation to strong recruitment (104% of required), retention (92% at primary outcome), and participant feedback. The group members described several benefits of contributing to this study and experienced personal and professional growth.

Conclusions:

The reflections highlight that it is possible to co-produce large complex multicenter RCTs with meaningful involvement of autistic individuals. This can in turn enhance the quality of the research and the experience of participants leading to higher levels of engagement and retention in such studies.

408.039 A Daily Living Skills Intervention through Executive Function Strategies for Adolescents/Adults with High Functioning Autism: A Pilot Study

S. Y. I. Wong¹, H. Y. V. Ngai¹, A. C. Poon² and M. S. M. Leung¹, (1)The Salvation Army PATH Center, Tsuen, Wan, Hong Kong, (2)The Salvation Army PATH Center, Tsuen, Wan

Background: High Functioning Autism Spectrum Disorder (HFASD) persons have daily living skills (DLS) deficits, which are skills generally required to function independently in home, community, school and workplace. Research have found that DLS is a significant predictor of success in areas such as employment, tertiary education and quality of life. Currently, there are very few group interventions aiming to improve HFASD's DLS. A pilot randomized controlled trial (RCT) targeting specific skills (grocery shopping, preparing/cooking a dish, cleansing cooking equipment/environment) was conducted to examine its effectiveness. While these specific skills targeted constitute only a subset of the entire DLS skillset, we specifically chose these skills to appeal to our HFASD persons' penchant for eating and food preparation.

Objectives: To examine whether executive functioning strategies could be incorporated into an group protocol to improve daily living skills of adolescents/adults with high functioning autism.

Methods: 110 adolescents/adults with HFASD were randomized to an 8-week treatment group or waitlist, and eventually the waitlisted group also completed the protocol. Each treatment session is structured to include all three skills that contain executive function elements of planning, time management and attention.

Results: Analyses of goal attainment scales of each DLS comparing both groups did not yield significant result. However, entire samples analyses demonstrated some gain in grocery shopping and preparing/cooking a dish, but not in cleansing cooking equipment/environment.

Conclusions: Current results provide some evidence that DLS can be improved, but aspects of DLS to be included in protocol and measurement to assess change in DLS can be examined further to improve the efficacy of the protocol.

408.040 Communication Training Using a Social Avatar for Young Adults with Autism Spectrum Disorders

H. Kumazaki¹, ユ. デシマ², Y. Yoshikawa³, A. Utsumi⁴, T. Miyashita⁵ and H. Ishiguro⁶, (1)Department of Neuropsychiatry, Graduate school of Biomedical Sciences, Nagasaki University, Hirokazu Kumazaki, Nagasaki, Japan, (2)Department of Neuropsychiatry, Nagasaki University, School of Medicine, Nagasaki, Nagasaki, Japan, (3)Graduate School of Engineering Science, Osaka University, Toyonaka, JAPAN, (4)ATR Brain Information Communication Research Laboratory Group., Sawara, Ktyoto, Japan, (5)ATR Deep Interaction Laboratory Group, Sawara, Ktyoto, Japan, (6)Graduate School of Engineering Science, Osaka University, Toyonaka, Japan

Background:

Young adults with autism spectrum disorders (ASD) face challenges in social interactions. They actively avoid social encounters which is associated with poor social communication and functioning. Social communication intervention approaches are effective when involving motivational activities and settings. In addition, enhanced self-confidence is important for addressing target situations and promoting social participation.

A growing body of literature suggests that young adults with ASD exhibit intrinsic motivation to operate teleoperated technological systems. To improve social participation, we developed a communication training system that uses social avatar (CSA). In CSA, social anxiety in young adults with ASD is expected to decrease, because they are not in the same physical space as unfamiliar people, they are not subjected to direct eye contact. Notably, even if they have an embarrassing experience, their self-esteem is less likely to be hurt because they are not observed by others.

Objectives:

The objective of this study was to assess the feasibility using CSA for young adults with ASD.

Methods:

Nine young adults with ASD participated in this study. The tele-operated social avatar used in this study was "Gene" (Figure 1; Lee Lab., NITech). A personal computer was placed in front of the user. In this setup, when the operator spoke through a microphone that was connected to the PC, the "Gene," repeated the words. The user's voice was converted using a voice-conversion system to match the avatar's appearance. Additionally, there was a motion-capturing system, so "Gene" reflected the user's gestures. In this study, users stayed in a familiar place with tele-operated "Gene" which is located in city streets to communicate with an unfamiliar person. There was a professional coach near the users who guided them on how to communicate with others and gave feedback on their communication. Subsequent trial procedures were conducted on days 1–5. Questionnaires (i.e., motivation, self-confidence, social anxiety, and comprehension of the perspective of others) were scored on a 7-point Likert scale. The ratings for communication performance ranged from 1 (very poor) to 7 (very excellent).

Results:

There was a significant increase in motivation and comprehension of the perspective of others, and a trend of increase in self-confidence and social anxiety to speak with unfamiliar people on day 6 (motivation; 5.33 ± 1.50 , comprehension of the perspective of others; 6.11 ± 1.05 , self-confidence; 3.44 ± 2.19 , social anxiety; 3.78 ± 2.05) compared to day 1 (motivation: 3.11 ± 1.36 , comprehension of the perspective of others; 3.56 ± 1.59 , self-confidence; 4.56 ± 2.40 , social anxiety; 5.22 ± 1.79) (motivation: $p < 0.01$, comprehension of the perspective of others; $p = 0.01$, self-confidence; $p = 0.08$, social anxiety; $p = 0.76$). As expected, motivation for training using this system was maintained during the session.

Conclusions:

This study evaluated the effectiveness of operating an avatar in young adults with ASD. Our program improved self-confidence and comprehension of the perspective of others in them. Further longitudinal studies with larger and more diverse samples of young adults with ASD are warranted to draw definitive conclusions regarding the effectiveness of CSA.

**408.041 Comprehensive Framework for Understanding Employment Barriers and Facilitators**

L. E. Smith DaWalt¹, G. A. Herbert², A. Sellers³, K. Bonnet⁴, D. Schlundt⁴ and J. L. Taylor², (1)University of Wisconsin-Madison Waisman Center, Madison, WI, (2)Department of General Pediatrics, Vanderbilt University Medical Center, Nashville, TN, (3)Vanderbilt University, Nashville, TN, (4)Psychology, Vanderbilt University, Nashville, TN

Background: A key research priority identified by the autism community is to understand ways to support autistic people to gain and sustain meaningful employment. In addition to examining facilitators of meaningful employment for autistic adults, it is crucial to find solutions to employment barriers. Our research aims to capture a comprehensive range of factors that contribute to improving employment outcomes for autistic adults.

Objectives: Using qualitative interviews, we will examine barriers and facilitators to meaningful work experiences among autistic adults.

Methods: Current analysis presents qualitative data collected at the second timepoint of an ongoing longitudinal study examining employment and education stability in autistic adults. Participants in this analysis included 80 autistic adults (58 biological males) between the ages of 18–45 ($M=31.52$), and 73 informants (51 mothers). Autistic adults were asked open-ended questions to describe workplace successes and challenges within the last six months with follow-up questions asking about strengths, difficulties and external supports while probing specifically for employment experiences. Informants who know the autistic adult well (e.g., parent, spouse, or friend) also were asked to report on the autistic adult's workplace successes and challenges. Interviews were audio recorded and responses were transcribed verbatim. Transcriptions were checked and verified for accuracy before coding.

Data coding and analysis was conducted by following the COREQ guidelines, an evidence-based qualitative methodology. A hierarchical coding system was developed and refined using a preliminary review of the transcripts. Coders established reliability using the coding system on one transcript. Coding was compared and discrepancies resolved through reconciliation. Remaining transcripts were independently coded by adult and informant dyads to consider each adult within their context. We used an iterative inductive/deductive approach to the qualitative data analysis. Deductively, the conceptual framework was informed by social ecological theory. Inductively, we used coded quotes to identify higher order themes and relationships between themes.

Results: Results of qualitative analysis suggested a multidimensional model of contributors to employment experiences (Figure 1). Emerging themes that influenced employment consisted of persistence, self-awareness, self-efficacy, coping, motivators, and expectations. The impact of these contributors to employment differed across context and were modified by mental health supports and involvement of family. Other workplace factors such as job settings, job characteristics, and employment logistics were commonly mentioned as affecting engagement in employment.

Conclusions: This study identified several individual strengths and challenges that contribute to employment experiences. Findings highlight mental health supports and family involvement as critical influences on employment outcomes for autistic individuals. This framework can help guide and inform future research and practice. Employers can benefit from implementing individualized workplace accommodations/adjustments that leverage adults' unique strengths and support their vulnerabilities. Researchers can benefit from having an organizing framework from which to consider the many factors that contribute to meaningful employment experiences.

408.043 Deception Detection in Neurodiverse Young Adults

M. Kurtz, J. A. Trapani, P. Argueta and R. K. Kana, *Department of Psychology, The University of Alabama at Birmingham, Birmingham, AL*

Background: Previous research suggests autistic individuals are susceptible to manipulation through lying and deception (Cooke et al., 2024; Kostin, 2022; Williams et al., 2018). This vulnerability can manifest in real-world situations causing difficulties for autistic individuals. Yet, the current literature investigating deception in autism does not directly address autistic individuals' ability to detect lies, instead, focuses on their ability to deceive others or pass false-belief tasks.

Objectives: The main objective of this study is to investigate the relationships between self-reported autism symptoms and executive functioning (EF) skills with deception detection performance across contrasting demeanor-based conditions in neurodiverse young adults.

Methods: Seventy-seven participants (ages 18 – 28 years) completed self-reported ratings of autism symptoms (i.e., Autism Spectrum Quotient, AQ; Social Responsiveness Scale, SRS-2), EF (i.e., The Behavior Rating Inventory of Executive Function for Adults, BRIEF-A), and a computerized deception detection task in which participants watched video interviews and judged whether the subjects were telling the truth or lying. Interviews represented matched (sincere truth-tellers and insincere liars) and mismatched (insincere truth-tellers and sincere liars) conditions. Two hierarchical regression analyses were conducted to examine the relationship between autism symptoms and deception task accuracy. A moderation analysis tested whether levels of EF moderated the relationship between AQ and deception task accuracy.

Results: In the matched condition, age, gender, and FSIQ were entered in step 1 and did not significantly predict accuracy rates ($F(3,73) = 0.69$, $p = 0.56$). The inclusion of SRS-2 Total T-scores and AQ Total score in Step 2 did not account for significant variance ($\Delta R^2 = .06$, $p = 0.12$). In the mismatched condition, Step 1 with age, gender, and FSIQ did not predict accuracy rates ($F(3,73) = 1.32$, $p = 0.28$). When AQ Total score and SRS-2 Total T-scores were added in Step 2, AQ emerged as a significant predictor, with higher AQ scores associated with increased accuracy ($\beta = .59$, $p = .002$) explaining an additional 16% of the variance ($\Delta R^2 = .16$). The BRIEF-A GEC scores significantly moderated the association between AQ and mismatched condition accuracy. Slopes were significantly different from zero at both low ($b = 1.29$, $t = 4.89$, $p < .001$) and high ($b = 0.58$, $t = 2.3$, $p = .03$) BRIEF-A GEC scores. At lower BRIEF-A GEC scores, the AQ- accuracy relationship was stronger; but at higher BRIEF-A GEC scores, the relationship was weaker, though significant.

Conclusions: The current findings suggest that when social cues and verbal content were congruent, greater autism symptoms did not provide an advantage or disadvantage in detecting deception. Conversely, those with greater autism symptoms were unlikely to be deceived by the senders' social cues, benefitting them in detecting deception when such cues were misleading. In participants with better self-rated EF, as autism symptoms increased, mismatched condition accuracy also increased. For participants with poorer self-rated EF skills, the positive relationship between autism symptoms and accuracy was still present although weaker, suggesting that some participants may leverage their EF abilities to perform well in the task despite their higher autism symptoms.

408.044 Depression Subtypes in Autism Spectrum Disorders

N. Brondino¹, M. Nola¹, M. Olivola², E. Galetti¹, C. Guio¹, C. Rossignoli¹, E. Casciaro¹ and P. Politi¹, *(1)Department of Brain and Behavioral Sciences, University of Pavia, Pavia, Italy, (2)ASST Fatebenefratelli Sacco, Milan, Milan, Italy*

Background:

Major depression disorder (MDD) episode is defined by a complex set of symptoms and signs, ranging from depressed mood and anhedonia to loss of appetite and poor sleep. It has been estimated that patients can satisfy the criteria for MDD in at least 227 different ways. Therefore, psychiatrists have more recently focused on better defining clinical subtypes of MDD in order to provide a more personalized treatment. Despite the relative abundance of data on the prevalence of depression in autism spectrum disorders (ASD), little is known about clinical subtypes of depression in this condition.

Objectives: The present study aims to evaluate MDD phenotypes in a cohort of autistic adults.

Methods:

We consecutively enrolled 53 autistic individuals who were also referred to our centre for major depression disorder (MDD). All subjects were evaluated by a senior psychiatrist with wide expertise in ASD according to DSM 5 criteria. Depression subtypes were described according to CANMAT guidelines; specifically, we used the following dimension: with anxious distress, with atypical features, with catatonic features, with melancholic features, with psychotic features, with seasonal pattern, with mixed features, with cognitive dysfunction, with sleep disturbances and with somatic symptoms. Additionally, we evaluate the presence of treatment-resistant depression defined as depression not responding to a least two different antidepressants at the maximum dosage for an adequate amount of time.

Results:

in 5.6% of subjects, MDD was not confirmed. Age range of the sample was 19-65 years. All the sample presented sleep disturbances. Most of our autistic adults (53%) present either with MDD with anxious distress or with atypical features, the latter having irritability as the main mood symptom. Nearly 23% have depression with melancholic features. 8% of the sample have treatment-resistant MDD. 8% of the sample have MDD with psychotic symptoms (all were males).

Conclusions: our data on clinical subtypes of MDD in ASD showed significant differences compared to MDD in the neurotypical population: as an example, treatment-resistant MDD has more than double prevalence compared to the general population. Identifying clinical subtypes of depression in ASD is important to provide the clinicians with more data for differential diagnosis. Additionally, it could be essential for the choice of treatment, in order to reduce mistreatment and lack of response.

408.046 Differences in Subjective Sensory Gating and Interoceptive Awareness in Autistic Adults

B. F. Bloomer¹, E. L. Gildea², E. N. Herms³, A. R. Bolbecker², B. F. O'Donnell², W. P. Hetrick³ and K. M. Wisner², *(1)SDSU/UC San Diego Joint Doctoral Program in Clinical Psychology, San Diego, CA, (2)Psychological and Brain Sciences, University of Iowa, Iowa City, IA, (3)Psychological and Brain Sciences, Indiana University, Bloomington, IN*

Background: Autism is a heterogeneous neurodevelopmental condition strongly linked to differences in sensory processing, including overall heightened exteroceptive experiences and mixed findings on interoceptive awareness. However, scant research exists which simultaneously assess subjective exteroceptive sensory gating and interoceptive awareness in autism, especially in adulthood. Importantly, subjective interpretations of these sensory-based experiences have far-reaching impacts for one's quality of life, via attention, decision making, and even emotional and social functioning. Thus, investigations into how subjective experiences of these processes may be altered in autistic adults may lend new insights to inform novel mechanistic research.

Objectives: The current study investigated group differences in subjective experiences of exteroceptive sensory gating and interoceptive awareness in autistic adults (AU) and neurotypical controls (NT), plus tested the associations with self-reported autistic traits. We hypothesized increased self-reported exteroceptive sensory gating difficulties and broad differences in interoceptive awareness in AU compared to NT. We also hypothesized that deviations would relate to elevated self-reported autistic traits.

Methods: 59 AU ($M=23.03$ years, 86% White, 44% male) and 44 NT ($M=22.80$ years, 68% White, 52% male) adults completed the Sensory Gating Inventory (SGI) and the Multidimensional Assessment of Interoceptive Awareness-2 (MAIA-2) surveys. AU additionally completed the Autism Spectrum Quotient-Full (AQ) to assess level of overall self-reported autistic traits across a variety of domains. Analyses employed t-tests to evaluate group differences. MAIA-2 scales demonstrating differences were tested for within-group correlations with SGI. Follow-up correlations tested associations with autistic traits in AU.

Results: Compared to NT, AU reported greater sensory gating impairments on all SGI subscales ($t=8.42-12.01$, $ps<0.001$); AU also reported lower tendencies to trust interoceptive sensations ($t=-5.75$, $p<0.001$), to not being distracted by ($t=-3.39$, $p=0.001$) and to not worry about ($t=-3.73$, $p<0.001$) them, plus lower tendencies to control attention to interoceptive sensations ($t=-3.73$, $p<0.001$) or to use them to self-regulate ($t=-4.08$, $p<0.001$). In the AU group there was a negative relationship between greater sensory gating impairments and the tendency to not be distracted by interoceptive sensations ($r=-0.37$, $p<0.01$). Finally, self-reported autistic traits were positively associated with greater sensory gating impairments ($r=0.36$, $p<0.01$), while they were negatively associated with tendencies to control attention to interoceptive sensations ($r=-0.30$, $p<0.05$) and using them to self-regulate ($r=-0.27$, $p<0.05$). These last two relationships with AQ were not explained by sensory gating impairments or co-occurring psychopathology.

Conclusions: Adults with autism show pervasive disturbances in subjective exteroceptive sensory gating and interoceptive processing, which were mutually related and also associated with overall self-reported autism phenotype. Findings extend existing literature and highlight the need for future research to investigate how this relationship between exteroceptive and interoceptive difficulties in autism is relevant to treatment and neurobiological mechanisms.

408.047 Disease and Mortality Trajectories of Autistic Individuals in Mid- and Later- Adulthood

Y. Pu¹, T. Ren² and F. Li³, (1)*Xinhua Hospital Affiliated to Shanghai Jiao Tong University School of Medicine, Shanghai, Shanghai, China*, (2)*Developmental and Behavioral Pediatric Department & Child Primary Care Department, Brain and Behavioral Research Unit of Shanghai Institute for Pediatric Research and MOE Shanghai Key Laboratory for Children's Environmental Health, Xinhua Hospital, Shanghai, Shanghai, China*, (3)*Department of Developmental and Behavioral Pediatric and Child Primary Care & Ministry of Education-Shanghai Key Laboratory for Children's Environmental Health, Xinhua Hospital, Shanghai Jiao Tong University School of Medicine, Shanghai, 200092, China., Shanghai, Shanghai, China*

Background:

An increasing number of autistic adults have entered their later life, but little is known about the disease trajectory in mid- and later adulthood.

Objectives: We aimed to examine the patterns of comorbidity progression in adults with autism spectrum disorder (ASD) that may affect their mortality.

Methods:

Participants were identified from the UK Biobank study. We first identified individuals with ASD diagnosis, each of whom were randomly matched to up to 10 participants without ASD diagnosis. Cox regression was used to estimate the hazard ratio (HR) of mortality. Disease trajectory analysis was performed to investigate temporal sequencing of medical conditions and mortality associated with ASD. A multistate model was used to investigate the association patterns between ASD and three common chronic conditions: cardiovascular disease, type 2 diabetes, and mental health problems.

Results:

The study included 659 ASD cases (66.8% male; mean age 52.0 [SD, 8.1]) and 6,590 matched non-autistic individuals. ASD were associated with a 90% higher all-cause mortality (HR, 1.90, 95% CI, 1.41-2.55) and also higher risks of 45 medical conditions across almost all body systems (all Bonferroni-adjusted $P<0.05$). Trajectory analyses exhibited three clusters of medical conditions that predisposed autistic adults to excess mortality: cardiometabolic diseases, external conditions, and infectious diseases. Autistic adults showed not only an overall increased risk of progression of multimorbidity but also distinctive association patterns across different disease transitions.

Conclusions:

Our findings show patterns of comorbidities among autistic adults in their mid- and later adulthood, which could provide information to their caregivers to implement appropriate disease management and prevention strategies.

408.048 Institutional and Social Stigma during School Trajectories and Its Impact on Labor Inclusion: A Women's and Non-Binary Autistic Adults' Perspective.

C. Tapia Fuenzalida^{1,2}, S. L. Castillo Palacios^{1,2}, B. C. R. Yamal Carrillo³, C. Alarcón⁴, M. T. Solis-Soto² and M. S. Burrone⁵, (1)*School of Health, Universidad de O'Higgins, Rancagua, Cachapoal, Chile*, (2)*Institute of Health Sciences, Universidad de O'Higgins, Rancagua, Chile*, (3)*School of Social Sciences, Universidad de O'Higgins, Rancagua, Cachapoal, Chile*, (4)*Faculty of Art and Social Sciences, University of Sydney, Sydney, NSW, Australia*, (5)*Institute of Health Sciences, Universidad de O, Rancagua, Chile*

Background:

Despite increasing awareness of neurodiversity, the intersection of autism and gender remains underexplored, particularly in relation to how students' experiences shape labor inclusion. In Chile, autistic individuals continue to face significant barriers to both educational and professional inclusion. It is essential to examine the stigmatizing processes encountered by autistic women and non-binary autistic adults, and their long-term consequences.

Objectives:

This study aims to analyze the institutional and social stigma experienced by autistic women and non-binary autistic adults during their educational trajectories and its impact on labor inclusion. Specifically, it seeks to understand how experiences of violence and discrimination within the educational context influence job opportunities for young autistic women and non-binary individuals in Chile.

Methods:

A qualitative approach was employed, conducting 16 in-depth interviews with cisgender autistic women (n=14) and non-binary individuals (n=2) from Chile. All the collected data was digitized and transcribed, creating a unique data corpus. An open coding process was used to assign meaning units to the information and construct thematic categories. The interviews were coded and analyzed to identify elements related to the transition from school to work, focusing mainly on institutional and social stigma. The study received ethical approval from an Accredited Ethics Committee.

Results:

The analysis revealed institutional and social stigma during the participants' educational trajectories, which negatively impacted their labor inclusion. Participants reported **discriminatory attitudes** from teachers, school professionals, and peers. One participant described how a teacher bullied her for appearing to fit a particular stereotype: *"A teacher bullied me for looking like Sheldon Cooper"* (DS07). Additionally, some educational professionals contributed to the participants' social isolation. For example, a participant recounted how a school psychologist blamed her for her loneliness: *"The psychologist said I was to blame for being alone"* (BS06).

Discriminatory attitudes also extended to peers, with participants reporting bullying that intensified their feelings of isolation: *"My classmates bullied me"* (DS04). These experiences of social exclusion and institutional violence directly affected the participants' **self-esteem** and their ability to integrate into the labor market. One participant expressed the internalized self-doubt fostered by such experiences: *"I've always struggled with self-esteem, and I feel like I'm not capable"* (DS01).

In the workplace, participants noted that **autistic traits** are often misunderstood, complicating their inclusion: *"These characteristics of autistic women are the same ones that cause conflict at work"* (MG04). Moreover, stereotypes about autism were also present in the school context, where participants were labeled as loners or incapable: *"She's autistic, she likes being alone, she doesn't talk much"* (DS04).

Conclusions:

This study highlights the profound and lasting impact of institutional and social stigma experienced by autistic women and non-binary autistic adults during their educational trajectories. Discriminatory attitudes and inadequate teaching practices not only perpetuate cycles of exclusion and violence but also limit opportunities for labor inclusion. The findings suggest the need for public policy interventions and educational programs that address stigma and promote inclusive practices in educational and labor environments.

408.049 Effects of Low-Dose Psilocybin on EEG-Derived Neural Complexity in Autistic and Non-Autistic Adults

C. L. Ellis¹, T. Whelan², R. Haartsen³, J. Ahmad⁴, M. Dimitrov⁵, F. Moruzzi⁶, M. J. Kangas⁵, N. Khalil⁷, G. Ivin⁸, E. Daly⁹, L. Mason⁵, D. Murphy⁹ and G. McAlonan¹⁰, (1)Institute of Psychiatry, Psychology and Neuroscience, Institute of Psychiatry, KCL, London, United Kingdom, (2)COMPASS Pathways PLC, London, United Kingdom, (3)Centre for Brain and Cognitive Development, Birkbeck University of London, London, United Kingdom, (4)University of Greenwich, London, United Kingdom, (5)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (6)King's College London, London, United Kingdom, (7)South London and Maudsley NHS Foundation Trust and Institute of Psychiatry, Psychology and Neurosciences, King's College London, London, United Kingdom, (8)South London and Maudsley NHS Foundation Trust Pharmacy, UK, London, United Kingdom, (9)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, UNITED KINGDOM, (10)NIHR-Biomedical Research Centre for Mental Health at the Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, UNITED KINGDOM

Background: Psilocybin is a partial serotonin agonist, primarily affecting the 5-HT_{2A} receptors, with smaller effects on 5-HT_{1A} and 5-HT_{2C} receptors. Psychedelic doses of psilocybin have been found to significantly increase EEG-derived measures of neural complexity. This increase in complexity is thought to reflect a more flexible, dynamic brain state, where rigid patterns of neural activity are temporarily disrupted. However, existing studies have focussed on large, psychedelic doses in neurotypical subjects, limiting broader therapeutic potential. It is unclear whether low doses of psilocybin, which do not produce marked psychedelic experience, can also increase neural complexity, and whether its effects could extend to autistic people with different baseline serotonergic function.

Objectives: Here we used two low (sub-psychedelic) doses of psilocybin, to examine whether EEG markers of neural complexity could be modulated in non-autistic people, and whether modulation is different in autism. Two types of EEG complexity measures were considered: Lempel-ziv complexity (LZc) and Detrended Fluctuation Analysis (DFA).

Methods: EEG data were recorded at rest in 67 adults with (37) and without (30) autism. Data were collected as 6 blocks of 1-minute trials where participants eyes were either open (3 trials) or closed (3 trials). All data were collected following a single dose of either placebo, 2mg of psilocybin or 5mg of psilocybin. The order of which was randomised and double blind. Data were pre-processed using the MADE-BOND automated pipeline in EEGLAB. Key steps included downsampling to 250Hz, bandpass filtering (1-35Hz), removal of flat/noisy channels, ICA for artifact removal (blinks, saccades, EMG), channel interpolation, and re-referencing to the average.

Results: We hypothesise that psilocybin will increase neural complexity (LZc and DFA) with increasing dose of psilocybin in non-autistic people. There are no previous studies reporting psilocybin pharmacological challenges in autistic participants; but consistent with response to other psychoactive drugs, we expect autistic participants to respond distinctively to psilocybin (either an increased or reduced response) in comparison with non-autistic participants.

Conclusions: For the first time, we will present findings on the modulation of neural complexity by low-dose psilocybin in both autistic and non-autistic adults. By comparing these groups, we aim to determine whether psilocybin's effects can be achieved at sub-psychedelic doses, focusing on autistic adults, who may exhibit distinct responses due to differences in serotonergic function. The findings will clarify whether lower, safer doses of psilocybin hold therapeutic potential, especially for autistic people.

408.050 Elevating Resilience Among Autistic Post-Transfer College Students

B. R. Nachman¹ and **B. E. Cox²**, (1)University of Pittsburgh, Pittsburgh, PA, (2)Michigan State University, East Lansing, MI

Background: Navigating new institutional spaces, college students in the United States enrolled in a four-year college or university following community college transfer are confronted with a bevy of unfamiliar experiences (Chin-Newman & Shaw, 2013; Rodriguez & Kerrigan, 2019). Transferring from a two-year college to a four-year college can be challenging for any student, prompting transfer shock (Lakin & Elliott, 2016; Scott et al., 2017) and negatively impacting their mental health (Daltry & Mehr, 2016; Mikell & Davis, 2022). However, it is unclear whether/how the distinct cognitive and behavioral profiles common to autism might affect that transition process.

Objectives: Current understandings of autistic college students' experiences generally do not disaggregate based on pre- or post-transfer status (for exceptions, see Anyinam et al., 2020). With the ultimate goal of facilitating autistic students' postsecondary success, this study explores how autistic students maintain resilience and honor self-care as they transition from a two-year to a four-year college.

Methods: This study draws on data from 21 interviewees identifying as transfer students, conducted as part of a nationwide, mixed methods, longitudinal study on autistic college student success. To ease students' comfort, we allowed them to choose the interview format (Zoom video, audio, or chat only) and shared interview protocols in advance. Our team conducted member checking through having participants review summaries of our conversations to share edits and clarify any points (Lincoln & Guba, 1985). Our research team of individuals with distinct autism expertise and connections developed an initial codebook of theoretical codes (Saldaña, 2016) related to our Identities, Psychological, Academics, Community, and Employment (IPACE) framework. We developed an initial codebook augmented by emergent codes. We extracted codes connected to issues around mental health, well-being, and executive functioning.

Results: We identified three themes that helped students maintain resilience and honor self-care. First, students leveraged college services that reduced their stress and anxiety, from counseling and disability services offices, to autism support programs and disability alliances. Second, they turned to people who provided support and reassurance, including faculty who validated their concerns and peers who they could rely on for friendship. Third, they practiced patience with themselves amid stressful times. For example, one student shared, "amidst it all, the grass still grows and I still smile. So, basically like no matter what is thrown my way, life still goes on." Student anecdotes elucidate the value of leaning into resources, other people, and their own self-worth in feeling resilient and supporting their mental health.

Conclusions: Our study illuminates that post-transfer students often encounter disorienting environments when moving from a two- to a four-year college. Although it may be impossible to entirely avoid such experiences, students report having employed multiple strategies to facilitate a successful transition. By making use of institutional resources, cultivating supportive relationships with instructors and peers, and practicing patience with themselves and others, autistic transfer students can maximize their likelihood of attaining their definitions of college success.

408.051 Emerging Adulthood Transitions and Support Networks within the Context of Autism

K. A. Anderson¹, **M. Radey¹**, **J. E. Rast²**, **M. Killian¹** and **E. Dolce³**, (1)College of Social Work, Florida State University, Tallahassee, FL, (2)A.J. Drexel Autism Institute, Drexel University, Philadelphia, PA, (3)College of Medicine, Florida State University, Tallahassee, FL

Background: Research on autistic transition-aged young adults (TAYA) has primarily focused on objective markers of adulthood, such as residential placement and employment, with limited attention given to the interrelationships between caregivers and their adult children. Additionally, much of the existing literature does not disaggregate by socioeconomic status. There is also a need for studies drawn from recent cohorts of TAYA that are reflective of more recent demographic changes or the evolving autism diagnostic criteria.

Objectives: The study's objective was to describe family support, public assistance support, indicators of adulthood, and health among TAYA. We compared those with an autism diagnosis to those without to inform future practice and policy.

Methods: We used the most recent wave (Year 22) of the Future of Families and Child Wellbeing data, a national, longitudinal sample of children born in cities in 1998-2000. Seventy-five percent of FFCWS children were born to parents unmarried at the time of their birth resulting in a sample with high levels of socioeconomic disadvantage. Mothers, fathers and caregivers were asked about FFCWS children with disabilities at key developmental points including at Years 1, 3, 5, 9, and 15. Young adults also did so at Year 22. The present analysis examines differences between young adults with an autism diagnosis at some point from age 3 to age 22 ($n = 69$) to those without an autism diagnosis at any point ($n = 2,114$).

Results: Autistic TAYA were more likely to live with their parents at age 22 (70% vs. 54%), but these arrangements did not translate to closer relationships. Those with autism reported similar levels of talking with, seeing, and feeling extra close to their parents as those without autism. Autistic TAYA were more likely to receive public assistance benefits, largely due to Social Security Income (SSI) receipt without differences on other cash or food benefits or socioeconomic indicators (e.g., poverty level, experiencing a hardship). Despite similar socioeconomic conditions, autistic TAYA were much less likely to achieve all measured indicators of adulthood including full-time employment (16% vs. 38%), full responsibility for bills (31% vs. 56%), marriage or partnership (17% vs. 38%), or parenthood (16% vs. 5%). Autistic TAYA also experienced lower levels of life satisfaction and self-reported health and higher rates of anxiety when compared to their counterparts without an autism diagnosis.

Conclusions: Findings suggest that the public safety net protects autistic TAYA from poor socioeconomic conditions, yet this protection does not extend to key well-being indicators. Lower levels of life satisfaction, health, and mental health may reflect autistic TAYA's lower likelihood of reaching traditional markers of adulthood. Their higher likelihood of living with their parents, for example, may reflect the lack of alternatives rather than preference as their level of contact and closeness to their parents is similar to those without autism. Public programs to support autistic TAYA transition to young adulthood may help to alleviate well-being disparities.

408.052 Examining Gender-Based Differences in Dating Experiences and Romantic Relationships Among Autistic Adults

G. Slater¹, B. Warner², C. T. Moody³, G. Sotomayor⁴, E. A. Laugeson⁵ and K. L. Fisher⁶, (1)Pepperdine University, Los Angeles, CA, (2)UCLA, Los Angeles, CA, (3)UCLA Semel Institute for Neuroscience and Human Behavior, University of California Los Angeles, Los Angeles, CA, (4)Semel Institute for Neuroscience and Human Behavior, University of California Los Angeles, Los Angeles, CA, (5)UCLA Semel Institute for Neuroscience and Human Behavior, UCLA PEERS® Clinic, Los Angeles, CA, (6)UCLA Semel Institute for Neuroscience and Human Behavior, UCLA PEERS Clinic, Los Angeles, CA

Background:

Autistic individuals often face challenges when it comes to dating, romantic relationships, and sexuality (Barnett & Maticka-Tyndale, 2015; Cheak-Zamora et al., 2019). These challenges may stem from differences in pragmatic communication skills and challenges with recognizing and responding to social cues and emotions that are associated with autism (Kohn et al., 2022; Kock et al., 2019). Gender differences in the prevalence, presentation, and experiences of autism are well-documented (Cooper et al., 2018; Milner et al., 2019). For example, higher rates of camouflaging, late-in-life diagnoses, and mental health challenges have been observed in autistic women (DaWalt et al., 2021; Zener, 2019). These factors, combined with well-established differences in dating experiences between men and women in the general population, highlight the need to better understand gender-based differences in the dating experiences of autistic adults (Kock et al., 2019; Martinez et al., 2021). Such research is essential to developing adequate support strategies that address the needs of this population.

Objectives:

This study aims to investigate gender differences in the romantic and dating experiences of autistic adults.

Methods:

Participants included 90 autistic adults (males, $n=75$; females, $n=15$) enrolled in a study investigating a novel social skills program focused on dating etiquette and developing healthy romantic relationships, PEERS® for Dating ($M_{age}=26.11$, $SD=5.74$). At baseline, adults reported on their dating history and completed measures such as the Social and Emotional Loneliness Scale for Adults (DiTommaso & Spinner, 1993), Dating Anxiety Scale (Glickman & La Greca, 2004), and a criterion-based measure of dating-related social skills taught in the curriculum, the Test of Dating Skills. Independent samples t-tests and chi-square analyses were conducted compare constructs by gender.

Results:

Independent samples t-tests indicated no significant gender differences in total dates in the past month $p=.189$, knowledge of dating-related social skills, $p=.268$, loneliness, $p=.234$, or dating anxiety, $p=.151$. Crosstabulation analysis indicated a trending relationship between gender and recent use of online dating platforms, with males marginally more likely to endorse usage, $\chi^2(2, N = 90)=3.31$, $p=.069$. Further, a significant relationship between gender and previous dating experiences emerged, $\chi^2(2, N = 94)=7.49$, $p=.024$. Specifically, autistic males were more likely to have had no previous dating experiences (53% of males, 29% of females), while autistic females were more likely to have had experiences with committed relationships (17% of males, 47% of females) prior to the start of the program.

Conclusions:

Results suggest that while male and female autistic adults have similar levels of loneliness, dating skills knowledge and dating anxiety, autistic men have less dating experience than autistic women. This may explain why autistic men were somewhat more likely to be engaging with online dating platforms. Given that autistic women are more likely to experience intimate partner violence (Douglas & Sedgewick, 2024), future research may explore factors associated with positive dating experiences to inform clinical supports for this vulnerable group. Additionally, investigating the dating and romantic experiences of gender-diverse autistic adults should be considered given the high prevalence of gender diversity in the autistic community (Strang et al., 2023).

408.053 Experiences of Autistic Adults Using Psychedelic Drugs Including Adverse Effects

J. Stroud¹, C. Rice², A. Orsini³, M. Schlosser⁴, J. Lee⁵, W. Mandy⁶ and S. K. Kamboj⁷, (1)University College London, London, England, United Kingdom, (2)University College London, London, United Kingdom, (3)Autistic Psychedelic Community, Los Angeles, CA, (4)University of California, Irvine, Irvine, CA, (5)Research Department of Clinical, Educational & Health Psychology, University College London, London, United Kingdom

Background: Research into managing social and emotional issues is a high priority in the autistic community. Recently, classic psychedelics have emerged as potential therapies for various mental health conditions. Anecdotal evidence suggests psychedelics may increase psychological well-being and social engagement in autistic people. However, there are few modern studies investigating this area.

Objectives: This exploratory study aims to investigate the experiences of autistic participants with psychedelics, particularly the extent to which they attribute changes in mental health and social engagement to their most 'impactful' psychedelic experience. We also examine associations between these changes and relevant variables, such as aspects of the acute psychedelic experience and changes in psychological flexibility.

Methods: Self-selecting autistic participants with high autism quotient scores ($n=233$), completed an online survey regarding their most impactful psychedelic experience. The largest demographic represented in our survey were well-educated men from North America or Europe (total sample mean age = 29.8 years, 48.7% identified as men, 23.7% identified as women, 21.1% identified as non-binary and 6.5% identified as other).

Questionnaires assessed the acute psychedelic experience and perceived psychedelic-induced changes in distress, social engagement, psychological flexibility, and other relevant constructs. We performed two exploratory linear regressions with change in psychological distress and social engagement as dependent variables. We controlled for age, years of education, gender identity and time since psychedelic experience, to explore the association between the dependent variables and changes in relevant constructs (e.g. loneliness, camouflaging, social connectedness, autistic characteristics and intensity of the acute psychedelic experience).

Results: Most participants attributed decreases in psychological distress (82%) and social anxiety (78%) and increases in social engagement (70%) to their selected psychedelic experience. A notable minority reported negative effects, including heightened anxiety (20%), with some describing their psychedelic experience as among the most negatively impactful of their lives. The only substantial predictor for reductions in psychological distress was increased psychological flexibility. We also present additional unpublished data regarding participants who reported decreased well-being, including autism quotient scores, relevant camouflaging subscale scores and measures of psychedelic 'integration'. We also present further unpublished data on the participants' mindsets preceding these experiences and the settings in which they occurred. We also reference an unpublished systematic review of adverse effects in 32 modern, randomised and placebo-controlled studies where psilocybin was administered to humans (a chapter of Jack Stroud's University College London (UCL) Doctoral Thesis), which provides results and recommendations relevant to future studies with autistic participants.

Conclusions: Participants in our study attributed changes in mental health and social engagement to a single impactful psychedelic experience.

While these findings are promising, they must be interpreted cautiously due to the non-experimental design and biased sampling. The results justify small proof-of-concept intervention trials to evaluate the feasibility and acceptability of psychedelic interventions for enhancing well-being in autistic individuals. Such studies should also consider the possibility of increased vulnerability to adverse effects in this population and implement careful design and monitoring to manage and assess these risks.

408.054 Experiences of Autistic Connectedness in a Virtual Group-Based Mindfulness Intervention: A Qualitative Analysis

N. Vashi¹, K. Smith², J. A. Wozniak², J. A. Weiss¹ and Y. Lunsky², (1)Psychology, York University, Toronto, ON, Canada, (2)Azrieli Adult Neurodevelopmental Centre, Centre for Addiction and Mental Health, Toronto, ON, Canada

Background: Autistic connectedness, defined as having a sense of belonging and shared experiences within the autistic community, being socially connected to other autistic people, and advocating for this community (Botha et al., 2022), has been shown to be linked with increased well-being, belonging, and resilience (Cage et al., 2022; Cooper et al., 2017; Crompton et al., 2020; Robeyns, 2016). Studies have commonly examined connectedness within the context of interventions that directly target improvements in social skills and communication. Fewer studies have investigated how connectedness can be fostered among autistic adults in more naturalistic ways. Mindfulness interventions may be uniquely poised to indirectly enrich aspects of autistic connectedness, as these interventions are grounded in principles of compassion, non-judgment, and present-moment awareness, which may, in turn, enable the development of more meaningful and accepting relationships (Block-Lerner et al., 2007; Birnie et al., 2010; Hutcherson et al., 2008; Welwood, 1996). It is warranted to examine whether this type of intervention may cultivate improvements in autistic connectedness when delivered using a neurodiversity-affirming approach.

Objectives: The current study qualitatively explored the impacts of an autistic co-designed and co-led virtual mindfulness intervention on experiences of connectedness among autistic adults.

Methods: Participants were recruited from agencies across Canada that provide services to autistic people and their families, in addition to recruitment conducted through social media (e.g., Twitter, Facebook). Sixty-three participants completed a virtually delivered six-week mindfulness intervention between November 2022 and July 2023, as part of a randomized controlled trial. Fifty-seven participants completed open-ended survey responses following the intervention. Open-ended questions queried what participants liked most and least about the group, their impressions of having an autistic person co-lead the group, and their impressions of participating with other autistic adults in the group. Participants were between 19 to 68 years of age ($M = 37.41$ years, $SD = 11.26$ years). Fifty-four percent of participants identified as women, 31% as men, and 25% as gender diverse (e.g., non-binary, gender nonconforming).

Results: A structured approach to thematic analysis (ST-TA; Robinson, 2022) revealed that autistic connectedness was reflected in overall themes of *safety*, *acceptance*, and *belonging*. With regard to safety, participants expressed that having an autistic person co-facilitate the group allowed them to trust in the group and feel reassured and comforted. Acceptance was related to participants feeling supported by fellow group members and facilitators and being able to be their authentic selves. Finally, belonging was linked with participants feeling a sense of community in the group, sharing and learning from others' challenges, and feeling represented. Notably, some participants expressed negative impacts of participating within the group (i.e., increased feelings of anxiety and masking behaviours), and others indicated a greater need for opportunities to connect with like-minded individuals.

Conclusions: Understanding naturalistic ways in which autistic connectedness can be nurtured is vital to promoting positive outcomes among autistic adults. Future research should explore both intervention-specific (e.g., mindfulness-related values of acceptance and non-judgment) and broad factors (e.g., connecting within a neurodiversity-affirming, shared space) that may facilitate increased connectedness among this group.

408.055 Experiential and Psychophysiological Emotional Coherence in Daily Life in Autistic Adults

X. Hu¹, J. B. Northrup², C. M. Conner², C. A. Mazefsky², L. N. Scott² and L. M. Bylsma², (1)University of Pittsburgh, Pittsburgh, PA, (2)Department of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, PA

Background: While studies predicting emotional experience from physiological signals often assume that the different components of emotion (e.g., experience, psychophysiology, behavior) change coherently, the existence of emotional coherence remains controversial. This issue is particularly relevant in autistic individuals, given the high prevalence of alexithymia (i.e., difficulties in experiencing, identifying and expressing emotions). Therefore, this study aims to examine emotional coherence in autistic adults' daily life and test whether autism diagnosis or alexithymia symptoms moderate this coherence.

Objectives: We aim to: (1) examine the presence of emotional coherence, defined as the within-individual association between experiential (self-reported arousal) and physiological (heart rate [HR] and skin conductance level [SCL]) components of emotion, in everyday life; (2) determine whether autism diagnosis or trait alexithymia symptoms moderate emotional coherence; and (3) explore the specific temporal scale at which the physiological and experiential components of emotion achieve the strongest coherence.

Methods: Data were drawn from an ongoing project involving 65 adults (50 autistic adults and 15 neurotypical controls, age = 32.50 ± 10.58 years, 46/16 assigned female/male at birth) who completed a 14-day ecological momentary assessment (EMA) and ambulatory psychophysiological monitoring. Before the EMA assessment, participants completed the Toronto Alexithymia Scale (TAS-20) to assess trait alexithymia symptoms. During each data collection day, participants received 8 prompts over their waking hours (at least 12 hours) to report current emotional arousal levels, while wearing electrocardiogram (ECG) and electrodermal (EDA) sensors to measure HR and SCL. Mixed-effects models assessed the within-individual associations between emotional arousal and HR/SCL metrics derived from the 30-minute period preceding each prompt. We also examined the potential moderation effects of autism diagnosis and trait alexithymia and explored the optimal time window (ranging from 5 to 60 minutes) for HR and SCL metrics to achieve the strongest emotional coherence.

Results: Significant emotional coherence was observed, with increased emotional arousal associated with increased HR ($\beta = 0.46$, $SE = 0.06$, $p < .001$) and SCL ($\beta = 0.30$, $SE = 0.06$, $p < .001$). These associations were not significantly moderated by autism diagnosis (HR*autism: $\beta = 0.23$, $SE = 0.13$, $p = .09$; SCL*autism: $\beta = 0.00$, $SE = 0.16$, $p = .99$) or trait alexithymia symptoms (HR*alexithymia: $\beta = 0.00$, $SE = 0.00$, $p = .23$; SCL*alexithymia: $\beta = 0.00$, $SE = 0.01$, $p = .33$). Additionally, HR and SCL derived from shorter time windows demonstrated better predictive fit for emotional arousal, with the 5-minute window yielding the best performance, although optimal time windows varied across individuals.

Conclusions: These preliminary results provide the first evidence that emotional coherence exists in both autistic and neurotypical adults in everyday life, with stronger physiological responses (HR and SCL) associated with higher emotional arousal. Contrary to expectations, autism diagnosis and alexithymia symptoms did not significantly moderate emotional coherence, suggesting that coherence may not be as disrupted by autistic traits as previously thought. However, our tests of moderation may be underpowered and data collection is still ongoing. The findings also highlight the importance of time window selection when examining emotional-physiological associations.

408.056 Exploring Determinants of Physical Activity in Adults with Intellectual and Developmental Disabilities

S. Suswaram¹, K. Hume², M. N. Savage³, E. Cort⁴, S. Saxena⁴, I. Y. Yang⁴, L. Hye⁴, H. Loeb⁵, A. Marx⁶ and B. Tomaszewski⁶, (1)Carolina Institute for Developmental Disability, University of North Carolina at Chapel Hill, Carrboro, NC, (2)School of Education, University of North Carolina, Chapel Hill, Chapel Hill, NC, (3)University of Arkansas, Fayetteville, AR, (4)University of North Carolina at Chapel Hill, Chapel Hill, NC, (5)Psychiatry, UNC TEACCH Autism Program, Chapel Hill, NC, (6)UNC TEACCH, Carrboro, NC

Background: Physical activity is important for maintaining overall health and well-being, as it has been shown to reduce the risk of noncommunicable diseases such as cardiovascular diseases, diabetes, and obesity. However, in adults with intellectual and developmental disabilities (IDD), participation in physical activities is significantly lower compared to the general population. The consequence of this reduced participation is an increased risk of health issues, including lower physical fitness levels, higher rates of obesity, and a decreased quality of life. Understanding the processes that contribute to engagement in physical activity in this population is crucial for developing effective interventions. **Objectives:** To qualitatively explore determinants of engagement in physical activities for adults with intellectual and developmental disabilities. **Methods:** Four focus groups of caregivers ($n = 16$), three focus groups of direct support professionals (DSPs; $n = 14$), two focus groups of exercise professionals ($n = 12$), and individual interviews with adults with IDD ($n = 15$) from racially and ethnically diverse backgrounds participated in semi-structured interviews to share their perspectives on physical activity engagement for adults with IDD. Data from the interviews and focus groups were systematically coded and analyzed using applied thematic analysis stratified by participant type.

Results: Participation in physical activities for adults with IDD is influenced by several factors. All participants, including adults with IDD, caregivers, DSPs, and exercise professionals, emphasized the importance of physical activity for quality of life. Adults with IDD mentioned physical activity in terms of enjoyment, extrinsic motivation, and social opportunities. Caregivers, DSPs, and exercise professionals highlighted challenges for adults with IDD in setting abstract goals, relying more on short-term goals with tangible outcomes. For example, adults with IDD were more motivated by rewards than overall health benefits for physical activity. These challenges affected their engagement in goal setting and progress monitoring for physical activity. The lack of resources to convey long-term benefits was a key issue. Other challenges included logistics, lack of services, and resources. Personalized programs and inclusiveness were seen as crucial for encouraging physical activity. Tailored programs and inclusiveness were considered more effective for long-term engagement.

Conclusions: This study highlights the multifaceted nature of physical activity engagement for adults with IDD. Insights from adults with IDD, caregivers, DSPs, and exercise professionals reveal that both intrinsic and extrinsic factors influence participation in physical activity. Adults with IDD often rely on external motivators, emphasizing the need for concrete goals and visual support. Tailoring programs to individual needs and ensuring inclusiveness can improve understanding of the benefits and importance of physical activity, encouraging continuous participation. Future research should focus on developing and evaluating interventions that effectively convey the long-term benefits of physical activity to adults with IDD. Additionally, exploring strategies to enhance intrinsic motivation and goal-setting abilities within this population is essential. Addressing these areas can lead to more effective interventions that promote long-term engagement in physical activities, ultimately improving the overall health and well-being of adults with IDD.

408.057 Exploring Factors Related to Vocational and Educational Engagement Among Autistic Young Adults with Low IQ

C. Moser¹, R. Adams², S. Zheng³, S. Bishop⁴ and J. L. Taylor⁵, (1)Vanderbilt University Medical Center, Nashville, TN, (2)Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (3)Psychiatry and Behavioral Sciences, The University of Texas at Austin, San Francisco, CA, (4)Psychiatry and Behavioral Sciences, University of California, San Francisco, San Francisco, CA, (5)Department of General Pediatrics, Vanderbilt University Medical Center, Nashville, TN

Background: Autistic transition-aged youth face low rates of employment and enrollment in post-secondary education programs. Even lower rates have been documented for autistic youth with low IQ. Notably, much of the work describing the vocational and educational activities of autistic individuals with low IQ was conducted over a decade ago, and the landscape of employment and post-secondary educational opportunities has changed immensely.

Objectives: The present study described the rate of involvement in vocational and educational activities of autistic youth with low IQ. We also explored differences in demographic and behavioral characteristics between those who were and were not involved in vocational and educational activities.

Methods: Participants were 91 parents of autistic youth with low IQ (defined as an IQ of 70 or below) enrolled in a larger study. All youth had exited high school (M age = 23.11 years). Parents reported on their youth's vocational and educational activities and demographics, including youth age, race, and ethnicity, caregiver education, household income (above or below \$60,000), and whether the family lived in a rural or urban residence, obtained by matching each family's zip code to USDA rural-urban commuting area codes. Caregivers also reported on youths' behavior characteristics via survey, including their daily living skills measured via the Waisman Activities of Daily Living Scale, autism traits indexed from the Social Responsiveness Scale-2, and internalizing and externalizing behavior measured from the Child/Adult Behavior Checklist. Frequencies and percentages were computed to describe daytime activities. T-tests or chi-square tests were conducted to investigate differences in demographic and behavioral characteristics for those who were versus were not involved in vocational and educational activities.

Results: Thirty-five percent of autistic youth with low IQ were not involved in any vocational or educational activity. Of the 65% of youth engaged in vocational and educational activities, 29% participated 10 hours or less per week. Autistic youth with low IQ who participated in vocational and education activities had significantly higher family income ($p=.043$) and daily living skills ($p=.007$) and lower internalizing behavior ($p=.006$), externalizing behavior ($p=.025$), and autism traits ($p=.042$) than those who were not engaged in activities. Refer to Table 1 for descriptive and test statistics.

Conclusions: The number of autistic youth with low IQ who were not involved in any vocational or educational activity is substantially higher than reported rates in earlier work, which could be due to a variety of reasons, such as movement away from segregated work settings without necessary investment to support community placement. Aligning with previous research, results suggest that behavioral characteristics, including daily living skills, autism traits, and internalizing and externalizing behavior, may be important targets in improving involvement in these activities. Results also indicate that families with greater socio-economic resources may be better equipped to support their youths' participation in vocational and educational activities, suggesting systemic change is needed to ensure these opportunities are accessible for all. Overall, findings point to a clear and immediate need to increase engagement in vocational and educational activities for autistic youth with low IQ.

408.058 Exploring Gender As a Moderator of the Relationship between Depression and Externalizing Behaviors in Autistic Adolescents

N. Musicant^a, C. T. Moody^a, G. Slater^a and E. A. Laugeson^a, (1)PEERS lab: UCLA PEERS Clinic, Los Angeles, CA, (2)UCLA Semel Institute for Neuroscience and Human Behavior, University of California Los Angeles, Los Angeles, CA, (3)Pepperdine University, Los Angeles, CA, (4)UCLA Semel Institute for Neuroscience and Human Behavior, UCLA PEERS® Clinic, Los Angeles, CA

Background: In the face of an adolescent mental health crisis (Benton et al., 2021), understanding pathways toward adolescent well-being is critical. This is especially true for autistic teens, who not only demonstrate significantly higher levels of both internalizing and externalizing symptomatology but are also more likely to have unmet mental health needs than neurotypical peers (Bauminger et al., 2010; Pezzimenti et al., 2019; Mandy et al., 2022). Among the general population of adolescents, previous research documents a positive predictive relationship between depression and externalizing behaviors, which is more robust in males than females (Little & Garber, 2005; Liu et al., 2023). However, this relationship, and the role of gender in it, has not yet been extensively studied in autistic adolescents. Given that gender differences commonly observed in the general population, such as higher rates of externalizing behaviors in male youth, do not always extend to autistic youth (Mayes et al., 2020; Woodman et al., 2016), this research would be informative to clinical practice in neurodivergent youth.

Objectives: This study aimed to test gender as a moderator of the relationship between depression and externalizing behaviors in autistic adolescents.

Methods: Participants included 137 autistic adolescents between the ages of 10 and 18 ($M_{age}=14.06$, $SD=1.9$) who presented for the evidence-based PEERS® for Adolescents social skills program. Thirty-five adolescents identified as female (25.5%; $n = 102$ male, 74.5%). Externalizing behaviors were assessed at baseline using caregiver reports on the externalizing subscale of the Social Skills Improvement System (SSIS-Ext; Gresham & Elliott, 2008). Depression was measured via self-report using the total t-score on the Children's Depression Inventory, 2nd Edition (CDI-2; Kovacs, 2011). To test gender as a moderator, a multiple regression model was conducted with depression, gender, and their interaction inputted as predictors of externalizing behaviors.

Results: An independent samples t-test indicated that there were no significant differences between autistic males and females in externalizing behaviors, $t(134)=0.65$, $p=.519$, or depression, $t(132)=0.03$, $p=.979$. In the full sample, CDI-2 scores were not significantly correlated with SSIS-Ext scores, $r=.043$, $p=.622$. In testing whether the predictive relationship between depression and externalizing behavior was moderated by adolescent gender, the regression revealed a non-significant interaction effect, $t(129)=-0.40$, $p=.69$, suggesting no gender differences in the relationship.

Conclusions: Results are consistent with previous literature that suggest a lack of gender differences in autistic youth and adults in levels of internalizing and externalizing symptoms (Mayes et al., 2020; Woodman et al., 2016) – despite data documenting gender differences in these domains in the general population (Girgus & Yang, 2015; Bauminger et al., 2010). Further, there was no significant relationship between depression and externalizing behaviors detected for either autistic males or females. It is possible that the strongest mechanisms of risk for both internalizing and externalizing behaviors are tied to neurobiological and environmental factors (e.g., high rates of peer victimization) that are present in autistic youth across gender. Overall, these data have important implications for clinicians in that traditional therapeutic conceptualizations about gender, mental health, and behavior may not be applicable to autistic populations.

408.059 Exploring Modifiable Factors That Shape Well-Being Among Autistic Adults

E. Hill, K. Barnes, J. Byas, E. Lane, N. Teope and C. Thompson, Curtin School of Allied Health, Curtin University, Perth, Western Australia, Australia

Background: Autistic individuals are more likely to experience increased mental health diagnoses, lower quality of life and poorer state of well-being than their non-autistic adults. Well-being is a multifaceted state of health that encompasses physical, mental, social and spiritual experiences. Involving life satisfaction, relationships and social engagement, employment, living arrangements, leisure activities and the broader economic and environmental context. The experience of well-being can differ significantly for autistic individuals compared to neurotypical individuals. A more inclusive understanding of wellbeing must recognise the unique aspects of the autistic community, including differences in sensory processing and experiences of burnout. Considering that autistic adults are at greater risk of mental health challenges. Several modifiable factors place an individual at greater risk of or protect them against, mental health challenges, as these can be enhanced to promote positive mental well-being. Modifiable wellbeing factors may include engagement in meaningful activities, access and engagement with social supports, intolerance to uncertainty, loneliness and positive autistic social identity, compared to camouflaging. There is much evidence of research investigating factors impacting the well-being of autistic adults in isolation. However, there is a gap in exploring multiple factors in combination.

Objectives: This study investigates the relationship between a series of modifiable factors and well-being among autistic adults.

Methods: This study utilised a cross-sectional mixed-methods convergent design comprising of an online survey and voluntary participation in a semi-structured interview. In total, $n=42$ participants ($M_{age}=28.6$) completed the questionnaire and, $n=11$ interviews ($M_{age}=31.1$). The survey included the following questionnaires: Autism Quotient-50 (AQ-50), Pittsburgh Sleep Quality Index, Godin Leisure-Time Exercise Questionnaire, Camouflaging Autistic Traits Questionnaire (CAT-Q), UCLA Revised Loneliness Scale (UCLA-RLS), Autism Spectrum Identity Scale, and the Personal Well-being Index (PWI). Relationships were explored within the quantitative data using SPSS. The qualitative data from the transcripts from the semi-structured interviews were analysed using reflexive thematic analysis were used to analyse the data.

Results: The quantitative analysis identified significant correlations between the PWI with AQ-50 ($r(40)=-0.438$, $r^2=-0.192$ $p=0.004$), camouflaging [$r(40)=-0.327$, $r^2=0.107$, $p=0.03$] and loneliness ($r(40)=-0.794$, $r^2=0.630$ $p<0.001$). The qualitative analysis identified four themes: (1) *being supported and socially connected enhances well-being*, (2) *to belong is to conform, to conform is to mask, to mask is to harm*, (3) *avoiding burnout through a balanced routine*, and (4) *responses to overwhelming situations*. Combining the quantitative and qualitative data emphasised the importance of belonging, engaging in support, forming meaningful connections, having balance, and managing overwhelming situations.

Conclusions: Findings suggest that while camouflaging can offer autistic adults benefits such as social acceptance with neurotypical individuals, the negative impact of increased loneliness, fatigue and stress, and not being accepted for their authentic self takes a toll on mental and physical well-being. Therefore, it is essential to develop strategies and supportive environments that encourage self-acceptance, reduce the pressure to mask, and promote a positive autistic identity. Information from this study may provide further knowledge to improve existing programs and develop supports specifically targeting camouflaging autistic identity and loneliness in the autistic community.

408.060 Exploring the Homeostatic Theory of Subjective Wellbeing in Autistic Adults

K. L. Ridgway¹, J. Walsh-Adams², C. M. Macmillan³, M. Hooley⁴, D. Hedley⁵, E. Westrupp⁶, M. A. Stokes⁴ and D. H. Demmer⁷, (1)Healthy Autistic Life Lab; School of Psychology, Deakin University - Healthy Autistic Life Lab, Melbourne, VIC, Australia, (2)Healthy Autistic Life Lab, Melbourne, VIC, Australia, (3)Murdoch Children's Research Institute, The Royal Children's Hospital, Parkville, VIC, Australia, (4)Healthy Autistic Life Lab; School of Psychology, Deakin University, Burwood, VIC, Australia, (5)Olga Tennison Autism Research Centre, La Trobe University, Melbourne, VIC, Australia, (6)School of Psychology, Deakin University, VIC, Australia, Melbourne, VIC, Australia, (7)School of Psychology, Healthy Autistic Life Lab, Deakin University, Melbourne, VIC, Australia

Background: The homeostatic theory of Subjective Wellbeing (SWB) proposes that SWB is homeostatically maintained within a set-point range (70- to 90-points on a scale of 0-100) by cognitive and social *buffers*, such as self-esteem and relationships. Individuals with ineffective buffers may be vulnerable to *homeostatic defeat*, and consequently experience low SWB, which when sustained leads to depression. Homeostatic defeat has been found when SWB falls below 50-points in very large global samples from over 40 nations. Autistic people may be at increased risk of homeostatic defeat in the maintenance of healthy SWB due to difficulties achieving the developmental milestones critical to establishing and maintaining buffers such as relationships.

Objectives: To examine the utility of homeostatic theory of SWB in understanding depression in autistic adults.

Methods: A cross-sectional quantitative study of 170 autistic adults ($M_{age}=30.59$, $SD=9.45$), 86 (50.6%) assigned male at birth, 81 (47.6%) assigned female at birth, and three (1.8%) did not specify. Participants completed an online survey between December 2023 and March 2024 on measures of autistic traits (Social Responsiveness Scale Second Edition), SWB (Personal Wellbeing Index-Adult [PWI-A]), and depression (Depression Anxiety Stress Scale-21).

Results: Our sample scored low in SWB ($M=48.89$, $SD=20.84$) with 50% scoring less than 50-points. Two thirds of our sample scored below the cut-off for depression: 26.6% moderately severe, and 39.4% severe depression symptoms. A stepwise regression revealed that age and assigned sex at birth did not significantly predict depression $F(2, 167) 2.95$, $p=.05$, $\eta^2=0.03$, autistic traits significantly predicted depression, $F(3, 166) 7.85$, $p<.001$, $\eta^2=0.09$, and SWB significantly predicted depression, $F(4, 165) = 38.91$, $p>.001$, $\eta^2=0.32$. This model explained 49% of the variance in depression ($R^2 = 0.49$, $p<.001$), SWB the strongest predictor ($b = -.64$, $p<.001$), then autistic traits ($b=.31$, $p<.001$), and assigned sex at birth ($b = .16$, $p<.05$). There was a significant difference in the mean depression symptoms between those with higher (>50 -points) and lower (<50 -points) SWB, $t(156.13) = 9.83$, $p<.001$, $\eta^2=0.38$, $d=1.57$; those with lower SWB ($M=13.87$, $SD=4.89$) reported higher depression symptoms compared to those with higher SWB ($M=7.34$, $SD=3.69$).

Conclusions: The current study's findings support SWB as a potential mechanism implicated in depression for autistic adults. The mean score in SWB for our sample was well below positive range expected based on adult population norms, suggesting this group were more vulnerable to homeostatic defeat. We suggest that SWB could be used to screen those at risk of depression, and that theorized buffers be explored as possible leverage points for intervention.

408.062 Exploring the Relationship between Loneliness and Externalizing Behaviors in Autistic Young Adults

M. Smith¹, M. Zheng¹, J. A. Yon-Hernandez², Y. Takarae³ and M. Solomon⁴, (1)University of California Davis MIND Institute, Sacramento, CA, (2)Department of Psychiatry and Behavioral Sciences, University of California, Davis, M.I.N.D. Institute, UC Davis, Sacramento, CA, (3)Department of Psychiatry and Behavioral Sciences, UC Davis, Sacramento, CA, (4)Department of Psychiatry and Behavioral Sciences, UC Davis MIND Institute, Sacramento, CA

Background: Loneliness is a prevalent concern for autistic children (Bauminger & Kasari, 2000) that worsens during the transition to adulthood, making this a critical period to investigate (Schiltz et al., 2024). Most research about loneliness in autism focuses on unidimensional measures of loneliness, failing to capture distinctions between emotional loneliness (the absence of close, intimate relationships, e.g. familial and romantic) and social loneliness (the lack of wider social networks or group connections). Existing literature shows associations between emotional and social loneliness and internalizing symptoms (e.g., social anxiety and depression) in autistic adults (Schiltz et al., 2021); however, the relationship between loneliness and externalizing behaviors (e.g., aggressive, rule-breaking, and intrusive behaviors) remains underexplored.

Objectives: To examine the associations of multiple dimensions of loneliness with externalizing behaviors.

Methods: Participants included 80 individuals, 41 autistic and 39 non-autistic individuals ages 18–22 ($M = 19.9$, $SD = 1.5$ and $M = 20.0$, $SD = 1.4$, respectively) with average IQ as measured by the Wechsler Abbreviated Scale of Intelligence-II (autistic group $M = 99.4$, $SD = 14.0$; non-autistic group $M = 108.9$, $SD = 12.3$). The Social and Emotional Loneliness Scale for Adults-Short Version (DiTommaso et al., 2004) measured loneliness via a total score and three subscales: social, family, and romantic loneliness. The Adult Self Report of the Achenbach System of Empirically Based Assessment measured externalizing problems. Independent samples t-tests and Spearman's correlations and partial correlations with autism symptoms (Schiltz et al., 2021) and IQ as covariates were used in analyses.

Results: There were significant between group differences in total [$t(61.3) = 3.950$, $p < .001$] and romantic [$t(46.9) = 5.391$, $p < .001$] loneliness. No significant group differences were found in family or social loneliness. There was a correlation with a medium effect size ($r = .4$, $p = .029$) between total loneliness and externalizing problems in the autistic group, and a partial correlation with a medium effect size when accounting for autism symptom severity ($r = .4$, $p = .042$). In addition, there was a correlation with a medium effect size between externalizing problems and family loneliness ($r = .4$, $p = .033$) in autistic individuals, which remained significant after accounting for IQ ($r = .4$, $p = .021$) and autism symptom severity ($r = .5$, $p = .005$).

Conclusions: Autistic participants reported higher total and romantic loneliness, highlighting the need for targeted interventions during this transitional period. As hypothesized, externalizing symptoms correlated with loneliness, particularly family loneliness, suggesting that family relationships influence the expression of externalizing behaviors. Future research should explore the mechanisms linking family loneliness to behavior and assess how family engagement can reduce externalizing symptoms and improve well-being in autistic adults.

408.063 Job Characteristics of Autistic Adults: Associations with Satisfaction

E. Durrani¹, C. Moser², S. Brandl-Mueller³, N. Libster⁴, T. J. Vogus³, M. R. Mailick³, L. E. Smith DaWalt³ and J. L. Taylor⁴, (1)Vanderbilt University Medical Center, Nashville, TN, (2)Owen Graduate School of Management, Vanderbilt University, Nashville, TN, (3)University of Wisconsin-Madison Waisman Center, Madison, WI, (4)Department of General Pediatrics, Vanderbilt University Medical Center, Nashville, TN

Background: Employment outcomes are an important aspect of quality of life for autistic adults (Clarke et al., 2021; Mason et al., 2018). In addition to understanding facilitators of gaining employment, it is important to also consider factors that contribute to autistic adults' satisfaction in the workforce (Hedley et al. 2017; Pfeiffer et al. 2018).

Objectives: The current study addressed this issue by examining the levels of job satisfaction for autistic adults and the association of various workplace characteristics with job satisfaction.

Methods: This analysis used baseline data from a longitudinal study of employment stability among autistic adults. Current analysis included 108 adults who were working in the community when data was collected. Autistic adults (67% male) between the ages of 18-45 ($M=28.4$) completed an interview that probed for information about vocational and educational activities (Taylor & Seltzer, 2012). The Occupational Network (O*net) was used to code jobs into sectors (broad occupational categories based on related activities) and whether the level of education needed for the job corresponded to the adult's education (over-educated/not over-educated)

Participants completed three workplace climate questionnaires (diversity climate, psychological safety, leader-member exchange; Edmonson, 1999; Mor Barak et al., 1998); scores from these measures were summed into a total workplace climate score. Higher scores indicate a safer and more supportive workplace climate. Job satisfaction was measured using the Job Descriptive Index (JDI; Smith et al., 1969), a 38-item questionnaire measuring job satisfaction across five facets: supervision, coworkers, pay, promotions, and the work itself. Descriptive statistics and linear regressions were conducted.

Results: 40.7% of the employed autistic adults were working full-time (≥ 35 hours/week), 25.9% were over-educated for their jobs, and 10% were receiving disability-related supports on the job. The most frequently reported occupations were in Transportation and Material Moving, Office and Administrative Support, and Food Preparation and Serving (Table 1). Median ratings of job satisfaction in the current sample were compared to medians obtained from a normed nationally representative sample ($n = 1,485$; Gillespie et al., 2016; Figure 1). Visual inspection suggested that overall, adults with autism across age ranges reported similar, if not higher, job satisfaction than the nationally representative sample across all facets.

Participants with higher workplace climate scores reported higher job satisfaction with coworkers ($b=8.52$, $p \leq .001$), supervision ($b=13.87$, $p \leq .001$), pay ($b=7.44$, $p \leq .001$), promotions ($b=12.16$, $p \leq .001$), and the work itself ($b=9.87$, $p \leq .001$). Autistic adults who had a full-time job ($b=6.47$, $p = .048$) and were not overeducated ($b=-7.96$, $p = .026$) for their jobs had higher satisfaction with pay. Receiving job supports was not associated with scores for any facet of job satisfaction.

Conclusions: The current findings suggest that facilitating obtainment of jobs that are consistent with a person's education and full-time positions may lead to the appraisal of pay as more fulfilling. These findings also highlight the impact of promoting a safer and more supportive workplace climate on job satisfaction be it through treating employees fairly, creating a safe environment to take risks within, or cultivating a workplace culture that values diversity.

408.064 Factors Influencing Dropout Among Autistic Students in Universities: A Meta-Synthesis of Qualitative Studies Involving Autistic Individuals

M. Freeth¹, G. M. Smith², E. Broglia³ and L. Powell¹, (1)Psychology Department, The University of Sheffield, Sheffield, United Kingdom, (2)Psychology, University of Sheffield, Sheffield, South Yorkshire, United Kingdom, (3)University of Sheffield, Sheffield, South Yorkshire, United Kingdom

Background: Current estimates suggest that approximately 2% of students in higher education are diagnosed as Autistic, which is likely an underestimation of the true prevalence due to non-disclosure and diagnostic challenges. Autistic students in higher education face unique challenges that impact their academic persistence and success. Despite possessing strengths such as detailed focus and strong memory recall, these students often experience higher dropout rates compared to their neurotypical peers and those with other disabilities. The benefits of higher education are substantial, particularly in enhancing quality of life through better employment prospects and greater independence. Identifying and addressing the factors leading to high dropout rates is essential for developing interventions that promote a more supportive academic environment for autistic students.

Objectives: This review systematically investigates and analyses the factors that influence dropout rates among autistic students in higher education, focusing on firsthand accounts of autistic students. It draws on qualitative and mixed-method studies to address the question: What are the key factors influencing dropout rates among autistic university students across various degree programs and institutions worldwide? The aim is to identify insights that can inform interventions to improve educational outcomes for autistic adults.

Methods: This meta-synthesis, adhering to PRISMA guidelines, utilised the PICOS framework for a systematic review. Searches across Scopus, PsychINFO, Medline via OVID, and ERIC yielded 2,303 initial articles. Thirteen studies were selected based on relevance and peer review, involving 521 participants aged 18 to 54, primarily diagnosed with Autism Spectrum Disorder and based in the UK, USA, and Australia. All participants had either considered dropping out, actually dropped out, or deferred a year. These studies examined dropout rates and potential contributory factors, with findings appraised for quality using the CASP checklist and determined to be of moderate to good quality.

Results: Analysis of the thirteen studies found significant challenges faced by Autistic students in higher education, revealing an overarching theme of 'Environmental Discord'—systemic mismatches between educational structures and autistic students' needs that exacerbate academic and mental health challenges. Mental health issues emerged as a critical factor influencing dropout rates, with students reporting exacerbated conditions such as anxiety and depression due to academic pressures and social isolation. Additionally, the studies highlighted academic challenges related to executive functioning and sensory sensitivities that hinder effective learning and engagement. The analysis also identified gaps in support strategies, indicating that existing services often fail to meet the specific needs of Autistic students, necessitating tailored interventions.

Conclusions: Advocating for the implementation of Universal Design for Learning, this review proposes proactive restructuring of educational environments to better accommodate diverse student needs and enhance their success. Further, the review calls for future research to develop and evaluate personalised interventions aimed at the specific mental health and academic challenges faced by Autistic students. Such research is crucial for not only improving educational outcomes and retention rates but also enhancing the overall quality of life for Autistic students.

408.065 Finding Safe Soulmates: Perspectives of Autistic Adults on Relationships and Sex Education

J. L. Eaton^{1,2} and A. M. Romualdez³, (1)The Charter School East Dulwich, London, London, United Kingdom, (2)Institute of Education, London, London, United Kingdom, (3)UCL Centre for Research in Autism and Education, London, United Kingdom

Background:

Relationships and Sex Education (RSE) became a Statutory Requirement in England in 2020 for all students, inclusive of those with Special Education Needs and Disabilities (SEND). This is important considering that research into the perspectives of parents and teachers over past decades revealed concerning misconceptions that some students, like autistic youth, do not need RSE (Gürol, Polat, and Oran, 2014) or that it is dangerous (Neufeld *et al*, 2002). Recently, research has revealed that RSE reduces autistic individual's vulnerability to exploitation (Strnadová *et al*, 2022), and offers increasing support for the value of RSE for all. Yet teacher confidence delivering RSE has been found to be low (Strnadová, 2022). RSE content has been debated in England, with the Government's draft guidance in 2024 dismissed by leading RSE groups like the PSHE Association.

Research into the most beneficial forms of how and what to teach in RSE is increasingly paramount. Research into RSE for autistic people predominantly focuses on the perspectives of teachers and parents, therefore this study focuses on the views of autistic adults who have experienced RSE in the British education system.

Objectives:

The study aims to support educational settings answering practical questions regarding what topics to teach as priorities to autistic students and how to teach them effectively to support students preparing to navigate real life adult experiences. The research aims to answer: 1) To what extent was RSE useful in supporting participants to navigate adult romantic and sexual relationships? 2) How might their experiences inform future teaching of RSE?

Methods:

Ten autistic adults were recruited from the Cambridge-based Safe Soulmates friendship and dating network for neurodivergent and disabled adults. The qualitative study entailed semi-structured interviews with them to ascertain their perspectives to answer the research questions. Data was analysed using a reflective thematic analysis (Braun & Clarke, 2006).

Results:

Analysis of data provided key themes relating to; a link between quality of RSE and wellbeing; an educational priority of supporting to navigate boundaries, communication and expectations in relationships; as well as the value of support networks and healthy, diverse representation of relationships in the media.

The data provides support for the desire for high quality RSE for autistic students and that negative experiences of RSE can be a barrier to learning and detrimentally affect adult wellbeing and experiences. It also emphasises that societal views and behaviour have an impact on an individual's safety and self acceptance.

Conclusions:

This research indicates specific Government guidance would be useful, which highlights key priorities for autistic students' RSE to include navigating communications and consent, LGBTQIA+ topics and emphasis on capacity to choose a range of relationship types. Teachers should receive in depth training to improve subject knowledge and confidence, also to teach explicit and clear information - particularly clarifying nuances in topics. Schools may wish to consider methods of facilitating healthy support networks, or providing additional information for parents. Emphasis should be placed on educating allistic students about sexual harassment, with the aim to reduce capacity for causing abuse.

408.066 Gaming Disorder As a Predictor of 24-Hour Movement Behaviors in Autistic Adults with and without Mild Intellectual Disabilities

L. K. McNulty¹, S. Kathiravan², X. Ji³, A. N. Bhat⁴ and D. Lee⁵, (1)Department of Health Behavior and Nutrition Sciences, University of Delaware, Newark, DE, (2)Physical Therapy, University of Delaware, Newark, DE, (3)University of Delaware, Newark, DE, (4)Department of Physical Therapy, University of Delaware, Newark, DE, (5)Health Behavior and Nutrition Sciences, University of Delaware, Newark, DE

Background: Autistic adults often display a greater susceptibility to excessive gaming behaviors due to their natural predilection for digital gaming and distinct strength in visuospatial learning. This affinity for gaming may negatively impact 24-hour movement behaviors, including physical activity (PA), sedentary behavior (SB), and sleep, in autistic adults, who are already predisposed to insufficient PA and sleep due to unique individual and environmental barriers, such as high sensory sensitivities and low intrinsic motivation for exercise.

Objectives: This study aimed to (1) identify the prevalence of gaming disorder and characteristics of 24-hour movement behaviors and (2) assess the relationship between gaming behavior, PA, SB, and sleep quality in autistic adults, including those with co-occurring mild intellectual disabilities (ID).

Methods: An online, self-report survey was developed using standardized instruments to assess demographic information, gaming behavior, PA, SB, and sleep in autistic adults. The survey was reviewed for content validity and took approximately 15 minutes to complete. Participants were recruited with the assistance from the Simons Foundation Powering Autism Research for Knowledge (SPARK) Research Match services. The inclusion criteria were: adults (1) aged 18 to 55 years, (2) formally diagnosed with an autism spectrum disorder by a medical professional or self-identifying as autistic, and (3) able to walk and process information independently without substantial support from assistive devices or others. Descriptive statistics were used to summarize demographic characteristics and patterns in the preventive health behaviors. Pearson correlation and stepwise multiple regression analyses were performed to examine the relationship between gaming behavior, PA, sedentary time, and sleep quality, as well as other demographic variables. Multicollinearity was not observed in regression models. SPSS v29.0 (IBM Corp., NY, USA) was used to analyze the data.

Results: Forty-six autistic adults (Mage 33.3±10.3; 80% females; 43.5% with mild ID) completed the survey. Autistic adults spent 625.8±910.3 min/week for video/online gaming, 86.9±102.0 min/week for moderate PA and 39.8±73.4 min/week for vigorous PA engagement. Sedentary time was relatively higher on weekend (583.0±304.2 min/day) compared to weekday (573.3±271.5 min/day). 15.2% of the participants were identified as potentially having a gaming disorder while 39.1% had poor sleep quality. The total gaming disorder score was significantly associated with total gaming time ($r=.43, p=.003$), vigorous PA ($r=-.30, p=.042$), weekday sedentary time ($r=.59, p<.001$), and weekend sedentary time ($r=.37, p=.011$). Stepwise multiple regression models revealed that the total gaming disorder score was one of the most influential factors in predicting vigorous PA, $F(3, 42) = 15.098, R^2 = .52$ and weekday sedentary time $F(2, 43) = 46.444, R^2 = .68$ (all $p<.001$).

Conclusions: The preliminary findings of this study align with previous research, indicating that autistic adults may be more susceptible to excessive gaming behaviors. Although no significant association was found between gaming behavior and sleep quality, gaming was correlated with increased sedentary time and reduced engagement in vigorous PA. These results suggest that gaming behaviors may contribute to sedentary lifestyles, underscoring the need for targeted, strength-based interventions that promote healthy 24-hour movement behaviors among autistic adults.

408.067 Genetic Liability for Psychiatric Disorders and Associations with Adolescent Psychiatric, Social, and Behavioral Outcomes Among Autistic and Non-Autistic Individuals

Z. He^{1,2}, K. S. Benke^{2,3}, J. Daniels^{2,3}, T. Cheng^{1,2}, K. Bartholomay⁴, C. DiGuseppi⁴, G. S. Dichter⁵, H. E. Volk^{2,3}, J. Daniels⁶, M. D. Fallin⁷ and C. Ladd-Acosta^{1,2,3}, (1)Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, (2)Wendy Klag Center for Autism and Developmental Disabilities, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, (3)Department of Mental Health, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, (4)Colorado School of Public Health, University of Colorado Anschutz Medical Campus, Aurora, CO, (5)Department of Psychiatry, School of Medicine, University of North Carolina, Chapel Hill, NC, (6)Gillings School of Global Public Health, University of North Carolina at Chapel Hill, Chapel Hill, NC, (7)Rollins School of Public Health, Emory University, Atlanta, GA

Background: Autism spectrum disorder (ASD) is commonly diagnosed in childhood and poses challenges for individuals and their families into adolescence and throughout the lifespan. Autistic individuals have higher risks of co-occurring psychiatric, social, and behavioral conditions across multiple life stages including adolescence. Genetic correlations of ASD with co-occurring conditions have been identified in childhood samples. However, evidence is limited on whether genetic risk factors related to ASD and other psychiatric disorders are associated with co-occurring conditions in adolescence.

Objectives: Test whether polygenic scores (PGS) for 5 psychiatric conditions, derived in childhood samples, show prospective associations with adolescent psychiatric, social, and behavioral outcomes in autistic and non-autistic adolescents.

Methods: Study to Explore Early Development (SEED) participants were enrolled, at age 2-5 years, from 6 US sites and classified into ASD cases, population-based controls (POP), or non-ASD developmental delays (DD) based on rigorous clinical evaluation. A follow-up survey was conducted among caregivers of a subset of SEED participants at age 12-16 years, which asked about healthcare provider diagnoses of adolescent psychiatric conditions (any psychiatric condition, attention-deficit/hyperactivity disorder (ADHD), anxiety, depression), and social (Social Responsive Scale (SRS) scores) and behavioral outcomes (speech/language disorder, sensory integration problems, verbal communication problems). Genotyping was performed on Illumina HumanOmni1-Quad BeadChip or Affymetrix Axiom KP array, and rigorous quality control metrics were applied. PGS for each of the following psychiatric conditions were derived using Bayesian shrinkage method (*LDPre2-auto*), leveraging external summary statistics of genome-wide association studies from Psychiatric Genomic Consortium or dbGap database: any psychiatric condition, ASD, ADHD, anxiety, and major depressive disorder (MDD). We calculated pairwise genetic correlations using linkage disequilibrium score regression and PGS correlations. We used a series of logistic regressions to test associations of each psychiatric PGS with adolescent outcomes in the overall sample and within childhood ASD classification strata.

Results: A total of 528 participants (125 ASD, 206 POP, 197 DD) were included, with mean age of 15 years old at follow up. C-statistics of PGS for any psychiatric condition, ASD, ADHD, anxiety, and MDD were 0.574, 0.629, 0.614, 0.533, and 0.597, respectively. Genetic correlations and PGS correlations were observed (Figure 1). ASD-PGS was associated with elevated adolescent SRS scores (odds ratio (OR) = 1.80, 95% confidence interval (CI): 1.22, 2.68) and communication problems (OR = 1.54, 95% CI: 1.04, 2.26) (Figure 2). ADHD-PGS was associated with adolescent ADHD (OR = 1.46, 95% CI: 1.15, 1.85). MDD-PGS was associated with any psychiatric disorder (OR = 1.33, CI: 1.02, 1.72) and ADHD (OR = 1.40, 95% CI: 1.09, 1.80), and marginally associated with depression (OR = 1.42, 95% CI: 0.97, 2.08). In the childhood DD group, we additionally observed marginal positive associations of any psychiatric condition PGS with adolescent ADHD, ADHD-PGS with anxiety and speech/language disorder, and anxiety-PGS with sensory integration disorder.

Conclusions: These results contribute to the growing evidence of shared genetic architectures between psychiatric disorders and ASD co-occurring conditions in adolescence. Psychiatric PGS, measurable at childhood, may provide insights into the developmental trajectories of individuals with ASD and guide early interventions.

408.068 Health Related Quality of Life Outcomes for Autistic Adolescents: A Population Based Study

C. Vavala, D. Jacobs and A. Brignell, Speech Pathology, Australian Catholic University, Fitzroy, VIC, Australia

Background: Health-related quality of life (HRQoL) is a broad concept that includes aspects such as physical, psychological and social functioning and well-being. Research on how HRQoL may differ between autistic and non-autistic adolescents and the predictive influence of early childhood characteristics on HRQoL outcomes in autistic adolescents is limited.

Objectives: This study used data from a large population-based longitudinal study, the Longitudinal Study of Australian Children (LSAC), to compare HRQoL between autistic and non-autistic adolescents. We also assessed the predictive association of early childhood characteristics on HRQoL outcomes in autistic adolescents aged 14-15 years.

Methods: Two cohorts of autistic children ($n = 145$ (Birth cohort); $n = 91$ (Kinder cohort)) were drawn from the population-based sample ($n = 3030$ (Birth cohort); $n = 2454$ (Kinder cohort)). Early predictor measures were assessed at 4 years for language, sex, socioeconomic factors, level of autistic symptoms, social functioning, and 6 years for nonverbal IQ. HRQoL was assessed at 14-15 years, using the Pediatric Quality of Life (PedsQL) Inventory. The PedsQL subscales (physical, social, emotional, school functioning), summary scores (psychosocial and physical health), and total HRQoL score were compared between autistic and non-autistic adolescents using independent samples t-tests. Multiple linear regressions were used to assess predictors of HRQoL for autistic adolescents at 14-15 years.

Results: In both cohorts, autistic adolescents demonstrated significantly lower scores across all PedsQL scores compared with non-autistic peers ($p < .001$ for all comparisons). The social functioning subscale had the largest effect size for the Birth ($d = 1.395$) and Kinder cohorts ($d = 1.360$). Level of autistic traits and receptive language ability predicted HRQoL in the Birth cohort, contributing 26.9% of the variability in HRQoL. No consistent predictors were identified in the Kinder cohort.

Conclusions: Our findings align with previous research indicating significantly lower HRQoL in autistic adolescents compared with non-autistic peers. Further research into modifiable factors that influence HRQoL may encourage investigation into targeted early interventions focused on improving outcomes for future autistic adolescents.

408.069 Identifying Daily Living Skills from Childhood and Adolescence Predictive of Adult Outcomes in a Longitudinal Study of Autism

E. B. Clarke¹ and C. Lord², (1)Graduate School of Applied and Professional Psychology, Rutgers University - New Brunswick, Piscataway, NJ, (2)UCLA Semel Institute for Neuroscience and Human Behavior, Los Angeles, CA

Background: Many studies have documented deficits in daily living skills (DLS) in autistic individuals (Smith et al., 2012); notably, strong DLS are associated with a higher likelihood of attaining some adult outcomes (Clarke et al., 2021). However, it is unclear whether specific DLS (e.g., bathing, cooking, toileting) are more important to adult success than others and how this may vary across development.

Objectives: 1) Examine growth patterns in VABS DLS mean item set scores from ages 5, 9, 14, and 18 in a longitudinal autism sample. 2) Identify VABS DLS mean item set scores from ages 5, 9, 14, and 18 that—controlling for IQ, autism symptomology, and other salient characteristics—predict employment, well-being, friendship, and residential outcomes at approximately age 33.

Methods: The current analyses include data from 230 participants enrolled in a well-characterized longitudinal cohort of autistic individuals (Table 1). Analyses were conducted separately for individuals with verbal IQ of 70 or greater (more cognitively able, or MA) and individuals with verbal IQ of less than 70 (less cognitively able, or LA). First, growth patterns in DLS mean item set scores by cognitive ability were examined from ages 5-18. The utility of DLS mean item set scores from ages 5, 9, 14, and 18 for predicting employment, well-being, friendship, and residential outcomes at approximately age 33 was then tested via multiple hierarchical and binary logistic regression. Given the number of tests required, the significance level was set at $p \leq .01$.

Results: For both MA and LA participants, item sets from the community subdomain of DLS had the lowest mean scores, with the least growth over time (Figure 1). For LA participants only, regression analyses indicated that higher scores at age 5 on two item sets from the personal subdomain of DLS, bathing and healthcare, predicted participation in employment activities in adulthood. Higher bathing and healthcare scores at ages 9 and 14 predicted higher caregiver-reported well-being in adulthood. For MA participants only, item sets from the community subdomain of DLS predicted adult employment and well-being. Specifically, regression analyses indicated that higher pre-job skills item set scores at age 9 predicted more participation in employment activities in adulthood. At age 18, higher pre-job skills and restaurant skills item set scores predicted higher caregiver-reported well-being. No DLS item sets predicted adult residential status or social relationships for LA or MA participants.

Conclusions: These results provide insight into specific DLS that may support adult outcomes for autistic individuals and, by extension, could be used to inform interventions for this population. Notably, the DLS that predicted adult outcomes appeared to vary more with participant cognitive ability than age. The limited growth in community DLS observed here is concerning, given that two item sets from the community subdomain emerged as significant predictors of employment and well-being for MA participants. For LA individuals, interventions targeting skills related to personal hygiene (e.g., showering independently) and health (e.g., covering one's nose when coughing or sneezing) may promote quality of life and improve the likelihood of employment in adulthood.

408.070 Implicit Preference for Communication Among Adults with Autism Spectrum Disorder Using the Implicit Association Test

A. Tsuchiya¹, T. Takahashi², N. Takada³, Y. Kurihara⁴, H. Naruse⁵, A. Minamide⁶, Y. Okamoto⁵, H. Kosaka³ and R. Osu⁶, (1)Waseda University, Tokorozawa-shi, Saitama, Japan, (2)Laureate Institute for Brain Research, Tulsa, OK, (3)University of Fukui, Eiheiji, Fukui, Japan, (4)Omiya Suzunoki Clinic, Saitama-shi, Saitama, Japan, (5)Tohoku University, Sendai-shi, Miyagi, Japan, (6)Waseda University, Tokyo, Tokyo, Japan

Background:

The preferences for communication may inherently differ from person to person. However, the Japanese adults with ASD may have been continuously taught to believe that communication is an enjoyable experience (e.g. Make lots of friends). The adults with ASD who are under such social pressures, may exhibit different tendencies between implicit measures from the typically developed (TD) adults.

Objectives:

Our aim is to compare the implicit preferences for communication, as assessed by the Implicit Association Test (IAT), with conventional ASD measures, the Autism Quotient (AQ) and the Social Responsiveness Scale Second Edition Adult (SRS-2: Adult). In addition, we investigated the relationship between IAT, and well-being and loneliness. We compared those results of the adults with ASD and the TD adults.

Methods:

Participants were 26 adults with ASD (mean age 31.1 ± 5.2 years, 26.9% female) and 26 TD adults (mean age 28.9 ± 7.4 years, 34.6% female). Participants performed the Implicit Association Test designed to measure attitudes towards being with someone. We used the concept words “together” and “alone” in Japanese (“一緒に” and “一人で”) and the attitude words “fun” and “boring” in Japanese (“楽しい” and “つまらない”). The adults with ASD completed the AQ and SRS-2 at their diagnosis, while the TD adults completed them before the IAT. For explicit assessments for well-being and loneliness, they completed the World Health Organization-Five Well-Being Index (WHO-5), and the UCLA Loneliness Scale (UCLA). This research was approved by the ethics committee of the Waseda University.

Results:

The IAT D score showed a significant correlation with the AQ and SRS-2 in the TD group (IAT - AQ: $r = -0.47$, $p = 0.015$; IAT - SRS-2: $r = -0.47$, $p = 0.015$), but no significant correlation was observed in the ASD group (IAT - AQ: $r = -0.085$, $p = 0.68$; IAT - SRS-2: $r = 0.0091$, $p = 0.96$). The slopes for the TD and ASD groups did not differ (IAT - AQ: $F = 0.77$, $p = 0.38$; IAT - SRS-2: $F = 2.79$, $p = 0.10$). Additionally, the IAT D score showed a significant correlation with the UCLA in the TD group ($r = -0.65$, $p < 0.01$) but no correlation in the ASD group ($r = 0.092$, $p = 0.65$). The slope of the regression line was significantly different between the ASD and TD groups ($F = 6.14$, $p = 0.017$). As a similar result, there was a significantly correlation between IAT and WHO-5 in the TD group ($r = 0.41$, $p = 0.038$) but no correlation in the ASD group ($r = -0.13$, $p = 0.53$). In this case, the slope of the regression line did not significantly differ between the ASD and TD groups ($F = 3.32$, $p = 0.074$).

Conclusions:

It's suggested that individuals in the TD group may exhibit consistency between what is measured by explicit and implicit assessments, while individuals in the ASD group may experience a discrepancy between explicit and implicit tendencies. This implicit indicator may explain differences in the tendency toward loneliness.

408.071 Impression Management and Camouflaging in French Autistic Adults of the Face-ASD National Cohort: Relationships with Sex-Assigned-at-Birth, Gender Identity, Gender Role Expression, and Autistic Features

W. Ai¹, A. Anchodorqu^{2,3}, O. Bogdanova⁴, V. Pomies^{2,3}, M. Leboyer^{2,5}, R. Coutelle^{2,6}, P. Atzori^{2,7}, A. Amestoy³ and M. C. Lai⁸, (1)Department of Psychology, University of Toronto, Toronto, ON, Canada, (2)Fondation FondaMental, Créteil, France, (3)Expert Center for ASD, CH Charles Perrens Hospital, Bordeaux, France, (4)Aquitaine Institute for Cognitive and Integrative Neuroscience, INCIA, UMR 5287, CNRS, Université de Bordeaux, Bordeaux, France, (5)INSERM U955, AP-HP, Université Paris-Est Créteil, Créteil, France, (6)Expert Center for ASD, Strasbourg University, Strasbourg, France, (7)Expert Center for ASD, Salvador Hospital, Marseille, France, (8)Campbell Family Mental Health Research Institute, Centre for Addiction and Mental Health, Toronto, ON, Canada

Background: Some autistic people camouflage to hide or compensate for their autistic differences. Although camouflaging overlaps conceptually with impression management (IM), few studies have directly examined IM tendencies in autistic people, especially outside English-speaking countries. Research in mostly English-speaking regions found that autistic women engage in greater camouflaging than autistic men, which could result in sex- and gender-related barriers to diagnosis. Two key questions are why these observed sex- and gender-related differences occur, and how camouflaging influences autistic clinical presentation over time, in different social-cultural contexts.

Objectives: 1) Specify latent dimensions of camouflaging and IM in French autistic adults; 2) Investigate how these dimensions associate with sex-at-birth, gender identity, and gender expression; 3) Examine how IM/camouflaging dimensions affect the stability of clinical autism profiles.

Methods: A total of 222 French adults diagnosed with autism (109 assigned-female-at-birth and 113 assigned-male-at-birth, $M_{age}=29.3$ yrs) participated. Measures for IM included the Camouflaging Autistic Trait Questionnaire (CAT-Q), Concern for Appropriateness Scale (CAS), and the Revised Self-Monitoring Scale (RSMS). Gender role expression was measured using the Personal Attributes Questionnaire (PAQ) and the Bem Sex-Role Inventory (BSRI). Clinical autism features were measured using the Autism Diagnostic Interview-Revised (ADI-R) and the Autism Diagnostic Observation Schedule Second Edition (ADOS-2) Module 4. We first performed Exploratory Factor Analysis (EFA) on the subscale-scores of all IM measures to identify their dimensional structure. We then examined the associations between identified IM dimensions and sex-assigned-at-birth, gender identity, and gender role expression using a combination of hierarchical and elastic-net regressions. Lastly, we examined how IM dimensions moderate the links between past (ADI-R) and present (ADOS-2) autistic presentations using multiple regression.

Results: The IM subscales loaded onto two dimensions. The CAT-Q and CAS subscales reflected an “intention” dimension capturing one’s conscious use of IM, whereas the RSMS subscales reflected an “ability” dimension capturing one’s self-perceived capability of enacting IM. The hierarchical regression showed that autistic assigned-females exhibited greater IM intention than autistic assigned-males, $b=21.6$, $p<.001$, and those with greater PAQ communion scores exhibited greater IM ability, $b=0.881$, $p<.001$. The elastic-net regression additionally revealed that, in terms of relative importance, sex-assigned-at-birth and gender identity were important predictors of IM intention, whereas gender role expression traits were more relevant predictors of IM ability (**Figure 1**). Finally, across multiple regression models (**Table 1**), we found one significant interaction, such that the association between ADI-R (ever/most-prominent) restricted-repetitive behaviors and ADOS-2 (present) restricted-repetitive behaviors weakens as IM intention increases.

Conclusions: In French autistic adults, camouflaging and concern for appropriateness converge to capture one’s IM intention, distinctive from one’s IM ability. Concurrent examination of sex-assigned-at-birth, gender identity, and gender role expression effects showed nuances that have not been reported by past research. Whereas IM intention differences may be substantially sex-related, how capable one is at executing IM may relate more to gender role expression traits. Developmental moderation of IM (intention) on autistic features seemed most observable in restricted-repetitive behaviors. These empirical insights reveal how IM/camouflaging may affect autism presentations and relate to several sex and gender factors in the French social-cultural context.

**408.072** A Multi-Study Exploration of Suicidality and Associated Influences in Midlife and Older Age

G. R. Stewart¹, E. Nuzum², R. Medeišytė³, S. Roper³, R. A. Charlton⁴, F. Happe⁵, A. John² and J. Stott⁶, (1)Social, Genetic and Developmental Psychiatry Centre, King's College London, London, United Kingdom, (2)UCL, London, England, United Kingdom, (3)King's College London, London, England, United Kingdom, (4)Psychology, Goldsmiths University of London, London, London, United Kingdom, (5)Social, Genetic and Developmental Psychiatry Centre, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, UNITED KINGDOM, (6)University College London, London, London

Background: Suicide is a leading cause of premature death in autistic populations (Cassidy et al., 2022). Despite an increased risk of suicidal behaviours being found in high autistic trait populations in midlife and older age compared to comparisons (Stewart et al., 2022), no study has yet examined suicidality in older populations with diagnosed autism. Additionally, it is unknown what factors are associated with suicide in older age in autistic populations and whether these differ from non-autistic populations.

Objectives: This study uses data from two complimentary datasets to explore the rates of self-harm and suicidality (study one) and associated influences (study two) in middle-aged and older autism with an autism diagnosis and with high autistic traits.

Methods: Study one uses data from the first wave of the AgeWellAutism project (collected in 2019), a sample of 265 autistic and 167 non-autistic adults aged 40 to 93 years old (mean = ~60 years; ~50% female). Study two uses data from PROTECT cohort, a sample of 9,978 adults aged 50 to 97 years old (mean = ~68 years; ~75% female), with 672 participants having high autistic traits [measured using the AQ-10 cut-off (Allison et al., 2012)]. Participants completed a range of questions related to suicidal behaviours (Stewart et al., 2022), mental health (Kroenke et al., 2001; Lang et al., 2012; Spitzer et al., 2006), and social isolation and loneliness (Lubben et al., 2006; Russell, 1996). In study one, differences in suicidality were explored between autistic and non-autistic participants. In study two, path models were used to ascertain factors mediating the relationship between having high autistic traits and suicidal thoughts and behaviours.

Results: In study one, the autistic group reported significantly higher rates of suicidality, including suicidal ideation [$\chi^2=131.52, p<.001$] and suicidal self-harm [$\chi^2=22.84, p<.001$], when compared to the non-autistic comparisons. In study two, direct paths between autistic traits and suicidal ideation [$b=.043, p=.174$] and suicidal self-harm [$b=.014, p=.076$] were not significant. However, indirect paths from autistic traits to suicidal ideation and suicidal self-harm through symptoms of poor mental health [e.g., $b=.008, p<.001$], social isolation [e.g., $b=.002, p<.001$], and loneliness [e.g., $b=.007, p<.001$], revealed that the relationships between autistic traits and suicide outcomes were being partially mediated by those factors.

Conclusions: The findings from these two complementary studies highlight that middle-aged and older people who are autistic or have high autistic traits are at an increased likelihood of experiencing suicidality vs. non-autistic/low trait comparisons. Findings from study two, albeit cross-sectional and correlational, suggest mental health problems, social isolation and loneliness may be driving this increased likelihood of suicidality and highlights possible targets for intervention to reduce rates of suicidal behaviours in autistic populations, particularly as they get older.

408.073 Does Social Connectedness Change in Midlife and Older Age? a Four-Year Longitudinal Follow-up Study of Autistic and Non-Autistic Adults

G. R. Stewart¹, A. John², R. A. Charlton³ and F. Happe⁴, (1)Social, Genetic and Developmental Psychiatry Centre, King's College London, London, United Kingdom, (2)UCL, London, England, United Kingdom, (3)Psychology, Goldsmiths University of London, London, London, United Kingdom, (4)Social, Genetic and Developmental Psychiatry Centre, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, UNITED KINGDOM

Background: Autistic people often experience high rates of social isolation compared to their non-autistic peers. Recent cross-sectional findings from the AgeWellAutism study found that middle-aged and older autistic people experience high rates of isolation, and this may increase with age (Stewart et al., 2024). Despite the negative impact that isolation has on health, wellbeing and life expectancy in older age (Holt-Lunstad, 2024), no study has yet examined how social connectedness changes in midlife and older age for autistic people using longitudinal methods.

Objectives: This pre-registered study (osf.io/mhf9j) explored how social connectedness changes across a four-year period in midlife and older age for autistic and non-autistic people recruited through various charities and community organisations in the UK.

Methods: Across the first (2019) and second (2023) wave of the AgeWellAutism project, 166 age-/sex-matched participants (n autistic=108, n non-autistic=58; 52% male) aged 40-84 years at baseline (mean age=60 years) completed widely used and standardised questionnaires, including the Lubben Social Connectedness Scale (Lubben et al., 2006). Paired samples t-tests and regression analyses were used to examine change across timepoints.

Results: Paired samples t-tests indicated that family and friendship connectedness scores significantly decreased between the two time points for both the autistic group [$t(107)=8.98, p<.001$; $t(107)=8.28, p<.001$] and non-autistic group [$t(57)=8.98, p<.001$; $t(57)=6.16, p<.001$].

A simple linear regression model showed a significant relationship between family connectedness at T1 and T2 and autism group membership [$R=.94, p<.001$], explaining 88% of the variance in family connectedness at T2 [T1 family connectedness $\beta_{\text{standardised}}=26.88, p<.001$; autism group membership $\beta_{\text{standardised}}=-3.83, p<.001$]. A separate simple linear regression model showed a significant relationship between friendship connectedness at T1 and T2 and autism group membership [$R=.91, p<.001$], explaining 82% of the variance in friendship connectedness at T2 [T1 friendship connectedness $\beta_{\text{standardised}}=17.14, p<.001$; Autism group membership $\beta_{\text{standardised}}=-9.36, p<.001$]. Neither model improved with the addition of age and sex as covariates.

When considering percentage change, the autistic group had a 16% reduction in family connectedness (vs. 9% reduction in non-autistic group) and 28% reduction in friendship connectedness (vs. 10% reduction in non-autistic group) over this period. This difference was statistically significant for both family [$t(164)=1.10, p=.045$] and friendship scores [$t(164)=3.74, p<.001$].

Conclusions: Over a four-year period, social connectedness with family and friends was found to decrease for autistic and non-autistic people in midlife and older age. Connectedness scores at baseline were a key predictor of change in scores over time, however, being autistic was also a significant predictor of decreased connectedness, particularly for friendship connectedness. Furthermore, the autistic group had greater decrease in their overall connectedness scores compared to the non-autistic group, placing them at greater risk of isolation. These findings highlight that middle-aged and older autistic people may be at an increased risk of accelerated decline of connections as they age and may be at a greater risk of becoming socially isolated compared to their non-autistic peers. Addressing declining connectedness in ageing autistic populations could be an important target for interventions to mitigate the negative sequelae of social isolation.

408.074 Factors Associated with Social Isolation and Loneliness in Middle-Aged and Older Adults with High Autistic Traits

G. R. Stewart¹, R. Medešytė², E. Nuzum², A. John² and J. Stott¹, (1)Social, Genetic and Developmental Psychiatry Centre, King's College London, London, United Kingdom, (2)UCL, London, England, United Kingdom, (3)University College London, London, London

Background: Autistic people often experience higher rates of social isolation and loneliness compared to their non-autistic peers, including in midlife and older age (Stewart et al., 2024). Despite older age being associated with increasing isolation and loneliness in the general population, no study has yet examined factors that are associated with, and may explain, increased isolation and loneliness in autistic or high autistic trait middle-aged and older populations.

Objectives: This study explored relationship between autistic traits, mental health symptoms and adversity, and social isolation and loneliness in a large sample of adults in midlife and older age.

Methods: Using data from the PROTECT cohort, a sample of 9,978 adults aged 50 to 97 years old (mean = ~68 years; ~75% female), with 672 participants having high autistic traits [measured using the AQ-10 cut-off (Allison et al., 2012)]. Participants completed a range of questions related to social isolation and loneliness (Lubben et al., 2006; Russell, 1996), mental health (Kroenke et al., 2001; Lang et al., 2012; Spitzer et al., 2006), and adversity (Grabe et al., 2012; Khalifeh et al., 2015). SEM was used to examine direct and indirect paths from autistic traits to social isolation and loneliness to understand what factors might play a role in any increased loneliness or social isolation in the high autistic traits group.

Results: The high autistic traits group reported more symptoms of loneliness [$W=4,028,518$, $p<.001$] and social isolation [$W=4,304,525$, $p<.001$] than the low autistic trait comparison group. The same pattern was found for symptoms of depression, anxiety, and adversity in childhood and adulthood [$W_s=1,765,687$ to $2,523,577$, $ps<.001$]. Autistic traits had a significant positive direct path to social isolation [$\beta=2.44$, $p<.001$] and loneliness [$\beta=0.38$, $p<.001$]. Symptoms of poor mental health and adversity partially mediated the relationship between autistic traits and social isolation and loneliness; however, these were of small-to-moderate effect [e.g., $\beta_s=0.01$ to 0.42 , $ps\leq.001-.015$] size. Male sex was associated with social isolation [large effect size], while loneliness was associated with female sex [small effect size]. In the full model with all direct and indirect paths added, the relationship between autistic traits and social isolation and loneliness remained significant [$\Sigma=1.45$, $p<.001$].

Conclusions: While symptoms of poor mental health and adversity partially mediated the relationship between autistic traits and social isolation and loneliness, the relationship between autistic traits and social isolation and loneliness persisted when accounting for their influence. Additionally, men were found to be at an increased risk of social isolation, while women were more likely to experience loneliness. Taken together, these findings highlight that people with high autistic traits in midlife and older age, particularly men, are at an increased likelihood of social isolation than their low autistic trait peers and that part of this may be related to poorer mental health and more adverse experiences. This highlights the need for additional help and support to mitigate the risk of social isolation and loneliness as people age. Further work is needed to see if this pattern of results extends to those with an autism diagnosis.

408.075 An All of Us Case Control Study Examining the Association between Dementia and Autism, ADHD, and Intellectual Disability

J. E. Rast¹, B. D. James², A. L. Rosso³ and B. K. Lee⁴, (1)A.J. Drexel Autism Institute, Drexel University, Philadelphia, PA, (2)Rush University, Chicago, IL, (3)University of Pittsburgh, Pittsburgh, PA, (4)Epidemiology and Biostatistics, Drexel University, Philadelphia, PA

Background: People with neurodevelopmental disorders (NDD; including autism, attention-deficit hyperactive disorder (ADHD), and intellectual disability (ID)) may be more likely to develop dementia than people without NDDs. Some studies have suggested that certain NDDs are associated with an increased risk of developing certain dementias. For example, Parkinson's disease may be more common in people with ADHD and autistic people than people without these conditions. Researchers have postulated this could be for several reasons, including genetic liability, pathophysiologic overlap between neurodevelopment and neurodegeneration, lower cognitive reserve, the presence of complex care needs that often go unmet, and differences in environmental exposures and stressors. As the population of people with autism, ADHD, and ID ages, it is important to understand their needs into older adulthood.

Objectives: To examine the association between NDDs and dementia/neurodegenerative diseases in a recent sample of adults in the U.S. from the All of Us Research Program.

Methods: Data for this study came from the All of Us Research Program (Controlled Tier Dataset V7), a longitudinal cohort study that combines electronic health records, surveys, laboratory assessments, physical measurements, and genetic data across a diverse set of adults in the United States supported by National Institutes of Health (NIH). Data was collected between May 1, 2018 and July 1, 2022. We conducted a nested case-control study to examine rates and risk of NDD in all participants with dementia in All of Us and a sex- and age-matched samples of adults without dementia. First, we examined the distribution of NDD and other covariates in the dementia cases and the matched controls. We then examined the same covariates within people with dementia stratified by NDD status. Finally, we used logistic regression models to examine the association of any NDD with dementia. We also separately examined the association of specific NDDs (autism, ADHD, and ID) with dementia.

Results: 7,275 adults were identified as cases, matched to 50,925 controls without dementia. Within dementia cases, 6.4% had an NDD, as did 2.0% of controls without dementia. ADHD was the most common NDD in dementia cases (5.5%), followed by ID (0.8%) and autism (0.5%). Just over half of cases and controls were female (53.7%) and the mean age was 74 years. People with any NDD had 3.4 times the odds of having a dementia diagnosis than did people without an NDD (95% CI 3.00, 3.83). When examining the association between individual NDDs and dementia, autistic people had 3.3 times the odds of a dementia diagnosis than people without autism (95% CI 2.89, 3.71). This was similar in people with ADHD and people with ID.

Conclusions: This national sample of adults from the U.S. identified a strong association of NDD diagnosis and dementia diagnosis, which was consistent across autism, ADHD, and ID. This finding supports the need for further research, policy, and funding into supporting these vulnerable groups. With an increased risk for dementia and an aging population, understanding care needs in people with dementia with an NDD is becoming increasingly important.

408.076 Individual, Service, and Environmental Risk Factors for Mental Health Hospitalization in Autistic Adults Enrolled in Medicaid

J. E. Rast, J. Wright and J. Ventimiglia, A.J. Drexel Autism Institute, Drexel University, Philadelphia, PA

Background: Mental health conditions are common in autistic adults, and when primary or outpatient treatment of mental health is not adequately addressed, behaviors may escalate to a level where hospitalization is needed. Mental health conditions are common reasons for inpatient hospitalization in autistic adults, with mood disorders (17%) and schizophrenia (9%) as the two most common reasons for hospitalization in autistic adults in 2017. This heightened rate of mental health hospitalization (MHH) compared to non-autistic peers may be driven in part by high co-occurrence of mental health conditions in autistic adults but is likely also due to inadequate care systems for autistic patients.

Objectives: The purpose of this study is to identify service patterns associated with MHH in autistic adults, and to discover if the predictors of MHH are different for autistic adults than non-autistic adults.

Methods: This study used Medicaid claims data from 2016-2019 focusing on people ages 14-64 enrolled in Medicaid for all four years. We examined the service use of four groups: autistic people with intellectual disability (ID; autism/ID), autistic people without ID (autism/no ID), people with ID without autism (ID), and people with neither autism nor ID. We examined receipt of mental health services in the year before MHH and compared to an age- and sex-matched sample that did not have a MHH in the same period. We included receipt of outpatient mental health care, emergency room visits, and psychotropic medication use as explanatory variables. We also examined the presence of mental health conditions that are commonly associated with increased risk of MHH, including schizophrenia and drug use disorders.

Results: Preliminary results are only from 2017; future work will look at 2018-2019. In 2017, 5.7% of people with autism/ID, 3.1% of people with autism/no ID, 4.0% of people with ID, and 1.8% of people without autism or ID had a MHH. People who had a MHH were more often white (56.7% versus 48.5% of those without a MHH) and female (27.5% versus 22.3%), and less often Hispanic (11.0% versus 19.5%) than those without a MHH. Most (93.1%) people with a MHH had an emergency department visit in 2016, as did 43.5% of those without a MHH. Controlling for demographic characteristics, having a mood disorder (OR 6.31, 95% CVI 6.06, 6.57), schizophrenia (OR 5.16, 95% CI 4.98, 5.33), or a drug use disorder (OR 3.79, 95% CI 3.65, 3.93) was associated with increased odds of MHH. People with ID (with or without autism) had 1.93 times the odds of MHH than people without ID (95% CI 1.87, 2.00). Future results will examine longitudinal patterns of service use, environmental characteristics, and psychotropic medication use on the risk of MHH.

Conclusions: Understanding the intervenable individual, service, and environmental factors that lead to MHH can help reduce emergency mental health care and shift the services focus to improving outpatient mental health care. Future work will examine follow-up care after a MHH, and how accessible mental health outpatient care can be improved to reduce readmission risk following a MHH.

408.077 Diagnostic Disclosure in Autistic Adults

M. Freeth¹, S. Au-Yeung² and A. Thompson³, (1)Psychology Department, The University of Sheffield, Sheffield, United Kingdom, (2)School of Psychology, University of Sheffield, Sheffield, South Yorkshire, United Kingdom, (3)Cardiff University, Cardiff, Glamorgan, United Kingdom

Background: After going through a diagnostic process and receiving an autism diagnosis, autistic people may choose to share their diagnosis with others. While clinicians are recommended to talk to the newly diagnosed person about the implications and concerns about the diagnosis and any future support needs, there is no advice about *how* clinicians should go about this. Accessing support post-diagnosis, such as reasonable adjustments under the Equality Act (2010), often requires an individual to disclose their diagnosis and it is therefore not only important that autistic people are receiving timely diagnosis, but also to be engaged in preparation to effectively communicate their diagnosis.

Objectives: To explore how autistic adults in the UK experience the process of disclosing their autism diagnosis to others. The study seeks to understand idiosyncratic contexts associated with decisions to disclose or not. It is interested in understanding where, why, and how, autistic people make sense of their experiences of disclosure following diagnosis in adulthood.

Methods: Interpretative phenomenological analysis was used to investigate autistic adults' experiences of disclosure. This approach facilitates detailed consideration of specific phenomena and has now been used widely in autism research. Twelve autistic adults participated in semi-structured interviews exploring their experiences of disclosure. Quality control procedures and reflexivity were used to ensure quality and reduce bias.

Results: Four group experiential themes emerged: "Functions of Disclosure" (Accessing Support; Becoming Myself; Activism and its Burden); "Approaching the Conversation" (Managing Disclosure and Reactions; Disclosure Started Pre-Diagnosis); "Negative Effects of Preconceptions" (Disbelief and Imposter Syndrome; Not Having My Needs Met; Caution and Avoidance), and "Acceptance, Openness and Finding Community". Our study demonstrates that autistic people disclose for the purpose of accessing adjustments, and to strive for support and understanding from others. However, for the autistic adults in our study seeking a diagnosis in adulthood also served an emotionally restorative function facilitating self-acceptance. As such disclosure was described as supporting being able to be more authentic and less dependent on masking.

Conclusions: Whether autistic adults disclose their diagnosis is a context dependent decision and is complex and challenging for autistic people to navigate. Disclosure could bring a sense of connection and being understood for autistic people and for some may represent an important act of self-acceptance and activism, though this can present a personal burden. Diagnostic disclosure may open opportunities for autistic people to access much needed support. However, other people's preconceptions of autism could lead to negative consequences, such as discrimination, that create barriers for autistic people to get their needs met and discourages further disclosures. Given the potential risks and benefit of disclosure, it is important that clinicians incorporate discussions about disclosure, including insights from experiences of others and consideration of potential consequences, as part of post-diagnostic support for autistic people.

408.078 Acceptability and Usability of the International Classification of Functioning (ICF) Coresets for Autism Platform Assessed By UK Autistic Adults

M. Freeth¹, M. Day², K. L. Leporcher², I. Kellar², S. Crowson², E. Broglia², D. Poole¹, L. Alehagen³, J. Hasslinger⁴ and S. Bolte⁵, (1)Psychology Department, The University of Sheffield, Sheffield, United Kingdom, (2)University of Sheffield, Sheffield, South Yorkshire, United Kingdom, (3)Psychology, University of Sheffield, Sheffield, South Yorkshire, United Kingdom, (4)University of Sheffield, Sheffield, United Kingdom, (5)Center for Neurodevelopmental Disorders at Karolinska Institutet (KIND), Department of Women's and Children's Health, Karolinska Institutet, Stockholm, Sweden, (6)Department of Clinical Neuroscience, Karolinska Institutet, Stockholm, Stockholm, Sweden

Background: A diagnostic label of autism does not provide sufficient information to understand how the world is experienced by an Autistic person, their areas of strength or what support they may need. The International Classification of Functioning (ICF) Core Sets for Autism provides a framework from which a more in-depth understanding of an Autistic person's strengths and needs can be acquired.

Objectives: To assess the acceptability and usability of the ICF CoreSets for Autism platform to Autistic adults in the UK via supported and unsupported completion.

Methods: Study 1: 20 Autistic adults completed the ICF CoreSets for Autism assessment with researcher support and provided feedback via think-aloud interviews. Platform refinements were made based on feedback following which acceptability and usability were assessed in this cohort using the Theoretical Framework of Acceptability (TFA) and the System Usability Scale (SUS). Study 2: 464 Autistic adults and 481 Non-Autistic adults completed the ICF CoreSets for Autism assessment independently online and completed the TFA and SUS as well as providing written qualitative feedback.

Results: Study 1: Responses on the TFA indicated that Autistic adults generally found the assessment to be 'acceptable' (acceptability mean = 3.8/5). Responses on the System Usability Scale (SUS) indicated that usability was generally rated as 'ok' or better by most participants (SUS total mean = 61). Study 2: Responses on the TFA indicated that both groups generally found the assessment to be 'acceptable' (Autistic adults acceptability mean = 3.9/5; Non-Autistic adults acceptability mean = 4.2/5). Responses on the SUS indicated that usability was rated as 'ok' by Autistic adults (SUS total mean = 67) and 'good' by Non-Autistic adults (SUS total mean = 73). Scores on acceptability and usability were similar in the subsets of Autistic adults who had clinically relevant levels of autistic traits (AQ10 ≥ 6 ; acceptability mean = 3.9/5; SUS total mean = 67), anxiety (GAD7 ≥ 10 ; acceptability mean = 3.9/5; SUS total mean = 66) and depression (PHQ9 ≥ 10 ; acceptability mean = 3.8/5; SUS total mean = 66). Further, Autistic adults who were unemployed scored acceptability (acceptability mean = 4.0/5) and usability (SUS total mean = 66) similarly to those who were employed.

Conclusions: These UK studies suggest the ICF CoreSets platform for Autism has potential as an evidence-based tool to assess strengths and needs in Autistic adults. It is generally considered to be an acceptable assessment by Autistic adults, including those who currently express clinically relevant levels of depression, anxiety and in those who are unemployed. This assessment tool and platform may contribute to improving understanding of Autistic people's strengths and needs both at an individual and a group level and, if used to effectively inform post-diagnostic support, to increase participation in activities and society.

408.079 Understanding Suicide-Related Internet Use in Autistic Adults

L. Bojanic¹, M. Pelton², S. Ibrahim¹, P. Turnbull³, S. Flynn⁴ and I. Hunt¹, (1)National Confidential Inquiry into Suicide and Safety in Mental Health, University of Manchester, Manchester, Greater Manchester, United Kingdom, (2)Department of Psychiatry, University of Cambridge, Cambridge, Cambridgeshire, United Kingdom, (3)National Confidential Inquiry into Suicide and Safety in Mental Health, Manchester, Greater Manchester, United Kingdom, (4)Division of Psychology and Mental Health, University of Manchester, Manchester, Greater Manchester, United Kingdom

Background: Autistic people are a high-risk group for suicide but scant research to date has identified unique risk factors for death by suicide amongst autistic people. A recent study reported autistic mental health patients who died by suicide were more likely to have accessed suicide-related material on the internet than non-autistic patients (Bojanic et al., 2024). Research has yet to explain why this is the case and there is no guidance tailored for autistic communication styles to explain how to stay safe whilst seeking support online for suicidality.

Objectives: We aimed to understand: (i) differences in socioeconomic, clinical, suicidality characteristics and suicide-related internet use between autistic and non-autistic people; (ii) types of suicide-related internet use, motivations for suicide-related internet use and the effectiveness of online suicide prevention messaging.

Methods: We carried out an online survey of self-reported suicide-related internet use amongst mental health patients, including questions about socio-economic demographics, recent and historical diagnoses, hospitalisation and prescription, satisfaction with service provision, previous suicidal thoughts and attempts, life events, social support and suicide-related internet use.

Results: Participants were 696 mental health patients (68% aged between 25 and 44; 68% female, n=169 (28%) self-reported a formal diagnosis of autism). Autistic participants were more likely than non-autistic participants to: (i) be younger, aged 18 and 24 years of age; (ii) identify as gender diverse; and (iii) have been a victim of violence. Autistic participants who engaged in suicide-related internet (n=137, 81%) use were more likely, than those who did not, to (i) be unemployed; and (ii) experience insomnia. As shown in Figure 1, the most common types of suicide-related internet use were: (i) searching for suicide-related content (n=116, 85%); and (ii) interacting with others for reasons of suicidality (n=75, 55%). The most common motivations to engage in SRIU were: (i) seeking information or support for suicidality (n=87, 64%); and (ii) seeking information about suicide methods (n=78, 57%). There was no significant difference in suicide-related internet use between autistic and non-autistic participants. 68% (n=115) of autistic participants noticed online suicide prevention messaging, 41% had engaged with this by following links or calling phone numbers, which they reported experiencing as, on average, mildly harmful (median=6, IQR: 4-7.4).

Conclusions: Results offer the first preliminary findings regarding suicide-related internet use amongst autistic mental health patients. Our sample reflect widely reported greater gender diversity, interpersonal victimisation amongst autistic than non-autistic patients and more frequent formal autism diagnosis in younger autistic adult patients in line with historic changes diagnostic criteria. In line with previous studies in the general population, our findings suggest possible harms and benefits of suicide-related internet use in autistic and non-autistic patients. Future research could extend these findings to explore whether: (i) distinct factors contribute to harmful or beneficial suicide-related online activity; (ii) autism-specific factors, such as insomnia or unemployment, contribute to suicide-related internet use; and (iii) findings are consistent amongst those with and without formal autism diagnosis. Online suicide prevention messaging could be reviewed with autistic people to improve the experience and effectiveness of signposting.

Poster Session

409 - Brain Structure (MRI, neuropathology) I

May 1st, 2025, 5:30 PM - 6:30 PM - Hall 4A

409.080 A Normative Modeling Analysis of Cortical Sex Differences in Young Autistic Children

D. S. Andrews¹, J. K. Lee², S. J. Rogers³, M. Solomon², A. Marquand⁴, D. G. Amaral² and C. W. Nordahl¹, (1)Department of Psychiatry and Behavioral Sciences, MIND Institute, UC Davis Medical Center, Sacramento, CA, (2)Department of Psychiatry and Behavioral Sciences, UC Davis MIND Institute, Sacramento, CA, (3)Department of Psychiatry and Behavioral Sciences, University California Davis, Sacramento, CA, (4)Donders Institute for Brain, Cognition and Behaviour, Nijmegen, Netherlands

Background: Autism is associated with significant differences between the sexes, with approximately 4 males diagnosed for every 1 female. Prevailing multifactorial liability models propose that males and females have different etiological thresholds to meet criteria for autism. The existence of a “female protective effect” in autism has been supported by both genetic and neuroimaging findings. Recently developed large-scale MRI models of neural development (i.e., normative modeling) offer a powerful framework to compare individual neuroanatomical measures against estimated population norms. Analogous to pediatric growth charts, normative modeling offers solutions to challenges presented by neural heterogeneity and classical case v control study designs making this methodology particularly well suited to test if autistic females experience greater differences in neuroanatomical structure than males.

Objectives: Following predictions of the multifactorial liability model, determine if measures of cortical thickness have greater differences from sex-specific peers in autistic females compared to autistic males.

Methods: This study included 257 (176 males / 81 females) autistic children ages 2-5 years. Cortical thickness was estimated using FreeSurfer 7.1.1 for 150 bilateral regions of interest (ROI). Each cortical reconstruction was visually inspected for quality with manual edits performed when required. For each ROI, lifespan trajectories of cortical thickness were modeled using Bayesian Linear Regression with likelihood warping leveraging MRI data from 88 sites (n=60,000; ages 2-100). Z scores, representing the degree of deviation from the normative model, were calculated for each individual ROI. Z scores were separated into positive (thicker cortex) and negative (thinner cortex) terms. Extreme deviations were defined as $Z > 2.6$ (positive values) and $Z < -2.6$ (negative values). Differences in the overall number of extreme deviations between autistic males and females were tested using non-parametric Mann-Whitney U tests. Additionally, differences in the proportion of extreme deviation in each ROI between autistic males and females were evaluated using permutation testing (n=10,000) and corrected for multiple comparisons using false discovery rate.

Results: Compared to autistic males, autistic females had significantly greater numbers of cortical ROIs with extreme negative deviations (male 0.82 v female 2.65, $p < 0.001$). A significant difference in the proportion of individual autistic males and females with an extreme negative deviation was found within the right inferior frontal gyrus, with 11.11% of autistic females and only 0.56% of males having an extreme negative deviation in this region (FDR $p = 0.01$). Males tended to have more ROIs with extreme positive deviations (male 1.85 v female 1.26, $p = 0.066$) although this difference did not reach statistical significance. After accounting for multiple comparisons, no additional ROIs had significant differences between the sexes in the proportion of individuals with an extreme deviation.

Conclusions: Greater numbers of extreme negative (thinner) cortical regions across autistic females as well as larger percentages of autistic females with such extreme deviations supports multifactorial liability models that indicate increased etiological load among autistic females that result in greater neuroanatomical differences for autistic females than males when compared to sex matched non-autistic peers.

409.081 Alterations in Trajectory of Large-Scale Brain Network Architecture in ASD during the Transition to Adulthood

A. L. Farmer¹, M. D. Prigge², S. Nelson¹, C. Traiser¹, E. Bigler³, A. L. Alexander⁴, J. E. Lainhart⁴ and **B. A. Zielinski⁵**, (1)Pediatrics, University of Florida, Gainesville, FL, (2)University of Utah, Salt Lake City, UT, (3)Brigham Young University, Provo, UT, (4)University of Wisconsin-Madison, Madison, WI, (5)Pediatrics, Neurology, and Neuroscience, University of Florida, Gainesville, FL

Background:

Previous evidence suggests that the brain's intrinsic connectivity networks may develop at different rates. These developmental network changes are reflected in gray matter morphometry and can be detailed using structural covariance. Alterations in structural architecture and connectivity of brain networks in autism spectrum disorder (ASD) have been reported previously; however, the development of these network differences has not been extensively studied. We applied structural covariance MRI (scMRI) to examine the developmental trajectory of network architecture in ASD from childhood into adulthood to determine when and where departures from typical development occur.

Objectives:

1. Identify alterations in the gray matter structure of intrinsic brain networks in ASD through the transition to adulthood
2. Examine the developmental trajectory of brain network differences in ASD, from adolescence into adulthood.

Methods:

We applied scMRI utilizing an existing longitudinal database of 188 males aged 11 to 35 years across 5 timepoints (834 scans). Structural MRI (MPRAGE) images were preprocessed and analyzed in SPM12. Data were binned by age (11 to 16, 16.1 to 20, over 20). To identify group and age differences in whole-brain covariance of gray matter, seed coordinates for network regions of interest (ROIs) were selected from known hubs of three large-scale networks implicated in ASD (default motor, executive control, and salience networks). We additionally probed cerebellar motor and cognitive covariance using previously reported motor and cognitive cerebellar regions. Signal intensities were extracted from 4-mm radius spherical seeds for each network hub ROI. For each age bin, one-sample t-tests were used to identify voxels with significant structural covariance with network seeds across participants for each diagnostic group across the entire brain, using total brain volume as a nuisance covariate. Group seed correlation maps were thresholded at family-wise error (FWE) corrected $p < 0.05$ and used to qualitatively compare across diagnostic and age groups.

Results:

Adults with ASD exhibited increased covariance between network seeds in the ECN and DMN with regions in the salience network (anterior insula and frontal operculum), as well as between ECN seeds and DMN regions and vice versa. Autistic adults also exhibited increased covariance between a motor region of the cerebellum (right lobule IV-V) and non-motor regions of the cerebellum and cerebral cortex that were not observed in typically developing adults. Right Crus II of the cerebellum, considered to be a cognitive region, also exhibited atypical covariance with cerebellar and cortical motor regions in autistic adults that was not seen in adult controls. Similar structural covariance deviations were also observed in autistic adolescents, although cerebellar alterations were not apparent before adulthood.

Conclusions:

1. Autistic adults exhibited structural covariance alterations in multiple large-scale brain networks involving the cerebral cortex and cerebellum.
2. Alterations in covariance between the ECN, DMN, and salience networks in ASD appear to persist in adulthood.
3. Our results suggest altered developmental trajectories and reduced segregation of cortical and cerebellar networks in ASD during the transition from adolescence to adulthood.

409.082 Altered White Matter Connectivity and Its Associations with Language Abilities in Young Children with Autism Spectrum Disorder

Y. Xiao¹, A. Yi² and K. Huang³, (1)Faculty of Life and Health Sciences, Shenzhen University of Advanced Technology, Shenzhen, Guangdong, China, (2)Department of Pediatrics, The Third Affiliated Hospital of Guangzhou Medical University (Women's and Children's Hospital of Guangzhou Medical University), Guangzhou, China, (3)Department of Psychosis Studies, Institute of Psychiatry, Psychology & Neuroscience, King's College London, London, United Kingdom

Background: Previous diffusion tensor imaging (DTI) studies have identified differences in white matter tracts involved in language processing, such as the arcuate fasciculus (AF), inferior longitudinal fasciculus (ILF), superior longitudinal fasciculus (SLF), and inferior fronto-occipital fasciculus (IFOF) in children with autism spectrum disorder (ASD)^{1,2,3}. Recent studies have explored the alterations in white matter connectivity in ASD using a newly developed approach, Automated Fiber Quantification (AFQ)^{4,5}. AFQ can identify localized changes in specific tracts that may be missed in traditional tract-wise DTI analyses⁶⁻⁸. However, the impact of these alterations on language variability, especially in preschool-aged children with ASD, remains understudied.

Objectives: This study aimed to investigate early white matter alterations in eight major white matter fiber tracts associated with language functions in young children with ASD as compared to the typically developing (TD) peers at both tract-wise and point-wise levels.

Methods: We analyzed DTI data from 50 Chinese preschool children aged 1.5 to 6 years old, including 28 ASD ($n=28$, 3.24 ± 1.26 years) and 22 TD (2.97 ± 1.31) children. All ASD children met the DSM-V criteria for ASD as assessed by the ADOS (Module 1 or 2) or CARS, and all children completed the Chinese version of Gesell Development Schedule (GDS)⁹.

Diffusion-weighted imaging data were processed using the Python Automated Fiber Quantification (pyAFQ) tool⁴, which automates tractography, registration, segmentation, cleaning, profiling, and visualization. We focused on four DTI metrics—fractional anisotropy (FA), mean diffusivity (MD), radial diffusivity (RD), and axial diffusivity (AD)—across 100 nodes in eight language-related tracts: the left and right AF, ILF, SLF, and IFOF.

Lateralization indices (LI) for each DTI metric were calculated using $(R - L) / (R + L)$, and one-sample t -tests were performed to assess the LI for each DTI metric in both groups. Two-sample t -tests compared LI between groups. We compared each DTI metric between the TD and ASD groups at both the tract-wise (mean across 100 nodes) and point-wise levels, controlling for age and gender. Relationships between each DTI metric and language scores were examined separately in the ASD and TD groups, along with correlations between DTI metrics and symptom severity in ASD.

Results: Our results revealed significant lateralization patterns within both groups, though no significant between-group differences in lateralization were observed (Figure 1A-D). ASD and TD groups showed different patterns in correlations between white matter lateralization and language abilities (Figure 1E-F). While no significant group differences were detected through tract-wise comparisons of DTI metrics, point-wise analyses revealed localized differences in FA, MD, RD, and AD between groups. These localized alterations were strongly associated with language abilities, showing distinct patterns in each group (Figure 1G). Furthermore, we identified significant correlations between DTI metrics and the severity of ASD symptoms (Figure 1H-I).

Conclusions: These findings suggest that microstructural changes in white matter play a critical role in both language abilities and symptom severity in ASD, offering potential avenues for further research and intervention strategies.

409.083 An Exploration into the Sensory Brain Structures in Infants with a Higher Likelihood of Neurodevelopmental Conditions

A. Javed¹, D. Fenchel², D. Batalle³, K. Colford⁴, A. D. Edwards⁵ and G. McAlonan⁶, (1)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, Kings College London, Insititue of Psychiatry, Psychology & Neuroscience, London, United Kingdom, (2)Department of Forensic and Neurodevelopmental Sciences, and the Sackler Institute for Translational Neurodevelopment, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (3)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (4)Centre for the Developing Brain Biomedical Engineering & Imaging Sciences Perinatal Imaging & Health, King's College London, London, London, United Kingdom, (5)Neonatal Unit, Evelina London Children's Hospital, London, United Kingdom, (6)NIHR-Biomedical Research Centre for Mental Health at the Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, UNITED KINGDOM

Background:

Sensory difficulties have recently been recognised as a core difficulty of Autism Spectrum Conditions (ASC) with up to 90% reporting sensory issues (Robertson et al., 2017) and other neurodevelopmental conditions (NC's). Recent Magnetic Resonance Imaging (MRI) research have provided evidence in adulthood suggesting neuroanatomical differences in sensory regions in ASC (Habata et al., 2021). However, adult studies make it difficult to untangle the primary and secondary consequences of living with ASC. Studies of infants with a first degree relative of NC's are more likely to receive a later diagnosis and provide an opportunity to examine sensory brain development prior to emerging behavioural symptoms. As sensory features are among the earliest signals of ASC in infancy, the development of sensory systems in the postnatal period is crucial to understand.

Objectives:

We tested the hypothesis that the volume of key sensory brain regions may differ at birth in neonates with and without a first degree relative with a neurodevelopmental condition.

Methods:

91 neonates underwent T2 weighted sequences on a 3T MRI scanner. 36 infants (n=22M and 14F) born (M=39.02, SD=1.94) and scanned (M=42.09, SD=1.81) were classified as higher likelihood (HL) of neurodevelopment infants. 55 infants (n=25M and 30F) born (M=39.80, SD=1.32), scanned (M=42.31, SD=1.40) were classified as lower likelihood (LL) with no family history of neurodevelopment conditions. Neonates with significant physical health condition and/or clinically relevant incidental MRI brain anomaly were excluded.

12 sensory volumes were examined including the precentral (PRG) (movement) and postcentral gyrus (POG) (touch), supplementary motor (SMC) and olfactory cortex (smell), the inferior, middle and superior occipital lobes (OL) (visual), superior temporal gyrus (STG) (auditory), insula, thalamus, hippocampus and amygdala. ANOVAs were run on individual sensory regions of interest, with total brain tissue volume, gestational age (GA) at birth, GA at scan, biological sex and biological sex*likelihood as co-variables.

Results:

There were no significant between group differences in biological sex, age at birth and age at scan. The results revealed no differences between HL and LL sensory volumes. However, interaction effects revealed significant differences between the HL male (M= 4901.4, SD= 859.2) and female (M= 4943.3, SD= 600.5) right postcentral gyrus ($p=0.025$). We also found significant differences between the HL male (M= 7797.5, SD= 1405.6) and female (M= 7659.9, SD= 1361.0) in the right precentral gyrus ($p=0.09$). However, this did not survive multiple comparisons.

Conclusions:

Our preliminary findings revealed no significant differences when comparing HL and LL sensory region-of-interest volumes. However, interaction effects between biological sex and likelihood group revealed larger POG in HL females compared to males and larger PRG in HL males compared to females. Although this did not survive multiple comparisons, these findings suggest biological differences may drive sensory development specifically within neurodevelopmental conditions as early as birth. As the POG is responsible for touch and the PRG for movement, these early findings may indicate differences in touch perception and motor movement in males and females with neurodevelopmental conditions. However, this warrants further examination of the developmental sensory trajectory.

409.084 Cortical-Thickness-Based Machine Learning Model for Diagnosing Autism: Investigation of Systemic Error and Feature Importance

Y. C. Wang^{1,2}, C. Y. Cheng³, C. C. Lee⁴ and S. S. F. Gau^{2,5}, (1)Department of Psychiatry, National Taiwan University Hospital, HsinChu branch, Taipei, Taiwan, (2)Graduate Institute of Clinical Medicine, College of Medicine, National Taiwan University, Taipei, Taiwan, (3)Department of Psychiatry, National Taiwan University Hospital, Taipei, Taiwan, (4)Department of Electrical Engineering, National Tsing Hua University, Hsinchu, Taiwan, (5)Department of Psychiatry, National Taiwan University Hospital and College of Medicine, Taipei, Taiwan

Background: There has been an increasing effort to establish classification models for autism based on brain imaging data. Although the potential for creating an objective biomarker from this data is significant, these models' explainability and systemic errors remain largely under-investigated. **Objectives:** This study aims to train models using cortical thickness data from individuals with autism and typically developing comparisons while investigating systemic error and establishing feature importance through explainable artificial intelligence.

Methods: Structural MRI data from 162 autistic participants (94.4% male, mean age $\pm$ SD: 13.4 $\pm$ 2.6 years) and 227 typically developing comparisons (70% male, mean age $\pm$ SD: 12.2 $\pm$ 2.9 years) were processed with Freesurfer to extract cortical thickness data parcellated by the Destrieux atlas. One hundred fifty variables from the left and right hemispheres were used as training features for various classification models, including support vector machines, random forests, K-nearest neighbors, linear discriminants, neural networks, decision trees, and XGBoost. We compared correct and incorrect classifications of autistic participants based on their sex, age, IQ, emotional and behavioral symptoms from the Child Behavioral Checklist (CBCL), and comprehensive autistic features assessed through standardized evaluation tools. The average SHAP (SHapley Additive exPlanations) values for each feature from the best-performing model were calculated to provide insights into the explainability of the machine learning models and identify potentially important features.

Results: Our classification model achieved high accuracy, with the XGBoost model yielding an area under curve (AUC) of 0.883, sensitivity of 0.822, and specificity of 0.781. In contrast to our previous study on behavioral data, the errors from the brain image-based model did not correlate with emotional or behavioral problems. Furthermore, these errors did not correlate with age or sex. However, they were associated with a wide range of autistic features and verbal IQ (VIQ), indicating that autism-specific brain patterns could serve as potential biomarkers for diagnosis. We identified the top 15 brain regions with the highest average SHAP values. Notably, the top four regions—right superior segment of the circular sulcus of the insula, right short insular gyri, right posterior ramus of the lateral sulcus, and right intraparietal sulcus and transverse parietal sulci—exhibited both the highest SHAP values and the best discrimination between autistic participants and comparisons.

Conclusions: Our findings suggest that classification models based on brain imaging can function as objective aids in the diagnosis of autism. These models demonstrate error patterns distinct from those based on behavioral data, offering crucial insights for their clinical use across diverse symptom profiles. Furthermore, the brain regions identified as top discriminators warrant additional exploration to enhance our understanding of brain-behavior relationships and identify potential therapeutic avenues.

409.085 Diffusion Weighted Imaging of the Anterior Cingulate Cortex in Toddlers and Preschoolers with Autism Spectrum Disorder
S. Tui^{1,2}, J. Hau^{1,2}, A. Rios³, M. Herrera³, S. Pedrahita³, R. A. Carper^{1,2,3,4}, I. Fishman^{1,2,3,4}, R. A. Müller^{1,2,3,4} and A. C. Linke^{1,2,3}, (1)Psychology, San Diego State University, San Diego, CA, (2)Brain Development Imaging Laboratories, San Diego State University, San Diego, CA, (3)Joint Doctoral Program in Clinical Psychology, San Diego State University/University of California, San Diego, San Diego, CA, (4)Center for Autism and Developmental Disorders, San Diego State University, San Diego, CA

Background: Postmortem studies in autism spectrum disorder (ASD) have identified cytoarchitectural differences in the anterior cingulate cortex (ACC) including increased cell packing density, laminar disorganization, and alterations in the ratio of short- vs long-distance axons beneath the ACC. Established associations between ACC and executive function suggest that these cytoarchitectural differences may contribute to co-occurring executive deficits in ASD. Alterations to ACC structure, function, and connectivity have also been associated with increased restricted and repetitive behaviors in ASD, with both ACC u-fiber volume and FA of the underlying WM negatively associated with RRB in independent studies. While diffusion-weighted imaging (DWI) is most commonly applied to studies of white matter, it is also sensitive to differences in gray matter microstructure.

Objectives: (1) To investigate gray matter microstructure (using DWI) in anterior cingulate cortex in toddlers with and without ASD; (2) To test for associations with executive function.

Methods: A sample of 34 toddlers and preschoolers aged 18-64 months (22 with ASD, 12 typically developing [TD]; mean age 42.56±13.80 months) were examined. ASD diagnoses were verified through clinical best estimate of DSM-5 criteria supported by the ADOS-2. The Mullen Scales of Early Learning assessed developmental skills and the Behavior Rating Inventory of Executive Function-Preschool (BRIEF-P) assessed executive function. T1-weighted and DWI scans were collected during natural nocturnal sleep. Rostral anterior and caudal anterior regions of interest (ROI) were identified bilaterally using FreeSurfer and the Desikan-Killiany atlas. Fractional anisotropy (FA) and mean diffusivity (MD) were averaged for each ROI using FSL software. Linear regression models tested for effects of age, diagnosis and their interaction for each ROI, and correlations tested for associations between ACC microstructure and executive function in the ASD group.

Results: Groups were matched on age, intracranial volume and image quality. FA significantly decreased with age in left caudal and right rostral ACC, while MD significantly increased in all ROIs. Diagnosis and age-by-diagnosis effects were not significant for FA or MD in any ROI. A significant correlation between right caudal ACC MD and higher (less proficient) BRIEF-P *Shift* t-scores ($r = .508, p = .031$) was found in the ASD group but didn't survive correction for multiple comparisons. No other significant correlations were found between DWI measures and BRIEF-P subscores in the ASD group.

Conclusions: Age trajectories of FA and MD were typical for developing gray matter as dendritic trees continue to expand in childhood. Although group effects were not significant when controlling for age, means were in the expected direction and consistent with previous findings from our group in older children and adolescents. That earlier study suggested elevated MD and decreased neurite density (using a multi-compartmental model) in the ACC, parietal lobe, and right superior temporal lobe, findings that align with the altered ACC cytoarchitecture found in postmortem studies. A correlation between higher right caudal ACC MD and greater impairment in task shifting did not survive FDR correction. A larger sample size is needed to detect potentially subtle effects, and application of a multicompartmental model (in progress) may provide greater sensitivity.

409.086 Elevated Extra-Axial CSF Volumes in Angelman Syndrome: Extending Beyond Autism to a Neurogenetic Syndrome
Z. Chen, D. Garic, Y. Xu, R. G. Smith, L. A. Weisenfeld, S. H. Kim, M. Styner, J. Piven, B. D. Philpot, H. Hazlett and M. D. Shen, University of North Carolina, Chapel Hill, NC

Background: Previous studies have demonstrated that young children with idiopathic autism have atypically enlarged volumes of extra-axial cerebrospinal fluid (EA-CSF) and an increased ratio of EA-CSF to brain volume, suggesting that EA-CSF is disproportionately increased beyond the brain enlargement often observed in autism. It is unknown whether enlarged EA-CSF is present in selected genetically-defined syndromes with shared and distinct features of autism. Angelman syndrome (AS) is a neurogenetic syndrome caused by loss of function, mutations, or deletions of the maternal *UBE3A* allele. AS shares some phenotypic features with autism (increased incidence of intellectual disability, seizures, and sleep problems) but is also characterized by microcephaly. Studying AS will provide insight into whether EA-CSF volume is disproportionately enlarged in a neurodevelopmental syndrome with smaller head size.

Objectives: This study aimed to investigate differences in total cerebral volume (TCV) and EA-CSF volume between children with AS and neurotypical (NT) children, as well as the relationship between EA-CSF, sleep, and seizures in AS.

Methods: We acquired high-resolution structural MRI scans in N=29 children with AS (18 males, 11 females; M[SD] age = 6.08 [2.14] years) and N=27 NT children (23 males, 4 females; M[SD] age = 7.96 (2.24) years). We collected the Children's Sleep Habits Questionnaire (CSHQ) to measure sleep quality and the Early Childhood Epilepsy Severity Scale (E-Chess) to evaluate seizure severity in the AS group. ANCOVA was employed to compare TCV and EA-CSF between AS and NT groups, controlling for age, sex, and interactions with group. The relationships between EA-CSF, sleep, and seizure problems in AS were analyzed using linear regression.

Results: AS children had significantly smaller TCV (24% difference) compared to NT individuals ($F_{1, 50} = 195.96, P < .0001$). Despite having much smaller brain volumes, the AS group had nearly equivalent EA-CSF volumes to the NT group ($F_{1, 50} = 0.91, P = .35$). The ratio of EA-CSF to TCV was 39% higher in AS, indicating that AS children have disproportionately high volumes of EA-CSF relative to brain volume ($F_{1, 50} = 24.49, P < .0001$). Higher EA-CSF in AS was significantly associated with problems initiating sleep ($P = .002; t_{15} = 3.79$) and the severity of seizures ($P = .032; t_{14} = 2.38$).

Conclusions: Similar to what has been reported in young children with autism, this study indicates that children with AS have atypically higher EA-CSF volume than would be predicted by their smaller brain size. Elevated EA-CSF volumes in children with AS were associated with sleep problems and seizures, which significantly impact quality of life and are key outcome measures in current clinical trials to reactivate the *UBE3A* allele. Excessive CSF suggests the possibility that CSF circulation is impaired in AS individuals, which would have important implications for current genetic therapies delivered via CSF intrathecally. We are currently analyzing MRI data in age- and sex-matched individuals with autism to compare with idiopathic autism, AS, and neurotypical controls.

409.087 Enhancing Multimodal Neuroimaging Classification in ASD Using Alternating Diffusion Mapping

Z. Jacokes¹, K. A. Pelphrey², **J. D. Van Horn¹** and G. A. Consortium³, (1)School of Data Science, University of Virginia, Charlottesville, VA, (2)Department of Neurology, University of Virginia School of Medicine, Charlottesville, VA, (3)Seattle Children's Research Institute, Seattle, WA

Background:

Incorporating multiple modalities into machine learning (ML) analyses is an emerging challenge in scientific exploration. Multimodal data collection is becoming increasingly more common, and complex developmental conditions like ASD can be better understood by synthesizing the complementary information provided by multimodal data. Alternating diffusion mapping (ADM) is a manifold learning algorithm that combines the lower dimensional embeddings from separate modalities into a unified matrix for ML. The benefit of this technique is twofold: intrinsic structure of each modality is preserved, and commonalities between modalities are highlighted. Thus, the low dimensional embeddings resulting from ADM represent the union of the multimodal components.

Objectives:

The objective of this analysis is to evaluate ADM's effectiveness in identifying salient differences between autistic and non-autistic individuals. To do so, we utilize volumetric brain data as the first modality and phenotypic survey data as the second modality. These two modalities are particularly well-suited for this task, as the literature suggests we should expect poor cohort-wise classification accuracy on the volumetric data alone and good classification accuracy on the phenotypic data alone. Improved classification accuracy on the ADM-fused data is the true test of this method.

Methods:

Participants included 312 individuals (162 female; mean age=151.32 months). 144 were autistic (68 female; mean age=151.17), and the remaining 168 were non-autistic controls. Volumetric data included the 168 Destrieux atlas regions preprocessed by dividing by intracranial volume. Phenotypic data included domain subscales from several behavioral measures: DAS-II, Vineland-II, SRS, RBS-R, BRIEF-II, and CBCL (42 total). Missing phenotypic data were imputed to maintain sample size. Each modality was scaled and centered such that predictors had means of zero and variances of one. Samples were split into training/testing sets, diffusion mapping was implemented on each modality separately, and cohort-wise classification accuracy was assessed using SVM. ADM was then implemented on both modalities and classification accuracy was reassessed.

Results:

Overall classification accuracy for volumetric data was 52.44% (autistic: precision=0.49, recall=0.97, F1-score=0.65; non-autistic: precision=0.86, recall=0.14, F1-score=0.24). Overall classification accuracy for phenotypic data was 87.30% (autistic: precision=0.82, recall=0.93, F1-score=0.87; non-autistic: precision=0.93, recall=0.82, F1-score=0.87). Overall classification accuracy for the fused data was 90.48% (autistic: precision=0.87, recall=0.93, F1-score=0.90; non-autistic: precision=0.94, recall=0.88, F1-score=0.91).

Conclusions:

The overall results suggest that ADM was effective for fusing multiple modalities together due to the increase in classification accuracy from the phenotypic data alone. Phenotypic surveys chosen for this analysis are designed to assess proficiency in various developmental domains, which explains the high accuracy in these data individually. Notably, these findings indicate that complementary information can be extracted from data sources that are seemingly less important independently: differences in brain volume between autistic and non-autistic individuals are not well-supported in the literature, a finding corroborated here by the poor classification accuracy of volumetric data alone. However, the improvement in accuracy after multimodal fusion implies that latent information shared between modalities helps ML algorithms distinguish between diagnostic groups. Further investigation into fusing other modalities, such as time-series modalities like EEG and fMRI, has the potential to uncover more complementary information unique to ASD.

409.088 Evaluating Deep Learning Methods for the Correlation of Motion Artifacts Correction in Structural MRI Scans

B. Hermila^{1,2}, H. Seelemeyer^{2,3}, J. Leyhausen^{2,3,4}, L. Berg^{2,3}, C. M. Pretzsch⁵, T. Schäfer⁶, E. Loth³, B. Oakly⁷, J. K. Buitelaar⁸, C. Beckmann⁸, T. Charman⁹, T. Banaschewski^{10,11}, E. Jones¹², T. Bourgeron¹³, D. Murphy⁵ and C. Ecker^{2,3,5}, (1)Goethe University Hospital, Frankfurt am Main, Germany, (2)Brain Imaging Center, Goethe University, Frankfurt am Main, Germany, (3)Department of Child and Adolescent Psychiatry, University Hospital, Goethe University, Frankfurt am Main, Germany, (4)Department of Biosciences, Goethe University Frankfurt, Frankfurt am Main, Germany, (5)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College, London, United Kingdom, (6)Fries Lab, Ernst Strüngmann Institut (ESI) for Neuroscience in Cooperation with Max Planck Society, Frankfurt, Germany, (7)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (8)Department of Cognitive Neuroscience, Donders Institute for Brain, Cognition and Behaviour, Radboud University Nijmegen Medical Center, Nijmegen, Netherlands, (9)Department of Psychology, Institute of Psychiatry, Psychology & Neuroscience, King's College London, London, United Kingdom, (10)German Center for Mental Health (DZPG), partner site Mannheim-Heidelberg-Ulm, Mannheim, Germany, (11)Department of Child and Adolescent Psychiatry, Central Institute of Mental Health, University of Heidelberg, Mannheim, Germany, (12)Centre for Brain and Cognitive Development, Birkbeck, University of London, London, United Kingdom, (13)Human Genetics and Cognitive Functions, Institut Pasteur, Paris, France

Background:

Magnetic Resonance Imaging (MRI) is a key non-invasive tool for studying brain anatomy, functioning, and connectivity in mental health conditions^[1]. On the downside, participant movement during MRI scanning can lead to image distortions such as blurring and ringing, which in turn can compromise overall data quality^[2]. This particularly applies to data coming from individuals with mental health conditions that are more sensitive to noise, or find it hard to lay still (e.g., ADHD individuals). While deep learning approaches are constantly being developed in a bid to reduce the long processing times^[3], or to enhance the resolution of low-field data^[4], the applicability of such approaches in correcting motion artifacts is yet to be validated.

Objectives:

In this current project, we aimed to 1) evaluate the accuracy of three AI-based methods to reduce motion artifacts, and 2) assess their potential impact on improving overall data.

Methods:

N=359 autistic individuals aged 6-30 (101 females, 258 males) underwent structural Magnetic Resonance Imaging (MRI) at 6 different sites^[5] using 3T head-scanners. T1-weighted images were assessed, edited, and processed using FreeSurfer v6.0.0 (<http://surfer.nmr.mgh.harvard.edu/>). Out of this sample, we retrospectively examined 65 pairs of motion-affected and motion-free images of the same participants. The high-quality scans served as the 'ground truth', to which the results of different AI-based pipelines were compared in order to evaluate their accuracy. The AI-based alternatives included: FastSurfer^[3], recon-all-clinical^[6-9], and SynthSR^[9,10] followed by the standard recon-all pipeline of FreeSurfer. The outputs of the three pipelines were compared at the vertex level. Additionally, we used the fsqc tool (<https://github.com/Deep-MI/fsqc>) to assess the quality of the reconstructions in terms of surface holes, defects, and signal-to-noise ratio.

Results:

All three pipelines produced comparable surface-based data that was highly correlated with the default pipeline applied to the reference scans. The highest spatial correlation was obtained for measures of cortical thickness (CT) with FastSurfer (mean spatial correlation=0.94 with a smoothing kernel of 15, see Fig 1A). SynthSR, on the other hand, produced the most reliable data for measures of surface area (SA) (mean=0.95 with a smoothing kernel of 10, see Fig 1B). There were no major differences in specific areas of the difference maps for both the CT and SA measures, comparing the resulting surfaces to those from the standard process (see Fig 1C-D). Last, SynthSR provided the highest increase in signal-to-noise ratio pre-normalization in both grey and white matter. It also significantly decreased the numbers of surface holes and defects in both hemispheres (see Fig 2).

Conclusions:

Our findings suggest that the deep learning approaches can reliably be used to salvage images that would have been otherwise discarded because of their poor quality. Notably, SynthSR appears to be producing comparatively high correlations while also enhancing image contrast and repairing surface defects without producing any changes in image orientation. This makes these techniques particularly well suited for studying the brain anatomy in neurodiverse study populations, and provide an opportunity to save resources and potentially avoid having to repeat the scanning procedure several times until high-quality images are achieved.

409.089 Immune Alterations at Brain Borders in Autistic Adults Revealed By Neuroimaging

C. E. Tseng^{1,2,3}, E. Guma^{1,2,3}, Y. Lila¹, E. Johnston^{1,3}, C. Canales^{1,3}, C. J. McDougle^{1,2,3}, J. M. Hooker^{1,2,3} and N. R. Zürcher Wimmer^{1,2,3} (1)Athinoula A. Martinos Center for Biomedical Imaging, Department of Radiology, Massachusetts General Hospital, Charlestown, MA, (2)Harvard Medical School, Boston, MA, (3)Lurie Center for Autism, Massachusetts General Hospital, Lexington, MA

Background:

Immune mechanisms have been associated with the pathophysiology of autism spectrum disorder (ASD), based on preclinical and epidemiology work (Careaga et al., 2017, Tiroleco et al., 2021). Recent studies have identified regions bordering the brain, such as the choroid plexus and skull, as key regulators of immune responses in central nervous system, (reviewed in Castellani et al., 2023). Positron emission tomography (PET) with the radiotracer [¹¹C]PBR28 allows for the *in vivo* measurement of translocator protein (TSPO), a mitochondrial protein involved in immune functions in humans. Translocator protein levels have not yet been assessed at brain borders in autistic adults.

Objectives:

Assess whether TSPO levels are altered in the choroid plexus and skull in autistic adults compared to age- and sex-matched controls (CON) using simultaneous [¹¹C]PBR28 PET and magnetic resonance imaging (MRI).

Methods:

Thirty-eight autistic adults (26 males, 12 females) and 29 age- and sex-matched healthy controls (19 males, 10 females) completed a [¹¹C]PBR28 PET-MRI scan. [¹¹C]PBR28 PET data from 60-90 minutes post radiotracer injection were reconstructed into standardized uptake value (SUV) normalized by a pseudo-reference region (SUVR). The choroid plexus region of interest (ROI) was manually segmented for all participants. The skull ROI was derived from an MRI-based pseudo-computed tomography image and segmented into frontal, parietal, temporal, and occipital regions. [¹¹C]PBR28 SUVR was extracted from subject space for the choroid plexus and skull. Multivariable linear regression models were used to test group differences while controlling for age, sex, and TSPO genotype and to assess group-by-sex interactions while controlling for age and TSPO genotype.

Results:

For the choroid plexus, elevated TSPO was observed in autistic females compared to CON female (p=0.01), but no alteration was seen in autistic males. For the skull, elevated TSPO was seen in the frontal (p<0.05) and temporal (p=0.03) lobar skull regions in autistic adults compared to age- and sex-matched CON.

Conclusions:

Elevated TSPO in the choroid plexus and skull in autistic adults *in vivo* suggests immune alterations at brain borders, which are areas increasingly understood as key immunological niches. Some of the elevations seen were sex-specific, such as the TSPO elevations in the choroid plexus which was seen in autistic females only. Overall, these regional elevations in TSPO density suggest that immune processes in regions bordering the brain should be further investigated in autism spectrum disorder.

409.091 Localized Mapping of White Matter Microstructural Alterations in Autism Using Advanced Tractometry

G. S. Kim¹, **B. Q. Chandio²**, **S. M. Benavidez²**, **P. M. Thompson³** and **K. E. Lawrence³**, (1)Neuroscience Graduate Program, University of Southern California, Los Angeles, CA, (2)University of Southern California, Los Angeles, CA, (3)Stevens Neuroimaging & Informatics Institute, University of Southern California, Los Angeles, CA

Background: Previous diffusion magnetic resonance imaging research (dMRI) in autism has reported altered white matter microstructure, but the affected white matter regions are inconsistently reported across studies, hindering our understanding of the brain in autism. These conflicting results may be due in part to limitations of commonly used dMRI analytic techniques or small sample sizes. The traditional microstructure model, diffusion tensor imaging (DTI), cannot resolve crossing fibers. Conventional dMRI analysis methods such as tract-based spatial statistics (TBSS) and tractography averaging across large portions of the tract are limited by skeletonization biases or poor spatial specificity, which can obscure subtle, localized differences. The tensor distribution function (TDF) model addresses limitations of DTI by fitting a continuous mixture of tensors at every voxel, modeling complex fiber orientations. The novel tractometry method, BUⁿdle ANalytics (BUAN), extracts individual white matter tracts as 3D models and yields fine-grained maps of white matter differences.

Objectives: Precisely map white matter microstructure alterations in autism within commissural and association tracts using the advanced microstructure model, TDF, and the novel tractography-based approach, BUAN.

Methods: We analyzed single-shell 3D dMRI scans from 365 participants (5-25 years; 34.0% females; 195 with autism) from 10 sites/scanners (7 NIMH Data Archive sites and 3 Autism Brain Imaging Data Exchange sites). Standard preprocessing included eddy current and distortion correction. A TDF-derived measure of fractional anisotropy (FA^{TDF}) was computed at each voxel, along with standard DTI metrics of fractional anisotropy (FA^{DTI}), and mean, axial, and radial diffusivity (MD, AD, RD). Whole-brain tractograms were generated using constrained spherical deconvolution (CSD) and local deterministic tractography (Figure 1). The auto-calibrated RecoBundles method was used to extract 9 standard commissural and association tracts. BUAN was then used to divide each tract into 100 segments and compare microstructural metrics between the autism and neurotypical groups. Nuisance covariates included age, de-meaned age squared, sex, full-scale intelligence quotient, subject, and site/scanner. The false discovery rate was applied for multiple comparisons correction.

Results: Microstructural alterations in autism were detected in localized regions of almost every tract examined; representative tracts and metrics are displayed in Figure 2. Overall, there was lower white matter integrity (FA^{TDF} , FA^{DTI}) and elevated diffusivity (MD, RD) across tracts. For commissural tracts, the *forceps minor* and midbody of the corpus callosum exhibited localized differences specifically in the central portion of the tract. For the *forceps major*, differences were specific to the lateral portions of the tract. For association tracts, significant differences were localized to the frontal projections for the arcuate and uncinate fasciculi. By contrast, for inferior fronto-occipital, inferior longitudinal, and middle longitudinal fasciculi the significant differences were more specific to the posterior or middle portions of each individual tract.

Conclusions: Our study using advanced dMRI methods indicates that white matter microstructure alterations in autism are detectable across diverse brain regions in a spatially-specific manner. These findings demonstrate the importance of considering widespread brain regions and nuanced differences therein to improve our understanding of the neural mechanisms underlying autism.

**409.092** Myelin Water Fraction and Relaxation Time Differences in Orienting Attention-Related Regions and Their Association with Social Behaviors in Autism

C. D. Yoon¹, **A. L. Alexander²**, **J. E. Lainhart²** and **D. C. Dean²**, (1)Waisman Center, UW-Madison, Madison, WI, (2)University of Wisconsin-Madison, Madison, WI

Background: While increasing evidence suggests widespread white matter microstructure alterations in autism, there is limited research on direct assessments of myelin in this population. Multicomponent relaxometry may provide a more specific assessment of myelin content through the myelin water fraction (VF_M). To date, only one study (Deoni et al., 2015) has used voxel-wise comparisons of VF_M in autism, revealing lower VF_M in autistic individuals in comparison to neurotypical individuals. The present study aims to investigate VF_M , along with quantitative relaxation-time estimates (T_1 , T_2), in white matter tracts involved in orienting attention (the corpus callosum [CC], cingulum, superior longitudinal fasciculus [SLF], and uncinate fasciculus [UF]; e.g., Dowe et al., 2020; Elison et al., 2013; Murray et al., 2016; Niogi et al., 2010), which is closely linked to social communication difficulties in autism.

Objectives: This study aims to: (a) examine whether VF_M , T_1 , and T_2 in the CC, cingulum, SLF, and UF differ between autistic and neurotypical individuals, including age-related group differences; and (b) explore whether these alterations are associated with parent-reported social behaviors (Social Responsiveness Scale [SRS]) in autistic individuals.

Methods: Imaging data were acquired from 48 autistic (92% male; $M_{age} = 16.3$; 5 to 42 years) and 71 neurotypical individuals (94% male; $M_{age} = 15.8$; 5 to 33 years) using mcDESPOT, a multicomponent relaxometry technique (Dean et al., 2014, 2016; Deoni et al., 2008). ANCOVA and multiple regressions were conducted to address the two aims, respectively, controlling for age in all analyses. A false discovery rate (FDR) correction (Benjamini & Hochberg, 1995) was applied to adjust for multiple comparisons.

Results: No significant group differences were found for VF_M . However, uncorrected results showed greater VF_M in the genu of the CC ($p=.045$) and SLF (right, $p=.022$; left, $p=.050$) in the autism group. T_1 was lower in the autism group in the CC (genu, $p=.040$; body, $p=.049$; splenium, $p=.046$), cingulum hippocampus (right, $p=.049$; left $p=.049$), and SLF (right, $p=.044$; left $p=.040$). There were no significant differences in T_2 or age-by-group interactions across VF_M , T_1 , and T_2 . Associations between SRS scores and VF_M , T_1 , and T_2 were found only at the uncorrected level. Specifically, mother-reported SRS-Social Cognition was positively associated with T_2 in the right UF ($p=.050$), while father-reported SRS-Social Motivation was negatively associated with T_2 in the genu ($p=.044$) and body of CC ($p=.039$). Additional associations were found for SRS-Social Communication across both parent reports, with varying patterns across regions.

Conclusions: Our findings suggest that myelination may not be a factor contributing to the differences in orienting attention between autistic and neurotypical individuals. In addition, myelin and tissue maturation may not differ between these groups. The results, particularly for T_1 , add to the mixed findings from relaxometry studies in autism. Although associations with social behaviors did not survive correction for multiple comparisons, the initial uncorrected results indicate a need for further investigation. Future studies may consider using more sensitive or objective measures of social behavior and orienting attentional mechanisms, as well as larger sample sizes, to clarify these relations.

409.093 Neuroanatomical Correlates of Adaptive Outcomes in Autism

H. Seelemeyer^{1,2}, C. Gurr¹, J. Leyhausen¹, L. Berg¹, C. M. Pretzsch³, T. Schäfer⁴, B. Hermila⁵, E. Loth⁶, B. Oakley⁷, J. K. Buitelaar⁸, C. Beckmann⁹, T. Charman¹⁰, T. Banaschewski¹¹, E. Jones¹², T. Bourgeron¹³, L. G. EU-AIMS¹⁴, D. Murphy¹⁵ and C. Ecker¹, (1)Department of Child and Adolescent Psychiatry, University Hospital, Goethe University, Frankfurt am Main, Germany, (2)Brain Imaging Center, Goethe University, Frankfurt am Main, Germany, (3)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (4)Fries Lab, Ernst Strüngmann Institut (ESI) for Neuroscience in Cooperation with Max Planck Society, Frankfurt, Germany, (5)Goethe University Hospital, Frankfurt am Main, Germany, (6)Department of Forensic and Neurodevelopmental Sciences, Flat 2, 116, South Hill Park, London, London, United Kingdom, (7)Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (8)Department of Cognitive Neuroscience, Donders Institute for Brain, Cognition and Behaviour, Radboud University Nijmegen Medical Center, Nijmegen, NETHERLANDS, (9)Department of Cognitive Neuroscience, Donders Institute for Brain, Cognition and Behaviour, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands, (10)Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, UNITED KINGDOM, (11)Department of Child and Adolescent Psychiatry, Central Institute of Mental Health, University of Heidelberg, Mannheim, Germany, (12)Centre for Brain and Cognitive Development, Birkbeck University of London, London, United Kingdom, (13)Human Genetics and Cognitive Functions, Institut Pasteur, Paris, France, (14)EU-AIMS Organization, London, United Kingdom, (15)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, UNITED KINGDOM

Background:

Autism is a common neurodevelopmental condition that is characterized by differences in social communication and interaction (SCI), restricted, repetitive, and stereotypical behaviors (RRB) and atypical sensory processing (ASP). These core symptoms are accompanied by neurodevelopmental variations in cortical thickness (CT)[1]. Typically, increased symptom scores are associated with decreased adaptive functioning, such as communication, daily living skills, socialization, and motor skills [2]. However, some individuals display a high level of adaptive functioning despite a high prevalence of autism symptoms and traits [3].

Objectives:

The aim of this study was therefore to investigate the neuroanatomical correlates of 'adaptive resilience/ vulnerability', where resilience is defined as a higher than expected adaptive outcome and vulnerability is defined as a lower than expected outcome as would be predicted based on symptom severity metrics.

Methods:

N=359 autistic individuals, aged 6-30 years (101 females, 258 males) underwent structural MRI-scanning at 6 sites [4] using 3T head-scanners. CT was extracted from T1-weighted images using FreeSurfer v6.0.0 (<http://surfer.nmr.mgh.harvard.edu/>). Adaptive Functioning was assessed using the Vineland Adaptive Behavior Scale (VABS)[2]. Symptom severity was measured using the Social Responsiveness Scale [5], Repetitive Behavior Scale Revised [6], and Short Sensory Profile [7]. To quantify interindividual differences in adaptive resilience, measures of symptom severity were regressed onto the VABS, controlling for age and IQ [8]. To quantify adaptive resilience/ vulnerability, we computed residuals from the predicted VABS scores using the three measures of symptom severity, controlling for age and IQ. Residuals were then mapped onto the brain by regression of a general linear model (GLM) with sex, age, IQ, site, and mean CT as covariates.

Results:

As expected, increased symptom severity was associated with decreased adaptive functioning across behavioral domains overall (see Fig. 1A). More positive residuals (i.e., higher than expected VABS scores) were associated with decreased CT in left middle frontal gyrus, pars opercularis, and pars triangularis (see Fig. 1B). On a behavioral level, more positive residuals were significantly reflected by increased mean resilience scores on the Child Health Illness Profile (CHIP), and increased scores on the Strength and Difficulty Questionnaire (SDQ) prosocial scale (see Fig. 1C). In addition, more positive residuals were accompanied by decreased subscores on the Autism Diagnostic Interview Revised (ADI-R) (see Fig. 1C).

Conclusions:

These results are in line with previous research showing that increased resilience is associated with decreased CT in the left prefrontal lobe, which in turn suggests that adaptive resilience may have neurodevelopmental origins [9]. The prefrontal lobe is crucial for social cognition, language production, and processing, which have previously been linked to social communication difficulties in autism [10, 11]. Understanding the neuroanatomy and ultimately the molecular mechanisms that underpin atypical brain development in these regions may help to develop targeted and personalized support and interventions, and provide novel insights into the neurobiology of adaptive resilience.

**409.094 Neurodevelopmental Subgroups in Autism: Structural Brain Feature Clustering and Age-Related Trajectories**

I. J. Chi¹ and A. C. C. Yang^{2,3,4}, (1)Institute of Brain Science, National Yang Ming Chiao Tung University, Taipei, Taipei, Taiwan, (2)Digital Medicine and Smart Healthcare Research Center, National Yang Ming Chiao Tung University, Taipei, Taipei, Taiwan, (3)Department of Medical Research, Taipei Veterans General Hospital, Taipei, Taiwan, (4)School of Medicine, College of Medicine, National Yang Ming Chiao Tung University, Taipei, Taiwan

Background: Autism encompasses a wide range of clinical phenotypes, yet the neurobiological underpinnings of this variability remain poorly understood. Emerging evidence suggests that autism may not be a singular condition but rather a collection of neurodevelopmental subtypes with distinct patterns of brain structure and function. Identifying such subgroups could be pivotal for advancing personalized treatment and assistance strategies and improving the accuracy of prognostic assessments. This study investigates whether subgroups of autistic males can be delineated based on structural brain characteristics and whether these subgroups exhibit differential neurodevelopmental trajectories over time.

Objectives: The primary aim of this research is to elucidate potential neurodevelopmental subtypes within the autistic male population by analyzing structural brain metrics, including gray matter volume, subcortical volume, cortical surface area, and cortical thickness. We hypothesize that hierarchical clustering will reveal distinct neuroanatomical subgroups with unique age-related developmental trajectories, potentially informing individualized therapeutic approaches. A secondary aim is to assess the clinical relevance of these subgroups by examining how their trajectories diverge across developmental periods.

Methods: This study utilizes structural magnetic resonance imaging (MRI) data from 307 males with ASD, aged 7 to 45 years, sourced from the ABIDE I dataset. Four neuroanatomical metrics were extracted: gray matter volume across 90 cortical regions, subcortical volume across 14 regions, cortical surface area across 70 regions, and cortical thickness across 70 regions. Hierarchical clustering was employed to identify subgroups within each feature set, with subsequent trajectory analysis conducted using Ensemble Empirical Mode Decomposition (EEMD). EEMD is a non-linear decomposition technique that enables the identification of intrinsic age-related changes in brain structure.

Results: The analysis identified discrete subgroups within the autistic cohort, with three subgroups emerging for both gray matter volume and cortical thickness, and two subgroups for subcortical volume and cortical surface area. Notably, each subgroup exhibited distinct neurodevelopmental trajectories. For instance, one whole-brain gray matter subgroup demonstrated a progressive reduction in brain volume with age (blue trend line in the figure), while another maintained stable volume across the lifespan (red trend line in the figure). A third subgroup exhibited an initial increase in gray matter volume during childhood, followed by a decline in later adulthood (black trend line in the figure). These findings reveal substantial heterogeneity in brain development trajectories among autistic individuals, suggesting the presence of neurobiologically distinct subtypes.

Conclusions: The identification of neuroanatomical subgroups within the autistic male population, each characterized by unique age-related trajectories, represents a significant advancement in understanding the neurobiological diversity of autism. These results highlight the need for precision assistant approaches in autism, where interventions and assessments are tailored to the specific neurodevelopmental profiles of individuals. The potential clinical implications of these findings are profound, offering a pathway to more personalized therapeutic strategies and refined prognostic tools. Future work will expand these analyses to female autistic populations and explore the translation of subgroup findings into clinical practice.

409.095 Perinatal Brain Growth and Autistic Traits in Toddlerhood

A. Tsompanidis¹, K. M. Chang², Y. T. Khan³, M. A. Radecki⁴, C. Allison⁴, R. A. Bethlehem⁵, T. Austin⁵, J. Suckling⁴, R. Holt⁶ and S. Baron-Cohen⁴, (1)Autism Research Centre, Department of Psychiatry, Autism Research Centre - University of Cambridge, Cambridge, United Kingdom, (2)Psychiatry, Autism Research Centre, Cambridge, Cambridgeshire, United Kingdom, (3)University of Cambridge, Cambridge, Cambridgeshire, United Kingdom, (4)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, Cambridgeshire, United Kingdom, (5)University College London, London, United Kingdom, (6)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, Cambridge, United Kingdom

Background: Autism is a heterogeneous set of neurodevelopmental conditions with a significant heritable component and perinatal origins. The earliest observable behavioural traits with which a diagnosis can be made emerge at 18 months of age. Previous studies have reported increased brain growth in infancy in autistic children, but less is known about their early brain development in the first 6 months of life – a critical period for brain development.

Objectives: To investigate if perinatal brain structure and growth are associated with autistic traits at 18 months.

Methods: Data from two independent cohorts, the developing Human Connectome Project (dHCP) and Cambridge Human Imaging and Longitudinal Development (CHILD), were assessed in late fetal and early infancy for brain structure with MRI. Global and regional brain volumes in the dHCP, were studied prenatally (mean age=29.27 [SD=3.8] weeks post-conception) and postnatally (mean age=41.28 [SD=1.93] weeks post-conception) and correlated with autistic traits measured after 18 months of age by the Quantitative Checklist for Autism in Toddlers ('Q-CHAT'). Nominally significant findings were further tested for association in the smaller independent CHILD cohort, where pregnant mothers were scanned during pregnancy (mean=31.98 weeks gestation, SD=1.52) and postnatally (mean scan age=50.45, SD=2.8 weeks post-conception).

Results: After controlling for cohort covariates (including maternal age, birth weight, sex and age post-conception at the time of scan), postnatal total brain volume (Figure 1), total grey matter volume, and total white matter volume were all negatively associated with autistic traits in toddlerhood. This was found in both the dHCP and the CHILD cohort but was not apparent when assessing prenatal brain volume or the linear perinatal growth of these variables in the same infants. Regional analyses in the dHCP cohort showed that postnatal white matter volume in regions of the right temporal lobe was associated with Q-CHAT scores, after controlling for total brain volume, with the direction of effect being positive for the right parahippocampal gyrus and negative for the posterior section of the right medial-inferior temporal gyrus.

Conclusions: Reduced total brain volume in the first two months of life is associated with greater autistic traits, as reported by parents at 18 months of life. Further research is required to understand if this extends to later ages and how it affects the development and connectivity of specific regions, particularly in the temporal lobes.

409.097 Sex Differences in Brain Structure at Birth

Y. T. Khan¹, A. Tsompanidis², C. Allison³, M. C. Lai⁴ and S. Baron-Cohen¹, (1)University of Cambridge, Cambridge, Cambridgeshire, United Kingdom, (2)Autism Research Centre, Department of Psychiatry, Autism Research Centre - University of Cambridge, Cambridge, United Kingdom, (3)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, Cambridgeshire, United Kingdom, (4)Campbell Family Mental Health Research Institute, Centre for Addiction and Mental Health, Toronto, ON, Canada

Background:

Males are diagnosed with autism at higher rates than females. One prominent hypothesis suggests that elevated prenatal testosterone levels may contribute to sex-typical brain differences which are more pronounced in autism - potentially explaining its higher prevalence in males. Investigating the neonatal period offers a unique opportunity to explore how perinatal factors, such as prenatal hormone exposure, may shape sex differences in brain development and contribute to the emergence of sex differences in neurodevelopmental outcomes.

Objectives:

To assess sex differences in brain structure at birth to understand whether they show an overlap with brain structure variations associated with autism.

Methods:

We assessed on-average sex differences in global and regional brain volumes in 514 newborns aged 0-28 days (236 birth-assigned females and 278 birth-assigned males) using data from the developing Human Connectome Project. We also assessed sex-by-age interactions to investigate sex differences in early postnatal brain development.

Results:

On average, males had significantly larger intracranial and total brain volumes, even after controlling for birth weight. After controlling for total brain volume, females showed significantly greater total cortical gray matter volumes, while males showed greater total white matter volumes. After controlling for total brain volume in regional comparisons, females had significantly increased white matter volumes in the corpus callosum and increased gray matter volumes in the bilateral parahippocampal gyri (posterior parts), left anterior cingulate gyrus, bilateral parietal lobes, and left caudate nucleus. Males had significantly increased gray matter volumes in the right medial and inferior temporal gyrus (posterior part) and right subthalamic nucleus.

Conclusions:

These findings demonstrate that sex differences in brain structure are already present at birth and overlap with structures implicated in autism. For instance, regions such as the corpus callosum, anterior cingulate cortex, and temporal gyrus show variations in autism and are associated with functions such as social cognition, language development, sensory processing, and inter-hemispheric communication. It is possible that the early-emerging sex differences identified in this research influence neurobiological development from the very beginning of life, potentially explaining the sex differences observed in autism. The early emergence of these differences also supports the hypothesis that prenatal factors play a pivotal role in initiating sex-specific neurodevelopmental trajectories.

409.098 Somatostatin-Expressing Interneuron Number Is Decreased in Prefrontal Cortex in Autism

V. Martinez-Cerdeno¹ and **W. Smith²**, (1)Pathology & Laboratory Medicine, UC Davis, Sacramento, CA, (2)University of California, Davis, Sacramento, CA

Background:

Past research has supported the presence of excitation-inhibition differences in autism that could be a result of differences within cortical circuitry. Somatostatin (SST) is a neuropeptide that is expressed throughout the brain. In the cortex, SST is expressed in a population of GABAergic neurons that encompass all the layers of the cortex. Functions of SST+ cells include modulation of cortical circuits and cognitive function. Reduced number of SST+ cells has been described in several disorders, including Alzheimer's disease and depression.

Objectives:

The number of SST+ cells in autism has not been investigated. Our objective is to quantify the number of SST+ cells in the prefrontal cortex in autism postmortem tissue.

Methods:

To quantify the number of SST+ cells, we cut slices of human prefrontal cortex (BA9, BA46, and BA47) of 10 autism and 10 control cases, and stained the tissue with an antibody against SST. We quantified the number of SST+ cells in 1mm wide area of cortex in all cases.

Results:

We found significant decrease in the number of SST+ cells in both the supragranular and infragranular layers of the cortex.

Conclusions:

Reductions in a specific SST+ cell type called Martinotti cells are likely to be the contributor to the reduced population of SST+ cells in the autism. Martinotti cells have axons that arborize within layer 1 where they promote inhibition through synapsing the apical dendrites of excitatory pyramidal cells. This reduction of SST+ interneurons within the prefrontal cortex may contribute to the excitation-inhibition imbalance in autism. Novel translational paradigms that target SST+ interneurons may prove to be a useful tool for autism treatment.

409.099 Specific Leftward Structural Asymmetry Underlying a Stronger Drive to Systemize Than Empathize in Children with Autism Spectrum Disorder

N. Pan¹, L. Lin², J. Jing³, X. Li³, M. Dai⁴, X. Weng¹ and X. Wang¹, (1)Key Laboratory of Brain, Cognition and Education Sciences, Ministry of Education; Institute for Brain Research and Rehabilitation, and Guangdong Key Laboratory of Mental Health and Cognitive Science, South China Normal University, Guangzhou, Guangdong, China, (2)Department of Occupational and Environmental Health, School of Public Health, Sun Yat-sen University, Guangzhou, Guangdong, China, (3)Sun Yat-sen University, Guangzhou, China, (4)Department of Children's Healthcare and Mental Health Center, Shenzhen Children's Hospital, Shenzhen, Guangdong, China

Background: Children with autism spectrum disorder (ASD) exhibit a greater empathizing-systemizing difference (D score) compared to typically developing (TD) children, reflecting an extreme male cognitive profile. While sex-related differences in brain asymmetry have been observed, the role of brain asymmetry in driving the empathizing-systemizing difference in ASD remains unclear.

Objectives: This study aimed to explore the association between structural brain asymmetry and D score in children with ASD and TD children.

Methods: We analyzed structural magnetic resonance imaging data from 58 children with ASD and 90 TD children aged 6-12 years. Cortical thickness, surface area, and volume asymmetries were assessed. A support vector regression (SVR) model was employed to predict the D score based on these asymmetries for each group.

Results: Increased rightward asymmetry in the postcentral sulcus correlated with higher D scores in TD children, while increased leftward asymmetry in the posterior ramus of the lateral sulcus (Sylvian fissure, SF) was linked to higher D scores in children with ASD. SVR models demonstrated significant accuracy in predicting D scores for both groups (TD group: $r=0.28$, $P_{\text{perm}} = 0.0067$; ASD group: $r=0.41$, $P_{\text{perm}} = 0.0015$).

Limitations: The smaller number of female participants may affect the generalizability of our findings, as ASD is more commonly diagnosed in males. Additionally, the cross-sectional nature of our study limits our ability to draw causal inferences between systemizing tendencies and lateralized brain structures in children with ASD.

Conclusions: This study identified a specific leftward structural asymmetry in the SF associated with a stronger drive to systemize over empathize in children with ASD. These findings suggest a neurobiological basis for the empathizing-systemizing imbalance in ASD and highlight the importance of brain lateralization in understanding ASD-related cognitive profiles.

409.100 The Relationship between Brain Structure and Autistic Characteristics across Restoration of Weight: A Longitudinal Neuroimaging Study

M. Sader¹, K. Gillespie-Smith² and K. Tchanturia³, (1)School of Medicine, Medical Sciences and Nutrition, University of Aberdeen, Aberdeen, Scotland, United Kingdom, (2)Department of Clinical Psychology, University of Edinburgh, Edinburgh, United Kingdom, (3)Institute of Psychiatry, Psychology and Neuroscience, Kings College London, London, England, United Kingdom

Background:

A growing body of research focuses on understanding the co-occurrence as well as the social, emotional and cognitive similarities reported between those with anorexia nervosa (AN) and Autistic individuals. Neuroanatomical studies have identified common regions of interest associated with both states of AN and autistic characteristics (Sader et al., 2022), but restoration of body mass index (BMI) in those with AN is reportedly associated with decreased presentation of autistic characteristics in some individuals with AN (Susanin et al., 2022). Due to a lacking consensus on this relationship, many individuals with acute AN (AAN) do not receive autism assessments due to being classified as "acutely ill", and that autistic characteristics may be secondary to states of starvation (Treasure, 2013; Kerr-Gaffney et al. 2021). This has potential for health services to overlook Autistic individuals with acute AN and contributes to limited understanding concerning which characteristics or phenotypes are associated with AN relative to being Autistic-driven.

Objectives:

This study aims to examine neuroanatomical correlates associated with Autistic characteristics across two time-points, during a current classification of AAN, and post-restoration of weight. This work also aims to establish whether Autistic characteristics and changes in brain structure across weight restoration are able to accurately predict levels of social anhedonia and alexithymia.

Methods:

Brain imaging of Emotion And Cognition of adolescents with Anorexia Nervosa (BEACON) study (Halls et al., 2021), will be used, which includes brain scans of 93 adult individuals across two distinct time-points will be analysed using the FreeSurfer neuroimaging software. A variety of questionnaires will be used to examine sociodemographic features, clinical AN levels, Autistic characteristics, levels of co-occurrence with other psychiatric conditions as well as features of social behaviour. Paired t-tests will be used to evaluate differences in sociodemographic characteristics and brain structure before and after weight restoration. Multiple linear regressions will be used to assess whether global or regional volumes are associated with Autistic characteristics across research time points. Lastly, a random forest regression model will evaluate whether brain volume alongside strength of Autistic characteristics are able to accurately predict levels of alexithymia and social anhedonia.

Results:

Data analysis is ongoing; anticipate that individuals considered weight restored at the second research time point will exhibit reduced levels of anxiety and depression. We also anticipate that structure of the orbitofrontal cortex, anterior cingulate cortex and medial frontal gyrus will be larger post-restoration of weight, but will be associated with Autistic characteristics both pre- and post-weight restoration. Lastly, we anticipate that changes in brain structure alongside presence of Autistic characteristics between research time-points will be able to accurately predict levels of social anhedonia and alexithymia.

Conclusions:

Findings from this research will be discussed and will largely focus on potential clinical applications highlighting the role (or lack thereof) played by malnutrition and weight restoration in how Autistic characteristics are expressed in those with AN. Preliminary findings from previous research in this cohort suggest that Autistic characteristics remain stable across weight stages, highlighting significant benefit towards screening for autism in those presenting with AN.

409.101 Virtual Ontogeny Links Regional Variation in ASD- and ADHD-Associated Cortical Surface Area and Cell-Specific Prenatal Gene Expression

D. Crocetti¹, J. B. Hengenus², J. McLaughlin¹, M. Markiewicz³, A. Sperry⁴, T. Paus² and S. H. Mostofsky¹, (1)Center for Neurodevelopmental and Imaging Research, Kennedy Krieger Institute, Baltimore, MD, (2)CHU Sainte-Justine Research Centre, University of Montreal, Montreal, QC, Canada, (3)Kennedy Krieger Institute, Baltimore, MD, (4)Center for Neurodevelopmental Imaging and Research, Kennedy Krieger Institute, Baltimore, MD

Background:

Global and regional cortical expansion is driven by biological events taking place during fetal and early post-natal development. Thus, cortical surface area (SA) in childhood provides a snapshot of early neurodevelopmental processes. Regional variations in cortical measures are often observed in children with neurodevelopmental disorders, yet the events contributing to these differences remain unclear.

Objectives:

Here, we applied a single-site data collection inclusive of autism spectrum disorder (ASD), attention deficit hyperactivity disorder (ADHD) and neurotypical (NT) prepubertal children to ask: (1) Are there differences in SA associated with diagnoses of ASD, ADHD, or both (ASD+ADHD)? (2) If yes, does the magnitude of such group differences vary across cortical regions, and (3) What might be their developmental (cellular) origins?

Methods:

948 children (8-12 years) - 65 ASD (without ADHD) (11 girls), 305 ADHD (without ASD) (90 girls), 137 ASD+ADHD (21 girls), 441 NT (141 girls) - completed a T1 MPRAGE on a Philips 3T scanner at a single site. FreeSurfer v6.0 was used to perform cortical reconstruction and extract SA from 11 cortical regions-of-interest (ROIs) for which typical mid-gestation gene expression data is available (PsychENCODE Consortium developmental data; Figure 1A). Linear regressions estimated regional group differences in SA (separately, ASD-versus-NT, ADHD-versus-NT, and ASD+ADHD-versus-NT), adjusting for age, scanner model and head coil. Virtual ontogeny (VO) analyses examined correlations between these three spatial group difference profiles and typical prenatal expression of 8 cell-specific gene panels across the same 11 regions (Figure 1C).

Results:

Linear regressions revealed that children with ASD showed regional profiles of greater SA compared to NT controls, particularly ASD girls versus NT girls. Conversely, children with ADHD showed regional profiles of lower SA compared to NT controls. The ASD+ADHD children showed a mixed group difference profile, with some ROIs exhibiting greater or lower SA relative to controls (Figure 1B).

In ASD, VO implicated proliferative cells (e.g., radial glia, intermediate progenitor cells) and, to a lesser extent, differentiated cells (e.g., excitatory neurons, mural cells). In ADHD, VO implicated differentiated cells (e.g., inhibitory neurons) and proliferative cells (oligodendrocyte progenitor cells, radial glia). In ASD+ADHD, VO implicated proliferative cells (radial glia, intermediate progenitor cells, oligodendrocyte progenitor cells) and differentiated cells (excitatory neurons, endothelial cells, mural cells). See Figure 1D. Notably, analyses in sex-stratified samples implicated similar cell types but sometimes showed reversed patterns of association for girls compared to boys.

Conclusions:

Consistent with prior observations across disparate datasets, we saw distinct patterns of diagnostic differences in regional SA, with ASD>NT while ADHD<NT. Notably, for a combined ASD+ADHD group profile (versus NT), we observed a mixture of increased and decreased regional SA. VO analyses implicate proliferative cells involved in neurogenesis and gliogenesis, as well as some mature cell types. Strikingly, VO suggests differing patterns of association in sex-stratified analyses (e.g., regions with higher radial glia-specific gene expression show lower-magnitude SA differences in boys with ASD but higher-magnitude SA differences in girls with ASD). Considering the smaller number of girls in our sample, further study is warranted to study these possible sex-specific relationships.

**Poster Session****410 - Cognition: Attention, Learning, Memory I**

May 1st, 2025, 5:30 PM - 6:30 PM - Hall 4A

410.102 Utilitarian Processing: A Strengths-Based Approach to Examining Attention and Cognition in Autism

A. F. Boatswain-Jacques¹, E. Pico², D. Brodeur³, E. Kelley⁴, G. Iarocci⁵, J. Burack⁶, A. Bertone⁷, N. Russo⁸ and A. Bouma⁸, (1)Educational & Counselling Psychology, McGill University, Montreal, QC, Canada, (2)Acadia University, Wolfville, QC, Canada, (3)Acadia University, Wolfville, NS, Canada, (4)Department of Psychology, Queen's University, Kingston, ON, Canada, (5)Psychology, Simon Fraser University, Burnaby, BC, Canada, (6)McGill University, Montreal, QC, Canada, (7)Department of Psychology, Syracuse University, Syracuse, NY, (8)BOUMA Woodworks, Woodstock, NB, Canada

Background: Consistent with the neurodiversity movement (e.g., Pellicano & den Houting, 2022), we explore potential strengths and unique styles of attending and thinking among autistic youth. We propose that autistic individuals are less influenced by prior experiences that guide their non-autistic peers (Pellicano & Burr, 2012; Van de Cruys et al., 2014) and instead adopt a utilitarian style that is most relevant to the task at hand (Burack & Brodeur, 2020), thus we hypothesize that autistic participants will prioritize this deliberate and task-specific information over prior knowledge, reflecting a distinct utilitarian processing style.

Objectives: We use strength-based approaches to examine unique styles of processing that are utilitarian between autistic and non-autistic youth on one task each of cognition and selective attention.

Methods: Nineteen autistic ($M_{age}=14.71$, $SD=1.77$) and 19 non-autistic participants ($M_{age}=14.42$, $SD=1.69$), matched on age ($p=.607$) and intellectual ability ($IQ_{autistic}=99.74$, $IQ_{non-autistic}=103.42$, $p=.584$) were administered computerized versions of the Cognitive Reflection Test (CRT) and Correlated Flanker task. The CRT involved answering six questions designed to elicit intuitive, but incorrect, responses unless overridden by deliberate processing (Toplak, 2022). Responses were coded as deliberate correct, intuitive but incorrect, or unexpected incorrect. In the Correlated Flanker, the participants identified a central target (car or table) presented in neutral (e.g., table only), congruent (e.g., table flanked by chairs), or incongruent (e.g., table flanked by car keys) conditions. The response times and accuracy rates were measured across five blocks to determine if incongruent flanker pairings would lead to attentional changes overtime. The majority of the trials on middle blocks were incongruent and on the first and last blocks all conditions were presented equally.

Results: On the CRT, no group differences were found in intuitive ($M_{autistic}=2.84$, $SD=1.68$; $M_{non-autistic}=3.37$, $SD=1.95$) and deliberate responses ($M_{autistic}=1.63$, $SD=1.77$; $M_{non-autistic}=2.11$, $SD=2.05$; $ps>.378$). However, the autistic participants provided more unexpected incorrect responses ($M_{autistic}=1.53$, $SD=1.54$; $M_{non-autistic}=0.53$, $SD=0.90$; $p=.019$). In the Correlated Flanker task, both groups responded slightly faster on the first block to the congruent trials ($M_{autistic}=660.09$, $SD=41.43$; $M_{non-autistic}=680.74$, $SD=41.43$) as compared to the incongruent trials ($M_{autistic}=706.09$, $SD=53.75$; $M_{non-autistic}=713.38$, $SD=53.75$), suggesting an initial benefit from the prior learned association. By block four, the autistic participants ($M=500.84$, $SE=44.25$) responded faster than the non-autistic participants ($M=682.29$, $SE=44.25$), but with similar accuracy when identifying neutral stimuli in an incongruent block ($f_{(8, 288)}=2.04$, $p=.042$). On this block, the autistic participants were 8% less accurate in identifying congruent targets than the non-autistic participants ($f_{(8, 288)}=2.04$, $p=.042$), suggesting that they learned the flanker incongruent associations so well it interfered with the congruent association detections. The reaction times and accuracy were similar across both groups on the other blocks.

Conclusions: These findings are preliminary evidence of utilitarian attention among autistic persons. Although both groups effectively disregarded prior associations to learn strongly correlated incongruent pairings in the Correlated Flanker task, the autistic participants were more sensitive to these task conditions. No differences were observed with the CRT, suggesting domain-specific processes.

410.103 A Large Online Study of People with Exceptional Memory: Its Relationship to Systemising

M. Balabanovska¹, M. Moniri¹, S. Braschi¹, M. A. Radecki¹, C. Allison¹, J. Suckling¹, J. Simons² and S. Baron-Cohen¹, (1)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, Cambridgeshire, United Kingdom, (2)Department of Psychology, University of Cambridge, Cambridge, Cambridgeshire, United Kingdom

Background: Exceptional memory is more common in autistic individuals relative to the general population (Treffert, 2009). Autistic traits such as superior attention to detail and stronger systemising, defined as the drive to analyse and construct rule-based systems, have been linked to exceptional memory skills (Baron-Cohen et al., 2009). However, no large-scale studies have investigated if exceptional memory is related to an enhanced drive to systemise. The aim of this study is to understand exceptional memory and its relationship to systemising in both autistic and non-autistic people.

Objectives: (1) To test if people with exceptional memory differ in systemising compared to people with average memory. (2) To test if people with exceptional memory differ in autistic traits compared to people with average memory.

Methods: **Sample:** N= 2,299 volunteers, aged 16 to 60 years old, completed an online Qualtrics survey. **Memory tests:** numeric working memory (digit span), visuospatial memory (spatial span), and visuo-associative memory (paired associates). Memory scores ≥ 3 standard deviations (SD) from the mean were defined as exceptional, while scores within 1 SD of the mean defined the average range. **Questionnaires:** 10-item versions of the Systemising Quotient (SQ), the Autism-Spectrum Quotient (AQ) and the Empathy Quotient (EQ). Memory training was recorded based on self-report. **Analysis:** Data were analysed separately for each task. Binary logistic regression analyses to examine the relationship between the group classification (average vs exceptional) and multiple predictor variables, including SQ-10, EQ-10 and AQ-10 scores. We controlled for age, sex, autism diagnosis, and memory training.

Results: Demographic statistics (Table 1) and group differences in systemising scores (Figure 1). Logistic regression outputs revealed significant coefficients for systemising on the digit span ($\beta = 0.12$, $p < 0.001$) and paired associates ($\beta = 0.16$, $p < 0.001$), but no effect on the spatial span ($\beta = 0.03$, $p = 0.266$). For each extra point on the SQ-10, the odds of being in the exceptional memory group increased by 1.13 times for the digit span and 1.18 times for the paired associates. No significant effects were found for EQ-10, AQ-10 or autism diagnosis across all three tasks. Sex differences were observed only for the spatial span task where the odds of being in the exceptional memory group were 3.4 times higher for males ($\beta = 1.23$, $p < 0.001$). Training effects were significant across all tasks (digit span, $\beta = 2.63$, $p < 0.001$; spatial span, $\beta = 1.46$, $p < 0.001$; paired associates, $\beta = 1.62$, $p < 0.002$). 11% of the exceptional group on the Digit Span task (10/86, Table 1) had a formal diagnosis of autism, compared to its population prevalence of 3% in the general population, and this was significant using a Chi Square test ($p < 0.05$).

Conclusions: This is the first study to demonstrate that people with exceptional memory have a higher systemising drive. People with exceptional memory did not differ in their number of autistic traits, perhaps because the 10-item version AQ cannot tease these apart. Future research should use the 50-item AQ, and examine the brain basis of the relationship between exceptional memory and systemising using MRI.

410.104 Association between Autistic Traits and Atypical Attention Orienting

S. Li, E. Materazzo and K. A. Johnson, Melbourne School of Psychological Sciences, The University of Melbourne, Parkville, VIC, Australia

Background: Previous research has found that autistic people are quicker to shift attention to external stimuli but slower to disengage attention based on internal goals. Existing research on attention orienting, the ability to change focus within space, has primarily compared people with and without a clinical autism diagnosis. It remains unclear how attention orienting varies with different autistic traits. Autistic traits, which are characteristics associated with autism, can be present in the general population, regardless of a clinical diagnosis. This study investigated whether autistic traits affect attention orienting in the general population.

Objectives: This study aimed to examine 1) whether autistic traits are associated with atypical exogenous (stimulus-driven) and endogenous (goal-driven) orienting in the general population, and 2) whether age, sex, and co-morbid symptoms of anxiety and attention deficit-hyperactivity disorder (ADHD) moderate the association between attention orienting and autistic traits.

Methods: One hundred and twenty adults ($M_{\text{age}} = 22.8$ years, 57% female) completed exogenous and endogenous Posner tasks on a computer. In both tasks, participants responded to a target location that was either validly, invalidly, or neutrally cued by a visual stimulus. Response times and accuracy were recorded. Autistic traits and symptoms of ADHD and anxiety were measured using self-report questionnaires. Based on preliminary analyses of the correlations among different autistic traits, we included the total score of autistic traits and three specific traits—attention to detail, imagination, and attention switching—in the data analyses.

Results: Exogenous orienting was not associated with different autistic traits, except for the attention to detail trait. Participants with a tendency to focus on details were quicker to disengage their attention in the exogenous orienting task. ADHD symptoms were found to be a significant moderator. When ADHD symptoms were low, participants with higher autistic traits were slower in the invalid cue condition. This association not found at average or high levels of ADHD symptoms. No significant moderating effects of anxiety symptoms, age, and sex were found. In the endogenous task, participants with higher autistic traits were slower at shifting attention. Anxiety symptoms were found to be a significant moderator. When anxiety symptoms were low, participants with a stronger imagination tendency were slower to shift their attention, which was not found at average or high levels of anxiety. Conversely, when anxiety was high, participants who tended to focus on details were quicker to disengage attention, which was not found at low or average levels of anxiety. No significant moderating effects of ADHD symptoms, age, and sex were found.

Conclusions: This study highlights that features of atypical attention orienting in autistic individuals are not generalisable to the general population with autistic traits. While the overall severity of autistic traits does not affect exogenous orienting, it slows the endogenous shift of attention. Our results also support the importance to consider effects of comorbid symptoms in autism-related research. Together, these findings improve our understanding of how autistic traits relate to attention orienting, warranting further research into the neural mechanisms and strategies to support attention functions in people with high autistic traits.

410.105 Association between Gut Microbes and Traditional Chinese Medicine Syndrome Types in Children's Cognitive Performance with Autism Spectrum Disorder

Y. Huang, Psychiatric Research Center, Taipei Medical University Hospital, Taipei, Taiwan, Taipei, Taiwan, Taipei, Taiwan

Background: Early diagnostic and early intervention of children with autism spectrum disorder (ASD) can present challenges due to various factors including heterogeneous symptoms, the absence of a conclusive genetic or medical test or objective assessment. Actionable and modifiable factors exist in the gut brain axis of ASD children. There is abundant Chinese literature about the application of food therapy for alleviating gastrointestinal symptoms and neurodevelopmental disorders. Functional capabilities of ASD vary with intellectual ability. In general, co-occurrence of intellectual disability in ASD is a predictor of less favorable prognosis.

Objectives: we aimed to investigate the eating behavior and gut microbiota profile in a cohort of children with ASD and to correlate TCM syndrome-differentiation with their cognitive developmental profiles.

Methods: ASD diagnostic assessment was performed by a well-experienced psychiatrist. All participants' eating habits also investigated by using Children's Eating Behavior Questionnaire (CEBQ). Three TCM syndrome (zhengs) types : Kidney Jing Deficiency, Liver Qi Stagnation, Deficiency of both the Heart and Spleen have been used for ASD children classification. A total of 28 ASD children were classified to three TCM syndromes based on their clinical manifestation by two experienced TCM attending physicians independently. Fecal microbiota analyzed by 16S rRNA NGS sequencing.

Results: Kidney Jing Deficiency group showed higher level of picky eating behavior than other two syndrome groups. Cognitive performance (Developmental Quotient) of the Kidney Jing Deficiency group was particularly low when compared with Deficiency of Both the Heart and Spleen and Liver Qi Stagnation. The gut microbiota richness of healthy children was not significantly different from that of autistic children with high intellectual ability, but was significantly different from that of ASD children with low intellectual ability. ($P=0.034$). Comparison of the richness of gut microbiota in the three TCM syndromes showed no significant difference, but the trend of lower alpha-diversity in children with Kidney Jing Deficiency is noted.

Conclusions: In our study, poor microbiota richness is more prevalent in those autistic children with lower cognitive performance. Classifications of ASD children further with TCM syndromes bring an alternative therapeutic strategy using syndrome related formula to increase their diet variability and thus lead to microbiota positive modulation and influence the gut brain axis to promote more positive behaviors and less parenting difficulties.

410.106 Beyond the Here and Now: Theory of Mind, Episodic Memory, Episodic Future Thinking

N. Ozden¹ and S. J. White², (1)Institute of Cognitive Neuroscience, University College London, London, London, United Kingdom, (2)University College London, London, UNITED KINGDOM

Background: Mentalising is the ability to understand and represent alternative mental states, which is crucial for inferring the feelings, thoughts, intentions, beliefs, and desires of others. It also plays a role in predicting possible behavioural reactions to various situations, as well as in self-referential cognition, including episodic memory and episodic future thinking. However, only two studies have directly explored these areas in individuals with autism, and the relationship between these abilities remains unclear.

Objectives: This study aims to investigate the interaction between episodic future thinking, episodic memory, and mentalising in autistic and non-autistic groups. It does so by differentiating between psychological and physical representations of past and future experiences through well-controlled tasks that vary only in the type of representation required.

Methods: This study used a between/within-group design. It involved 40 autistic individuals aged 18-60 and 41 non-autistic adults in a control group, matched for age and IQ. Participants engaged in an adapted self-reference effect (SRE) task, where they made judgments about themselves across three temporal frames: past, present, and future. In addition, they completed a "strange stories" film task and a monetary temporal discounting task. These tasks were designed to assess both psychological and physical self-referential processing.

Results: The analysis is ongoing, but preliminary findings indicate significant differences in response times and accuracy scores between the physical and psychological domains. Although no group differences were found in the SRE task, the two groups exhibited differences in mentalising abilities. Furthermore, results from the monetary temporal discounting task revealed that the autism group had higher indifference scores and lower k-values, suggesting that they may be more patient regarding delay discounting—a finding that contradicts existing literature.

Conclusions: These results imply that autism may involve distinct differences in how the present physical self is represented in self-referential encoding. This finding is discussed in relation to recent advancements in cognitivist theories of autism, particularly the notion that challenges in episodic memory, future thinking, and psychological processing may reflect differences in the general capacity for self-projection.

410.107 Cognition and Executive Function in Aging Autistic Adults

A. Delpak¹ and E. Anagnostou¹, (1)University of Toronto & Bloorview Research Institute, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (2)Bloorview Research Institute, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada

Background:

Despite growing research on autism, little is known about aging in this population. Neurotypical aging is often associated with declines in cognitive and executive function, but how these processes unfold in autistic adults remains unclear. This study aims to compare the cognitive and executive function performance of aging autistic adults with neurotypical individuals, providing insights to support the development of systems and interventions tailored to aging autistic individuals.

Objectives:

1. To investigate how executive function ((working memory, inhibitory control, and cognitive flexibility)) domains change across age across groups.

Methods:

The cohort is in progress but at the time of this analysis, it includes 80 autistic (mean age 50 +/- 10) and 64 neurotypical (mean age 58.5 +/- 12.5) aging adults. Cognitive and executive function assessments included three subtests of the Cambridge Neuropsychological Test Automated Battery (CANTAB), and the Behavior Rating Inventory of Executive Function – Adult (BRIEF-A). Group differences were overall assessed using general linear regression models.

Results:

Considering three outcome measures from the CANTAB battery—OTSPSFC (Problems Solved on First Choice), MTTTIC (Total Incorrect Trials), and SSTSSRT (Stop-Signal Reaction Time)—used to assess executive functions, adjusting for FSIQ reveals that age-related changes in performance do not significantly differ between the ASD and Control groups. Exploring the BRIEF-A assessment in those with FSIQ over 80, both the ASD and Control groups show changes with age but the age trajectories are different in the Plan/Organize (Estimate = 2.199, $p = 0.047$) and Task Monitor (Estimate = 2.578, $p = 0.033$) domains. However, other domains i.e. Inhibit, Shift, Emotional Control, and Working Memory) do not exhibit significant differences between groups with age. ($p = 0.858$, $p = 0.383$, $p = 0.834$, $p = 0.284$, respectively).

Conclusions:

In this preliminary analysis, we found some evidence for differential aging profiles in executive function. The full analysis will be presented at the meeting.

410.108 Concurrent Learning of Linguistic Adjacent and Nonadjacent Dependencies in Autistic Adults

Z. Wu¹, C. Y. Cheung¹ and C. K. S. To², (1)the University of Hong Kong, Hong Kong, HKSAR, China, (2)Academic Unit of Human Communication, Development and Information Sciences, Faculty of Education, The University of Hong Kong, Hong Kong, HK SAR, China

Background:

Language comprises both adjacent and distant structures, leading to frequent co-occurrence of adjacent dependencies (AD) and non-adjacent dependencies (NAD). For example, in "He is sleeping," the words "He" and "is" form an AD, while "is" and the "-ing" in "sleeping" form a NAD. Previous studies on statistical learning in autistic individuals have examined AD and NAD separately, primarily using non-linguistic visual patterns as input (Obeid et al., 2016). However, since statistical learning may operate through domain-specific mechanisms (Conway & Christiansen, 2005), it is possible that learning AD and NAD in a linguistic context presents particular challenges for autistic individuals.

Objectives:

The present study investigated the abilities of autistic adults to concurrently learn AD and NAD concurrently in the linguistic domain.

Methods:

Fifteen autistic adults (aged 21-39) and 15 age-matched neurotypical (NT) controls (aged 19-37) participated in the study. The study consisted of two phases: an exposure phase and a learning outcome test phase. During the exposure phase, participants were presented with eight-element linguistic sequences, where two elements formed AD and the other two elements formed NAD (Figure 1). Eye-movements were recorded.

Learning was inferred if participants showed shorter response time (RT) or gaze latencies for AD or NAD elements compared to four unrelated elements. In the outcome test phase, participants judged the familiarity of the sequences that either conformed to or violated AD or NAD patterns.

Results:

During the exposure phase, both groups demonstrated decreased RTs for AD and NAD elements compared to unrelated elements ($p < 0.001$), with no significant difference in the magnitude of RT decreases between AD and NAD elements ($p = 0.170$). Gaze latency results mirrored the RT findings. In the outcome test phase, the NT group exhibited above-chance accuracy in judging the familiarity of both AD and NAD sequences, indicating explicit awareness of these patterns. In contrast, the autistic group performed at a chance-level when judging either AD or NAD sequences.

Conclusions:

Autistic adults, like their NT counterparts, were able to track the statistical regularities of linguistic input and form both AD and NAD associations. However, unlike the NT group, autistic adults did not show explicit recognition of the learned AD and NAD patterns, suggesting that the memory storage or retrieval of newly learned linguistic patterns may be weaker in autistic individuals.

410.109 Creating a Dataset of Autistic and Non-Autistic Individuals' Experiences of Everyday Events

K. E. Hannah, E. Rivet, R. A. Stevenson and K. McRae, University of Western Ontario, London, ON, Canada

Background:

Everyday life is composed of patterns of activities and behaviours, called events, such as *brushing your teeth* and *going grocery shopping*. People perceive and gain knowledge of events by experiencing them personally or vicariously, and each person's interpretation of their experience of an event may be unique. In particular, autistic individuals have social communication differences, repetitive behaviours and restricted interests, and sensory sensitivities that may result in different experiences of events, both between autistic individuals and compared to non-autistic individuals.

Objectives:

- (1) Conduct a quantitative assessment of autistic individuals' experiences of events.
- (2) Provide an open-access dataset for future studies.

Methods:

We compiled a set of normed ratings of event experience-related dimensions, such as familiarity, social interaction, valence, predictability, and duration. Data was collected for 384 events from 152 autistic and 150 non-autistic adults aged 18-30 (approx. 50 participants per event).

Participants rated events on 14 dimensions and completed questionnaires assessing autism-related traits. Correlations between dimensions were calculated within autistic and non-autistic groups separately. Dimension ratings, and correlations between dimensions, were compared between groups.

Results:

Overall, autistic and non-autistic individuals rated events differently on 10 dimensions (Figure 1). For instance, autistic individuals rated events higher on sensory stimulation and arousal, suggesting they may experience events differently than non-autistic individuals due to sensory sensitivities. Autistic individuals also rated events lower on control and predictability, which may be related to restricted, repetitive behaviour patterns. Autistic and non-autistic individuals did not differ in their familiarity of events or how much they experienced events previously.

Differences in correlational patterns (Figure 2) also suggest that autistic and non-autistic individuals experience the interplay of event dimensions differently. The largest differences were seen in the relationships with the dimensions of social interaction, sensory stimulation, and arousal. For example, there was a larger, positive correlation between arousal and valence for non-autistic individuals, suggesting that non-autistic individuals more strongly associate arousing events with being pleasant than autistic individuals. Additionally, sensory stimulation was negatively correlated with desire to participate for autistic individuals, whereas this correlation was positive for non-autistic individuals. This suggests that these groups' desire to be take part in different events is related to the sensory experiences involved in the event.

Conclusions:

Overall, the results are in line with our existing knowledge of autism, and contribute to our understanding of autistic (and non-autistic) individuals' everyday life experiences. Notably, events are likely experienced differently by autistic and non-autistic individuals due to the sensory stimulation and arousal involved. Events being more stimulating or arousing likely affects an autistic person's perception and understanding of events, which could have broader implications for life outcomes and social communication.

Our study will offer the largest open access dataset available of autistic and non-autistic individuals' experience of events. These data also provide a resource for researchers using event-based stimuli in future studies.

Further analyses are planned to investigate differences in dimension ratings between genders and between social and non-social events. We additionally aim to explore how levels of autistic traits relate to dimension ratings.

410.110 Differences in Academic Achievement and Association with Executive Function in Siblings at High and Low Likelihood for Autism

T. St. John¹, A. M. Estes², H. Hazlett³, J. Pandey⁴, R. T. Schultz⁵, N. Marrus⁶, K. Botteron⁷, L. Zwaigenbaum⁸, S. R. Dager⁹, J. Piven³ and ... *The IBIS Network³*, (1)University of Washington, Seattle, WA, (2)Speech and Hearing Sciences, UW Autism Center, Seattle, WA, (3)University of North Carolina, Chapel Hill, NC, (4)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (5)The Center for Autism Research/CHOP, Philadelphia, PA, (6)Washington University in St. Louis, St. Louis, MO, (7)Washington University School of Medicine, St. Louis, MO, (8)University of Alberta, Edmonton, AB, Canada, (9)Radiology, University of Washington, Seattle, WA

Background: Academic achievement is associated with later educational attainment, employment, and mental and physical health. Nearly two-thirds of autistic children show below average or lower than expected achievement in at least one academic area, which may increase the odds of later educational or employment challenges. Relatively little is known about academic achievement in high-likelihood (HL) siblings, who are at increased likelihood for autism and other developmental and clinical concerns. Executive functioning (EF) contributes to academic achievement in the neurotypical population. However, despite the high prevalence and early onset of EF problems in autistic and HL children, the relations between EF and academic achievement are not yet understood in this population.

Objectives: 1) Characterize academic achievement in HL siblings with and without autism at school-age, 2) determine if EF and academic achievement are associated, and 3) evaluate whether this association differs based on autism diagnosis and familial likelihood for autism.

Methods: Participants were 251 high-likelihood (HL; HL-ASD=72, HL-noASD=179) and 108 low-likelihood (LL) children from the Infant Brain Imaging Study. EF was directly assessed at age 24 months using the A-not-B and at ages 6-14 years (school-age) using parental ratings on the Brief Inventory of Executive Functioning, Second Edition (Global Executive Composite, GEC) and directly using the NIH Toolbox Flanker Inhibitory Control and Attention Test (inhibition) and Dimensional Change Card Sort (cognitive flexibility). Math and reading achievement were directly assessed using the Wechsler Individual Achievement Test, Third Edition. Covariates were intelligence (General Conceptual Ability, GCA; Differential Abilities Scales, Second Edition), maternal education, and gender.

Results: The HL-ASD group had significantly lower scores than the LL group on all math and reading indices and subtests, and lower scores than the HL-noASD group on all the math but not the reading indices and subtests ($p < .05$). The HL-noASD group had significantly lower scores than the LL group on the Math Problem Solving and Word Reading subtests ($p < .05$). Better EF at age 24-months was associated with better math (Math Problem Solving; Table 1) but not reading achievement at school-age across all groups (group x EF interaction; ns). Parent-reported executive functioning problems at school-age were associated with lower math (Numerical Operations) but not reading achievement across all groups (group x EF interaction, ns; Table 2). The HL-ASD group demonstrated greater increases in math and reading achievement compared to the LL group as cognitive flexibility increased (DCCS) but this effect did not survive correction for multiple comparisons ($p = .031$; $p = .031$, respectively). Inhibitory control (Flanker) at school-age was not associated with math or reading achievement (main effects and group x EF interactions; ns).

Conclusions: Early emerging executive functioning problems are related to later math achievement in school age children (HL-ASD, HL-noASD, and LL). Math achievement followed an endophenotypic pattern (HL-ASD < HL-noASD < LL), implying an association of math achievement with heritable factors contributing to autism. Findings have the potential to inform early intervention to improve EF and suggest that targeting cognitive flexibility for children on the autism spectrum could improve academic achievement.

**410.111** Revisiting Bouba and Kiki in Autism

K. E. Prescott¹, M. J. Stabile¹, C. Larson² and **I. M. Eigsti¹**, (1)Psychological Sciences, University of Connecticut, Storrs, CT, (2)College of Health Sciences, University of Missouri, Columbia, MO

Background: Beginning in early childhood, neurotypical (NT) individuals across cultures and languages associate “round” pseudowords like *bouba* or *maluma* with globular shapes, and non-rounded pseudowords like *kiki* or *takete* with angular shapes (Cwiek et al., 2022; Fort et al., 2018; Kohler, 1929). However, the tendency to make systematic connections across auditory and visual modalities in the *Bouba-Kiki* task may not extend to autism (Gold & Segal, 2017; Krol & Ferenc, 2020; Oberman & Ramachandran, 2008; Occelli et al., 2013). Because the *Bouba-Kiki* task is thought to tap integration across auditory and visual sensory domains, we probed the role of language and sensory processing in autistic individuals’ performance in addition to replicating these previous studies.

Objectives: We investigated whether autistic and NT individuals endorsed expected auditory-visual correspondences (i.e., demonstrate the *Bouba-Kiki* effect) to a similar extent. We also tested relationships between task performance and sensory processing, language, nonverbal cognition, and intensity of autism traits.

Methods: Participants. Participants (recruited as part of a larger study) completed the Autism Diagnostic Observation Scale – 2nd Edition (ADOS-2; Lord et al., 2012); the autism group met stringent DSM-5 diagnostic criteria. The sample included 27 autistic and 33 NT participants. The groups did not differ in age or nonverbal cognitive ability; see Table 1.

Procedure. Participants completed an online two-alternative forced-choice *Bouba-Kiki* task comprised of eight spoken pseudowords with English phonotactics. Four of the words contained “round” phonemes (e.g., /m/, /b/) and four contained “angular” phonemes (e.g., /t/, /k/). On each trial, participants were asked “Which one is ____” while viewing side-by-side images of round and angular shapes. Trial order was randomized across participants. They also completed the Penn Matrix Reasoning Test (PMAT; nonverbal cognition), Penn Verbal Reasoning Test (PVRT; Gur et al., 2010; language ability), and the Sensory Reactivity in Autism Spectrum questionnaire (SR-AS; Elwin et al., 2016). The subscales of the SR-AS (hyper-reactivity, hypo-reactivity, sensory motor, and sensory interest) measured sensory processing and ADOS-2 CSS scores measured intensity of autism traits.

Results: Logistic mixed-effects models revealed no significant group differences ($p=.064$). However, the NT group demonstrated the *Bouba-Kiki* effect at a level significantly above chance, $\beta=0.84$, $SE=0.35$, $z=2.42$, $p=.016$; the autistic group did not, $p=.570$; see Figure 1. Within the autistic group, Kendall’s tau correlations indicated that *Bouba-Kiki* effect strength was associated with sensory-motor differences ($r=-0.33$, $p=.032$), though significance was not retained following Holm-Bonferroni corrections. Correlations with language and cognitive ability, intensity of autism traits, hyper-reactivity, hypo-reactivity, and sensory interest were non-significant ($ps>.05$).

Conclusions: These findings contribute to a growing body of evidence suggesting the *Bouba-Kiki* effect may be less robust in autism. However, individual variation was evident, which may be related to sensory-motor processing. This potential link between autistic individuals’ sensory-motor processing and audiovisual correspondences probed by the *Bouba-Kiki* task may speak to difficulties integrating stimuli across sensory modalities and could be consistent with findings of reduced embodiment experiences in autism.

410.112 Emotional Dysregulation As a Mediator of Task-Based and Day-to-Day Executive Functioning in Adolescents

A. W. Peters¹, R. G. McDonald², S. Khawar³, E. Lynch³, N. M. McSorley⁴, S. Houston¹, M. T. Bixter⁴ and E. Kang²; (1)Autism and Neurodevelopment Lab, Montclair State University, Montclair, NJ, (2)Department of Psychology, Montclair State University, Montclair, NJ, (3)Department of Pediatrics/Masonic Institute for the Developing Brain, University of Minnesota - Twin Cities, Minneapolis, MN, (4)Psychology, Montclair State University, Montclair, NJ

Background: Autistic people face emotion dysregulation (ED) and executive functioning (EF) challenges at a higher rate than their peers (McDonald et al., 2024; Kenworthy et al., 2009). EF refers to cognitive skills that enable one to cater their behavior to a goal (Udhmani, 2020). Differences in autistic individuals are found in EF tasks measuring inhibition, generativity, and flexibility (Brady et al., 2015). However, there is a distinct gap between performances on task-based measures of EF and measures of everyday EF skills, both impacted by ED (Conner et al., 2023; Kenworthy et al., 2009). ED is defined by one’s inability to modify their emotional state (e.g., emotional dysphoria) and manage behaviors accordingly (e.g., emotional reactivity) in response to environmental triggers (Aldao et al., 2016; Mazefsky et al., 2014). Prior literature suggests that lower EF performance on task-based measures is associated with elevated ED in autism. However, further work is needed to elucidate ED’s role between task-based and everyday EF (Cotescu et al., 2023; Cibralic et al., 2019).

Objectives: 1) Examine the relationships between task-based and day-to-day EF, and 2) assess whether facets of ED (e.g., dysphoria [ED-D] and reactivity [ED-R]) mediate this relationship in neurodiverse youth.

Methods: Sixty-two youth ($M_{age} = 13$, $SD_{age} = 2.90$; 53% male; 38 autistic; 59.7% white, 6.5% black, 14.5% Asian/South Asian/MENA, 11.3% Multiracial) completed the Delis-Kaplan Executive Functioning System (D-KEFS, Delis et al., 2001) to assess task-based EF (see Table 1 for DKEFS variables used). Caregivers completed measures of everyday EF (BRIEF-2 Behavior Regulation Index [BRI] and Cognitive Regulation Index [CRI]; Gioia et al., 2000; Flexibility Scale [FS], Strang, 2017) and ED-D, ED-R (Emotion Regulation Index, Mazefsky et al., 2018).

Results: Bivariate correlations suggest some associations between task EF and everyday EF skills (Table 1). Path models assessing ED-D and ED-R as independent mediators suggested slower (processing) relates to more ED-R ($b=-.32$, $p<.01$), while worse ED-R positively relates to BRI, CRI, and FS difficulties (all $b>.32$, $p<.01$). Slower VF (verbal inhibition/generativity) relates to more ED-D ($b=-.29$, $p<.01$) while ED-D positively predicted BRI, CRI, and FS challenges (all $b>.36$, $p<.01$). ED-R was a significant mediator between DF-FD and BRI ($CI[-.25, -.03]$), DF-FD and FS ($CI[-.02, -.02]$, Figure 1). No other mediations were significant.

Conclusions: Results suggest inconsistent associations between task and everyday EF, and that ED has broad implications on EF. Specifically, the presence of indirect effects of ED especially when there are no direct effects between task-based EF and everyday EF underscores the importance of considering ED when examining how task-based EF abilities translate into real-world everyday EF behaviors. Furthermore, it is likely that task-based and everyday EF are related through multiple mediators (that can cancel out and obscure the zero-order relationships), and future research should address possible additional mediators (e.g., comorbid ADHD or internalizing symptoms; Hollocks et al., 2014; Demetriou et al., 2019). Due to the likelihood of less favorable outcomes for individuals with poor EF and ED skills, future research should target intervention methods strengthening both areas.

410.113 Examining Neurophysiological Markers of Increased Perceptual Capacity in Autistic and Non-Autistic Adults

J. Brinkert¹, A. Remington², E. Milne³, C. Hamilton⁴, B. Irvine⁵, F. Elise⁶, E. Farran⁷ and G. Scerif⁸, (1)Centre for Research in Autism and Education, UCL Centre for Research in Autism and Education (CRAE), London, United Kingdom, (2)UCL Centre for Research in Autism and Education, London, UNITED KINGDOM, (3)The University of Sheffield, Sheffield, United Kingdom, (4)UCL Institute of Education, London, London, United Kingdom, (5)Centre for Research in Autism and Education, Centre for Research in Autism and Education (CRAE), UCL Institute of Education, University College L, London, United Kingdom, (6)Centre for Research in Autism and Education, CRAE, London, United Kingdom, (7)DevElop, University of Surrey, Guildford, United Kingdom, (8)Experimental Psychology, University of Oxford, Oxford, Oxfordshire, United Kingdom

Background: Over more than a decade, studies have shown that the amount of sensory information processed at any one time (perceptual capacity) is greater for autistic people compared to non-autistic people. Evidence from quantitative behavioural studies (Remington et al., 2009; 2012) and qualitative studies indicate a perceptual advantage for autistic people (Irvine et al., 2023). This increase in capacity may be linked to both positive (superior perception skills) and negative (increased distractibility) aspects of the autistic experience. It remains unknown, however, what underlying neurological mechanism is driving this difference.

Objectives: In this study, we used electrophysiological indices of attention allocation (P3b) as a marker of perceptual capacity in a visual search task. Finding the driver of this increased capacity is vital to capitalise on the additional capacity while supporting associated challenges.

Methods: We tested 73 participants aged between 18-40 (Autism Group: $n=31$; non-autistic group $n=42$) who were matched in age ($p=.34$) and FSIQ-2 ($p=.16$; Autism group: $M_{age}=25.18$, $SD=5.2$; $M_{IQ}=114.63$ $SD=9.4$; Non-autistic group: $M_{age}=25.46$, $SD: 4.5$; $M_{IQ}=110.97$ $SD=12$).

Participants completed a visual search task in which they identified whether a target shape was present or absent, with varying numbers of distractors on the screen while concomitant EEG activation was recorded. We averaged data over the P0z electrode over the 330-370ms interval and entered the data into a mixed analysis of variance.

Results: Preliminary analyses suggest a three-way interaction between group (autistic and non-autistic participant) search condition (target absent vs present) and set size (1, 2, 4 and 6), indicating evidence for an increased perceptual capacity in the autism group ($F(1,71)=5.6$, $p=.02$). While post-hoc tests did not survive correction, visual inspection shows a markedly greater P3b amplitude in the target-present condition at set size 6 for the autistic group compared to non-autistic participants.

Conclusions: These findings provide initial evidence for EEG biomarkers of perceptual capacity differences between autistic and non-autistic adults. Further, an increased P3b amplitude in the autistic group during target-present trials at larger set sizes supports the hypothesis that the P3b component reflects increased perceptual experience. Whilst less attentional resources were used during the target-absent condition. Demonstrating the presence of a neurological marker for perceptual capacity differences in autistic people may offer the potential for a) further understanding of cognitive mechanisms underpinning the difference and b) the development of accessible implicit tasks of perceptual capacity that could be used with less able individuals (e.g. young children, those with intellectual impairments).

410.114 Examining the Longitudinal Relation between Early Executive Function and Later School Readiness in a Sample of Autistic Preschool Children

M. Moravvej¹, J. Kim² and S. Faja², (1)Laboratories of Cognitive Neuroscience, Boston Children's Hospital, Boston, MA, (2)Boston Children's Hospital, Harvard, Boston, MA

Background: Previous literature suggests a link between executive function (EF) and school readiness, especially in math learning. However, research regarding the relation between EF and school readiness in the autistic population is limited. A cross-sectional study with 3- to 5-year-old participants found that autistic children score significantly lower on school readiness and EF measures compared to non-autistic peers matched on age and IQ (Pellicano et al., 2017). This study suggests EF skills are associated with school readiness in autistic children. Furthermore, a longitudinal study with autistic school-age children reports EF at age 6 predicted better math learning at age 9 (St. John et al., 2018).

Objectives: We examine whether EF longitudinally predicts school readiness beyond Nonverbal IQ (NVIQ) in autistic preschoolers.

Methods: From an ongoing longitudinal study investigating the development of EF in autistic and non-autistic 2- to 5-year-olds ($n=272$, 149 autistics, 73% male), 55 participants have returned for their two-year follow-up visits to date, including 43 autistic (77% male) and 12 non-autistic children (42% male). We administered ADOS and ADI-R to determine the diagnostic group at baseline. We administered Mullen Scales of Early Learning as a measure of cognitive functioning. Additionally, children completed behavioral tasks (e.g., Tricky Box, Hide and Seek, A-not-B, and Flip Book) that evaluate several EF domains, including Inhibition, Delay, Shifting, and Working Memory. We administered DAS Early Year School Readiness Early Number Concepts, Matching Letter Like Forms, and Phonological Processing Forms subtests to measure school readiness in the two-year follow-up visit (4 to 7 years old). A single EF factor score was created for each child with confirmatory factor analysis using maximum likelihood estimation with robust standard errors. With a mean of 0 and a standard deviation of 1, these scores are standardized and can be interpreted as z-scores. We then used Spearman's and Pearson's correlations to examine the relation between age, Mullen Nonverbal Developmental Quotient (NVIQ), EF factor score, and school readiness subtests t-scores and composite standard score. Finally, we fit four sequence multivariable linear regressions to examine whether EF factor scores predict school readiness scores, controlling for NVIQ.

Results: Controlling for initial NVIQ at baseline, EF scores at baseline predicted Early Number Concepts scores two years later ($F_{change}=5.67$, $p<.021$), Phonological Processing Forms scores ($F_{change}=5.11$, $p<.035$), and overall School Readiness composite scores ($F_{change}=6.24$, $p<.021$). In the autistic group, we observed positive correlations between NVIQ, EF, Early Number Concepts, and Matching Letter Like Forms scores. Initial EF scores predicted later Early Number Concepts scores beyond initial NVIQ ($F_{change}=4.25$, $p<.046$).

Conclusions: Our findings replicate earlier studies showing that EF is strongly associated with math school readiness beyond cognitive ability. Our study extends that work by exhibiting a longitudinal relation between EF and math school readiness in autistic preschoolers. These findings have important implications for research and practice in understanding and improving the standard of assessment and intervention to close the school readiness gap between autistic and non-autistic children.

410.115 Exploring Cognitive Flexibility in Children with ASD: The Role of Visual Cues and Task Conditions

T. Y. Huang¹, C. Y. Kuo² and K. L. Chen¹, (1)National Cheng Kung University, Tainan, Taiwan, (2)Department of Psychiatry, National Cheng Kung University Hospital, College of Medicine, National Cheng Kung University, Tainan, Taiwan, (3)Department of Occupational Therapy, College of Medicine, National Cheng Kung University, Tainan, Taiwan

Background: Cognitive flexibility (CF) is the ability to efficiently switch between tasks or demands in changing contexts. Children with autism spectrum disorder (ASD) often struggle with CF. However, results from common CF tasks, such as Dimensional Change Card Sort (DCCS) and Wisconsin Card Sort Test (WCST), have been inconsistent, particularly regarding perseverative errors—repeated responses despite task demands change. These inconsistencies complicate the design of interventions for children with ASD. Factors such as explicitness of task instructions and cognitive demands, like working memory, may explain these discrepancies. Working memory helps individuals hold and manipulate information during switching (i.e., CF). Clarifying how different contexts and working memory demands impact perseveration could provide a deeper understanding CF in children with ASD and how it differs from that of typically developing (TD) children.

Objectives: The study aimed to examine how different assessment contexts influence perseveration in children with ASD compared to TD peers.

Methods: Twenty children with ASD and TD (10 per group, 8.91 years old $\pm$ 1.48), matched by age and gender were recruited. Each child completed two card-sorting tasks: an explicit condition with clear sorting rules (computerized DCCS), and an implicit condition requiring rule discovery based on feedback (computerized WCST). They also completed the Wechsler Intelligence Scale for Children, Fifth Edition (WISC-V). T-tests were used to analyze group performance differences across conditions. A linear regression model was conducted to determine the contribution of Digit Span and Picture Span of the WISC-V to perseverative errors in the computerized WCST, controlling for potential confounding variables (e.g., full-scale IQ).

Results: Table 1 shows group performance differences. No significant difference was found between children with ASD ($M = 3.95$, $SD = 1.81$) and TD ($M = 3.37$, $SD = 2.01$) in the explicit computerized DCCS ($t = -0.934$, $p = 0.356$). However, children with ASD ($M = 27.33$, $SD = 12.86$) made significantly more perseverative errors than TD ($M = 16.58$, $SD = 8.04$) in the implicit computerized WCST ($t = -3.031$, $p = 0.005$). Regression analysis showed that Picture Span, but not Digit Span, predicted perseverative errors in the computerized WCST, controlling for group and full-scale IQ (Table 2).

Conclusions: Children with ASD performed similarly to their TD peers in explicit and well-structured task. However, in less explicit, more complex tasks, children with ASD showed more perseverative errors, possibly due to increased working memory demands. These findings highlight the importance of considering task contexts and cognitive load when assessing CF in children with ASD. Moreover, this results also support that compared to auditory system, visual sensory system of individuals with ASD seems to be similar to TD peers. This advantage may explain why children with ASD performed similarly to their TD peers in explicit tasks—not necessarily because their CF is intact, but because the explicit visual cues provided in these tasks help compensate their CF deficits. Further research with a larger sample size is warranted to validate these findings and explore the role of visual information in supporting CF in children with ASD.

410.116 Exploring Gaze Patterns for Autism Diagnosis with Lstm and Attention Mechanisms

T. Bakhtiarvand¹, J. Kalita², C. Foster³, E. Barney⁴, M. Kim⁵, B. Li⁶, P. E. Ventola⁷, C. Y. Cheng⁸, K. J. Dommer⁹, **F. Shic¹** and A. Atyabi¹, (1)Computer Science, University of Colorado Colorado Springs, Colorado Springs, CO, (2)Computer Science, University of Colorado Colorado Springs, Colorado Springs, CO, (3)Binghamton University, Binghamton, NY, (4)Center for Child Health, Behavior and Development, Seattle Children's Research Institute, Seattle, WA, (5)University of Virginia, Charlottesville, VA, (6)Computer Science and Engineering, University of Washington, Seattle, WA, (7)Yale Child Study Center, Yale University School of Medicine, New Haven, CT, (8)National Taiwan University Hospital, Taipei, Taiwan, (9)Seattle Children's Research Institute University of Washington, Seattle, WA

Background: Eye-tracking objectively measures overt attention by quantifying the direction of the eye over time. This technology is a valuable tool for studying visual attention in autism spectrum disorders (ASD), revealing atypical attention biases, such as reduced fixation on social stimuli. Previous studies have shown that incorporating dynamic stimuli in eye-tracking tasks can improve engagement and reveal more profound insights into social cognitive processes in ASD.

Objectives: This study investigates how spatiotemporal patterns in eye gaze can be used to discriminate among typically developing (TD) children, children with ASD with higher-IQs, and children with ASD with lower-IQs. Bidirectional-Long-Short-Term-Memory (LSTM) recurrent neural networks are used to classify and describe gaze patterns reflective of social and cognitive differences in ASD. We focus on building models that capture meaningful temporal sequences in eye-tracking data.

Methods: This study comprised 86 participants ($n=54$ ASD; $n=32$ TD, 6-month to 17-year). Participants were stratified into four age cohorts (0–1, 2–4, 5–9, 10–17 years) and classified by gender. Eye-tracking data were acquired using a set of video clips reflecting following tasks: Activity-Monitoring (AM), Dyadic-Bid-Sensitivity (DB), Social-Referencing (SR), and Theory of Mind (ToM). The eye-tracking data, recorded as spatiotemporal sequences of gaze coordinates (x, y) over time, were input to a LSTM network. The LSTM's architecture consisted of two bidirectional LSTM layers, each comprising 128 hidden units, followed by fully connected dense layers. To enhance the model's interpretability, an attention mechanism was integrated to dynamically weigh time steps of particular importance, particularly those corresponding to moments of social interaction. The model was trained using the Adam gradient-descent optimizer, and early stopping used to decrease overfitting. Since the data was imbalanced across TD, higher-IQ autism, and lower-IQ autism, the SMOTE was used to balance the classes in training. The LSTM's generalization accuracy was assessed by k-fold cross-validation to ensure the model's performance was not reliant on just one subset of the data. **Results:** LSTM classified TD, high-IQ, and low-IQ autism with $\text{acc}=91.4\%$. It excelled social engagement tasks (DB and ToM $\text{acc}=95\%$) owing to identifying the link between spatiotemporal patterns to social engagement. AM accuracy was 78%. Confusion matrix analysis revealed most successful differentiation between high-IQ autism and TD (F1 scores: 0.92, 0.90). LSTM's attention weights emphasized fixations during key social interactions, highlighting attentional differences in ASD, especially in DB and ToM. Performance remained robust across age groups and genders. Stratifying by age did-not cause any major deterioration in performance, with the 2–4, 5–9, 10–17 year age groups having accuracy scores of 85.2%, 87.8%, and 90.8%, respectively. Gender differences were minimal (male: 92.0%, female: 90.7%).

Conclusions: This study demonstrates the power of combining eye-tracking with deep-learning models like Bidirectional-LSTM to identify meaningful gaze patterns in ASD. The model not only achieved high classification accuracy but also offered interpretable insights into cognitive and behavioral processes in ASD. The attention mechanism provided valuable focus on critical moments of social interaction, highlighting the role of explainable AI in neurodevelopmental research.

410.117 Exploring Visual Statistical Learning in PRE-School Verbal and Minimally Verbal Autistic Children : An Electrophysiological Study

M. Petit¹, A. Calcut¹, B. BeLAS Consortium², E. Demurie³, M. Kissine⁴, I. Noens⁵, H. Roeyers⁵, L. van Esch⁵, M. Weyland⁶ and A. Destrebecqz⁷, (1)Université Libre de Bruxelles, Bruxelles, Belgium, Belgium, (2)Université Libre de Bruxelles, Ku Leuven, U Gent, Bruxelles, Belgium, Belgium, (3)Department of Experimental-Clinical and Health Psychology, Ghent University, Ghent, Belgium, (4)ACTE — Center of research in Linguistics — ULB Neuroscience, Université libre de Bruxelles, Brussels, Belgium, (5)Parenting and Special Education Research Unit, Faculty of Educational Sciences, KU Leuven, Leuven, Belgium, (6)ACTE — Center of research in Linguistics — ULB Neuroscience Institute, Université libre de Bruxelles, Brussels, Belgium, (7)Université libre de Bruxelles, Brussels, Brussels, Belgium

Background:

Implicit statistical learning (ISL) refers to the domain-general ability to learn statistical regularities through mere exposure and without the intention to learn. ISL is potentially relevant to language development, particularly in speech segmentation, which relies on sensitivity to transitional probabilities between speech sounds. Research has seen a growing interest in tracking individual performance in SL task, mainly as a predictor of linguistic abilities. This issue is therefore of particular importance in the field of autism because approximately 30% of people with autism spectrum disorder (ASD) will not develop language during their development, for reasons that are not yet elucidated. Indeed, individuals with ASD have diagnostic impairments in domains, such as language, that are associated with ISL. The identification of word boundaries in continuous speech is a critical first step in language acquisition that can be accomplished via statistical learning and reliance on speech cues. However, it is unclear whether individuals with ASD have specific ISL deficits. Here, we use EEG during statistical learning to explore these questions.

Objectives:

This study investigates the relationship between ISL and language abilities in typically developing children and children with ASD. In the long term, children's performance on the ISL task will be used as a predictor of their language abilities.

Methods:

In this study, we investigated the electrophysiological correlates of visual statistical learning in young verbal and minimally children with ASD using an event-related potential sequence learning paradigm. The experimental paradigm is a modified version of the task developed by Jeste et al. (2015) in which children look at a sequence of centrally presented little monsters, made up of the random presentation of three pairs of items. After an exposure phase, the predicted little monster was replaced by another one in 10% of the trials (oddball condition). A sample of 54 verbal autistic children and 10 minimally verbal autistic children, for a total of 64 children with ASD (mean age: 56.40 months) and 45 typically developing peers (mean age: 53.98 months) took part in the experiment.

Results:

Compared to typically developing (TD) controls, the ASD groups as a whole showed reduced evidence of learning as defined by P300 (attention to novelty) component. Examining the groups of children with ASD, we find no difference in the P300 component between verbal children with ASD and minimally verbal children with ASD.

Conclusions:

Through this work we have demonstrated a global reduced learning in SL in ASD. Further research is needed in order to test whether this deficit at 56 months of age corresponds to a delay or a genuine impairment in learning. Crucially, our results show that electroencephalography can be used to measure ISL in preschool verbal and minimally verbal children with ASD. In the longer term, we hypothesize that children who perform well in the statistical learning task are those who are most likely to access language in the course of their development. This task therefore is suitable for future studies to investigate ISL during development or in clinical populations.

410.118 Flow and Similar Attentional States in Autism and ADHD: A Scoping Review of Similarities and Differences

C. Pace-Tonna¹, M. Murtaza¹, T. Rodak², N. Farb¹, W. S. Ryan¹ and M. C. Lai³, (1)Psychology, University of Toronto, Toronto, ON, Canada, (2)CAMH Mental Health Sciences Library, Department of Education, Centre for Addiction and Mental Health, Toronto, ON, Canada, (3)Campbell Family Mental Health Research Institute, Centre for Addiction and Mental Health, Toronto, ON, Canada

Background: Flow is a state of deep immersion and engagement achieved when challenge and skill are balanced. While research has largely focused on flow in neurotypicals (NTs), emerging evidence suggests that in autism and attention-deficit/hyperactivity disorder (ADHD), the experience of flow may be distinct from traditional definitions, including the constructs of hyperfocus (intense concentration on a task), autistic inertia (difficulty initiating or shifting tasks), and monotropism (narrow attentional focus on specific areas). Understanding these distinctions could support neurodivergent individuals in managing focus, reducing task-related stress, and optimizing productivity. A scoping review aimed at addressing this research gap provides a comprehensive overview of existing evidence and identifies key concepts related to flow and similar states in neurodivergent populations.

Objectives: This scoping review examines flow, autistic flow (including autistic inertia and monotropism), and hyperfocus. It aims to address the gap in understanding how these states manifest in individuals with autism and ADHD, highlighting their similarities and differences compared to conventional flow characterizations.

Methods: This review adheres to PRISMA-ScR guidelines and includes studies from peer-reviewed articles and grey literature, identified through a systematic search of bibliographic databases (Web of Science, APA PsycInfo, Embase, MEDLINE, ProQuest Dissertations & Theses Global, CINAHL), Google Scholar, and citation searching. The search applied no limits on publication type, study type, language, location, or year of publication. Two independent reviewers screened titles and abstracts, resolving discrepancies through discussion, with a third reviewer consulted as needed. Data extraction focused on study design, methodology, flow-related constructs, and findings.

Results: This review imported 2,677 studies from databases and 5 from other sources for screening. After removing 31 manually identified and 1,028 automatically identified duplicates through Covidence, 1,623 studies remained for title and abstract screening. Of these, 1,431 were excluded, leaving 192 for full-text screening, and finally excluding 153. Ultimately, 39 studies were included: 33 empirical (including 4 theses/dissertations), 4 reviews, 1 book, and 1 reflective narrative conference paper (see Figure 1). Neurodivergent attentional experiences differed notably from typical flow. For autistics, monotropic focus and sensory integration drove flow, with special interests sustaining attention. However, these factors led to challenges, such as autistic inertia, making task initiation and transitions difficult. Hyperfocus in ADHD involved intense concentration, but lacked the structured goals and control typical of flow. While all attentional states shared common features, the most overlap occurred within neurodivergent states (see Table 1).

Conclusions: There are similarities among flow, hyperfocus, autistic inertia, and monotropism, with even greater overlap within neurodivergent attentional states. Unlike NTs, who are unlikely to transition between these states, those with autism and/or ADHD may shift fluidly during a single focus period. This fluidity can be beneficial, as hyperfocus and monotropism may enhance productivity and engagement, particularly when tasks align with personal interests. However, neurodivergent individuals may also face increased vulnerability to the effects of being locked into or out of these states. Understanding these interactions and their relation to flow helps provide tailored support, enabling neurodivergent individuals to manage focus and mitigate negative impacts.

410.120 Hot or Cold? Executive Functions in Autistic and Non-Autistic Adolescents

N. Amantayev¹ and A. Nadig²; (1)Communication Sciences and Disorders, McGill University, Montreal, QC, Canada, (2)McGill University, Montreal, QC, Canada

Background: Executive functions (EFs) are control processes that are essential for goal-directed behavior.^{1,2,3} Researchers have highlighted a distinction between cold EFs, involved in non-emotional tasks, and hot EFs, engaged during tasks with affective or motivational demands.^{4,5,6} Hot EFs appear to require emotion regulation, an area known to differ in autism,⁷ and are thought to be more impacted in autism than cold EFs.⁸ However, only two studies have directly compared them in autistic samples.^{8,9}

We use the Executive Function Challenge Task (EFCT)⁵, a measure of hot EFs in social interaction, and the Wisconsin Card Sorting Test (WCST)¹³ to explore the hot-cold EF distinction in adolescence, a key period for EF development.¹⁰ As a control, we use the Behavior Rating Inventory of Executive Function (BRIEF)¹¹, which provides an informant-based assessment of real-world executive functioning.¹²

Objectives: We explore relationships between hot and cold EF tasks in autistic and non-autistic adolescents. We hypothesize that emotion regulation difficulties in autism may reduce performance on hot EF tasks in particular, resulting in little relationship with cold EF performance. Non-autistic participants, however, may show a stronger correlation between hot and cold EFs. Additionally, on the basis of shared ecological validity,³ we expect the BRIEF to show a stronger correlation with hot than cold EFs in both groups.

Methods: Data collection is ongoing, with 14 autistic and 27 non-autistic adolescents (ages 14-18) tested. They were matched on age, gender, and nonverbal IQ (all p-values > .05). **Cold EFs** were assessed by the number of perseverative errors on the WCST. **Hot EFs** were measured by the EFCT total raw score. The Parent Report Form of the BRIEF was our **control** measure. Higher scores on all measures indicate greater EF difficulties.

Results: Consistent with our first hypothesis, preliminary data show a stronger relationship between hot and cold EF tasks in non-autistic ($\rho = 0.18$) than in autistic participants ($\rho = 0.08$), although associations are modest (Figure 1, top right panel). Our hypothesis concerning the BRIEF was not supported. For the non-autistic group, correlations between the BRIEF and both EF tasks were negligible ($\rho = -0.07$ vs. -0.03). In the autistic group, we found moderate correlations, however in different directions. There was a small-medium positive correlation between the BRIEF and hot EF as predicted ($\rho = 0.22$), and a stronger inverse correlation with cold EF ($\rho = -0.35$). This would indicate that better performance on the WCST in the lab was associated with *worse* EF as observed by caregivers in daily life.

Conclusions: Our preliminary findings suggest that non-autistic participants show a stronger correlation between hot and cold EFs than their autistic peers, supporting our hypothesis that emotion regulation may specifically impact hot EFs in autism. In the non-autistic group, the weak association between informant-based BRIEF and adolescents' EF task performance may reflect reduced caregiver insight into their child's cognitive skills during adolescence. For autistic individuals, the inverse relationship between cold EF task performance and BRIEF scores may indicate differences between lab-based and real-world EF abilities as perceived by caregivers.

410.121 Information Processing during a Sequence of Social Problem-Solving: Comparison between Adolescents with and without HFASD

O. E. Hetzroni^{1,2} and **A. Y. Jacobovich**³, (1)Special Education, University of Haifa, Haifa, Israel, (2)Mount Carmel, University of Haifa, Haifa, Israel, (3)TZOHAR LATOHAR, RECHASIM, Israel

Background:

Social problem-solving is a critical skill for adapting into a dynamic social environment. Difficulties in the ability to solve social problems within a social environment may lead to challenges in social adaptation. Social Information Processing (SIP) model proposes several steps of cognitive processing to solve social problems: encoding, interpretation, goal selection, generating responses and decision-making. SIP has been used to examine social problem-solving patterns among various populations, including high-functioning autism. Findings regarding the autism population are mixed; whereas some findings demonstrated that autistic individuals generate ineffective solutions and tend to attribute anti-social intentions to others, other studies did not demonstrate such discrepancies. As SIP was not specifically designed for ASD, further research is critical to identify the cause for such mixed results. Recent research on patterns associated with information processing of high-functioning autistic individuals demonstrated a tendency to focus on perceptual and local information rather than on semantic global components that creates coherence. However, when provided with explicit guidance on how to process the information, this pattern was not evident.

Objectives:

To examine associations between unique information processing patterns found among autistic individuals and social problem-solving processes according to the SIP model, with the use of adapted research tools.

Methods:

Participants: 15 high-functioning autistic and 15 age-matched neurotypical adolescents, ages 10-16. A text describing a series of typical social situations was developed for the study. The tool included scripts describing various problems that arose during school-break, which required decoding and decision-making on how to behave following each scripted situation. The situations were interconnected, creating an overall occurrence forming a chain of events. Each scripted situation included open-and closed-ended questions.

Results:

Findings demonstrate significant differences between groups in answers to the open-ended questions, with the autistic participants tending to focus on non-essential information components related to each situation, while making limited connections between various scenes across and within situations. In contrast, when presented with the possibility to choose between answers in the close-ended options provided to each of those questions, there were no significant difference between the groups.

Conclusions:

Results demonstrate a clear pattern in which when presented with open-ended questions and a wide range of possibilities, autistic adolescents tended to select local limited solutions to the social problems with little regard to previous situations. However, when faced with close-ended possible solutions, sufficient hints were provided thus enabling them to process the information and provide better social problem-solving solutions. Hence, findings demonstrate how the unique information processing patterns of autistic individuals might be manifested in everyday social problem-solving. The findings suggest that difficulties in this area might be related to information processing patterns with a variety of options and minimal guidance toward a preferred choice. These findings may explain the inconsistency found in studies on SIP model and autism, as differences between answers could relate to the method used for obtaining information, i.e., open- versus closed-ended questions rather than the social problem-solving issues.

410.122 Investigating Spontaneous Musical Improvisation As a Mediating Cognitive Language in Children with Autism Spectrum Disorder

J. E. Teich¹, **J. Kowaleski**² and **M. H. Thaut**^{2,3}, (1)Faculty of Music, The University of Toronto, Toronto, ON, Canada, (2)Faculty of Music, University of Toronto, Toronto, ON, Canada, (3)Faculty of Medicine, University of Toronto, Toronto, ON, Canada

Background: Research has shown that autistic children often have an unusual interest in and response to music, excelling in pitch and timbre processing, melodic memory, and rhythm synchronization. This study explores spontaneous musical improvisation in autistic children compared to their neurotypical peers to reveal music's potential as a mediating cognitive language.

Objectives: This study aims to analyze the quality of spontaneously produced tone sequences of children with autism spectrum disorder (ASD) compared to neurotypical (NT) children. Additionally, it investigates music as a medium to facilitate performance and response in children with ASD.

Methods: Thirty participants aged six to twelve were recruited, with fifteen diagnosed with ASD and fifteen neurotypical children. Participants engaged in free, spontaneous improvisation on a xylophone, and their performances were recorded and analyzed using a Musical Analysis Scale (MAS) across dimensions such as rhythm, restriction, complexity, rule adherence, and originality. Independent samples t-tests were conducted to compare the groups. The study also examined the effects of age and diagnosis on performance using a two-way ANOVA.

Results: The analysis indicated that the tone sequences produced by children with ASD did not significantly differ from those of their neurotypical peers, with one exception. A significant difference was found in the originality component, with the ASD group scoring lower than the NT group ($p = .03$), suggesting that the NT group demonstrated more unique musical elements. For the total score, representing overall musicality based on the MAS, there was no significant difference between the ASD group and the NT group ($p = .36$). Additionally, a significant interaction effect between diagnosis and age group was found for the total score ($p = .02$), indicating that younger children with ASD had lower total scores compared to older children with ASD and younger NT children. Further testing revealed no significant differences in mean total scores between the ASD and NT groups ($p = .37$) or between the younger and older age groups ($p = .46$), indicating that the interaction between diagnosis and age primarily drives the observed differences.

Conclusions: The findings of this study indicate that music facilitates the performance and response of autistic children, supporting the limited existing research on this topic. The improvisational nature of the test allowed autistic children to engage more freely, suggesting that music can help overcome typical challenges faced by individuals with autism. Understanding how children with autism interact with music provides valuable insights into using music to facilitate non-musical skills, such as language and motor abilities. These findings highlight the potential for developing structured tests to evaluate musical skills in greater detail, ultimately leading to more effective educational and therapeutic interventions that leverage the strengths of autistic individuals and improve their overall development.

410.123 Investigating the Associations between Arousal Level, Distracter Filtering, and Autistic Traits

Y. Kim¹, K. Ma², M. A. Duong³ and B. Keehn¹, (1)Speech, Language, and Hearing Sciences, Purdue University, West Lafayette, IN, (2)Purdue University, Lafayette, IN, (3)Purdue University, West Lafayette, IN

Background: Arousal level plays an important role in the ability to filtering irrelevant information. Arousal regulation difficulties are present in autism, and autistic individuals commonly report atypical hyper- and hypo-responsivity to external sensory stimuli. However, relationships between arousal level, distracter filtering, and autistic traits are not well understood.

Objectives: To investigate the associations between arousal level, as measured by resting pupil diameter and EEG alpha power, distracter filtering in visual (cued flanker) and auditory (word-in-noise) domains, and autistic traits in neurotypical adults.

Methods: Participants included 80 undergraduate students. Autistic traits were measured by Broad Autism Phenotype Questionnaire (BAPQ) and attention to detail score was measured by average z-score of attention to detail subscale of AQ and Detailed and Flexibility Questionnaire (DFlex).

The study included three experiments: 1) a resting EEG and eye-tracking task to measure pupil diameter and alpha power as indirect measures of resting-state arousal level, 2) a cued-flanker paradigm to measure congruency effect (RT of incongruent-congruent conditions), and 3) NIH toolbox Word-in-Noise as measures of distracter filtering irrelevant information in visual (2) and auditory (3) domain. For resting-state task, participants were asked to look at a black central crosshair, which was displayed on a gray background. For a cued-flanker paradigm, isoluminant stimuli (cue, arrows) were presented on a gray background. Participants were instructed respond to the direction of center arrow. Pupil diameter was monitored using an EyeLink 1000 Plus remote eye-tracking system and EEG was recorded using 128-channel high-density Geodesic electrode array. For NIH toolbox Word-in-Noise task, participants are asked to say the word that they hear from right or left ear when noise is presented.

Results: Congruency effect during a cued flanker task was not significantly correlated with any arousal measure. The Word-in-Noise task raw score for left-ear and across both ears was negatively related to resting pupil diameter. In addition, increased resting-state alpha activity at left posterior ROI was positively correlated to Word-in-Noise task raw score for right-ear ($p < .05$). Contrary to hypothesis, our arousal measures were not significantly correlated to autistic traits, including attention to detail. The attention to detail was negatively correlated to Word-in-Noise task raw score for left-ear and across both ears ($ps < .05$). BAPQ total was marginally related to congruency effect ($r = -.21, p = .066$) and word in noise raw score across both ears ($r = -.22, p = .054$).

Conclusions: As hypothesized, our findings show that increased arousal level is associated with greater difficulty filtering irrelevant information. This pattern was present for auditory, but not visual, stimuli. Additionally, autism traits were associated with both visual and auditory filtering, and attention to detail was significantly related to auditory filtering abilities. These findings expand our understanding of arousal regulation in filtering distracters in visual and auditory domains that may be linked to attention to detail of autistic traits.

410.124 Is Home Literacy Environment (HLE) Associated with Reading Performance in Brazilian Children with Autism Spectrum Disorders (ASD)?

N. Becker¹, A. C. O. Biagio², K. C. L. Santos², A. B. S. Honda², J. M. L. Tenorio³ and C. S. de Paula¹, (1)Human Developmental Sciences Graduate Program, Universidade Presbiteriana Mackenzie, São Paulo, SP, Brazil, (2)Human Developmental Sciences Graduate Program, Mackenzie Presbyterian University, São Paulo, SP, Brazil, (3)Mackenzie Presbyterian University, São Paulo, SP, Brazil

Background: Autism spectrum disorder (ASD) is a neurodevelopmental disability that significantly affects communication, which contributes to reading difficulties for individuals with ASD. Although literacy is not a core impairment of ASD, many studies have shown that children with ASD are disproportionately affected by literacy challenges. The home literacy environment (HLE) refers to a combination of literacy-related resources, attitudes, and activities provided by caregivers. The HLE has been proven to contribute to the development of children's oral language and literacy skills, especially in typically developing children. Despite the potential benefits of home reading activities on the literacy development of children with ASD, few studies have examined this issue, and none have been conducted with Brazilian children from diverse socioeconomic backgrounds. **Objectives:** To investigate the relationship between the HLE and reading accuracy and comprehension performance in children with ASD and Level 1 support.

Methods: This correlational study included 22 Brazilian children ($M = 11.3$ years, $SD = 3.55$), 81% boys, all diagnosed with ASD and with preserved formal oral language. The measures used were parental education (mother's and father's years of education as a component) and the Early Literacy Questionnaire (completed by parents). The children were evaluated individually with the Teste de Desempenho Escolar – TDE II (a Brazilian validated test assessing reading accuracy, spelling, and arithmetic according to elementary school grades) and the Teste de Compreensão Leitora Textual - COMTEXT-ANELE 2 (a Brazilian validated test assessing text reading comprehension). Data were analyzed using Spearman's correlation.

Results: The correlations indicated that parental education was positively associated with reading accuracy in children with ASD ($\rho = .478$, $p = .03$). The amount of time parents spent reading books to their child at once was positively associated with text reading comprehension ($\rho = .424$, $p = .04$). However, the frequency of parental reading was not significantly associated with either reading accuracy or text comprehension ($p > .05$). **Conclusions:** The results suggest a positive impact of the HLE on the development of different reading skills and potential educational gains when children with ASD are exposed to shared reading, as is observed in typically developing children. The HLE may be influenced by parental education, making it important to investigate how parental education mediates the direct effects of the HLE on reading development in children with ASD. The findings indicate that Brazilian children with ASD from diverse socioeconomic backgrounds can benefit from a rich HLE in achieving reading proficiency.

410.125 Is Learning You Are Autistic Earlier in Development Associated with Success in College for Autistic Students?

K. Gillespie-Lynch¹, B. R. Nachman² and B. E. Cox³, (1)Department of Psychology, CUNY Graduate Center, Staten Island, NY, (2)University of Pittsburgh, Pittsburgh, PA, (3)Michigan State University, East Lansing, MI

Background:

Project PEACES takes a strengths-based approach to improving postsecondary outcomes for autistic students by learning from successive waves of autistic students what success in college means to them. One factor that may impact outcomes is age of learning one is autistic. Learning one is autistic earlier was associated with greater Quality of Life (QoL) and well-being among autistic students (Oredipe et al., 2021). Females and older students learned they were autistic later. However, age of learning vs. age of diagnosis were not distinguished. Autistic females in a non-college study were also diagnosed later; later diagnosis was associated with lower QoL and heightened autistic traits (Atherton et al., 2022). A pre-registered non-college study revealed positive baseline correlations between learning one is autistic/being diagnosed earlier, QoL and well-being (Leung et al., 2023). However, associations were no longer apparent after including autistic traits, age and gender. Large and diverse college-student samples are needed to determine if age of learning one is autistic is reliably associated with positive outcomes.

Objectives:

1. Explore disparities in age of autism identification among autistic college students;
2. Determine if age of learning one is autistic and/or age of diagnosis are associated with success among two diverse waves of autistic college students.

Methods:

Autistic college students in the U.S. completed an online survey assessing demographics, age of learning one is autistic, age of diagnosis, and perceived success in college across 5 domains (IPACE; Identity, Psychology, Academics, Community, and Employment).

In Fall 2022 (Wave 1; Table 1), 288 participants reported an autism diagnosis (required to investigate associations between age of diagnosis and outcomes). In Fall 2023 (Wave 2), 310 participants were diagnosed.

Results:

In Waves 1&2, younger students and men were diagnosed and learned they were autistic earlier; non-binary students learned and were diagnosed later ($ps < .02$). In Wave 2, women learned later ($p < .05$). Ages of diagnosis and learning were unrelated to race/ethnicity ($ps > .19$).

In Wave 1, earlier ages of diagnosis and learning were associated with greater self-reported employment and community success ($ps < .04$) but not other IPACE domains.

In Wave 2, earlier diagnosis and learning were associated with greater success in the psychological domain ($p = .003$). Gaps between learning and diagnosis were unrelated to success ($ps > .19$).

Conclusions:

Gender minorities and older autistic college students experience persistent disparities in access to autism diagnoses/information, which may impact self-understanding. Although age of learning one is autistic/age of diagnosis were associated with adult outcomes in this and prior studies, the pattern of associations is not consistent. Wave 1 findings align with evidence that earlier autism diagnoses are associated with better organizational self-esteem and reduced workplace discrimination among autistic employees (Johnson & Joshi, 2016). Wave 2 findings align with the aforementioned associations between age of learning one is autistic and/or receiving a diagnosis and psychological outcomes. Findings highlight the value of large-scale replications for understanding factors that shape outcomes for autistic students. Future work should investigate potential explanatory factors including autistic traits and mental health conditions.

410.126 Reduced Serial Dependence during Perceptual Learning in ASD Is Linked to over-Specificity of Learning

N. Pinchuk-Yacobi¹, D. Sagi², M. Behrmann³, H. Harris-Miller⁴ and Y. S. Bonne⁵, (1)School of Optometry and Vision Science, Bar Ilan University, Ramat Gan, Israel, (2)The Weizmann Institute of Science, Rehovot, Israel, (3)Carnegie Mellon University, Pittsburgh, PA, (4)Sheba Impact Ltd., Ramat Gan, Israel, (5)School of Optometry and Vision Science, Bar-Ilan University, Ramat Gan, Israel

Background:

Perceptual decisions are often biased toward recent stimulations (the serial dependence effect), which is thought to support sensory integration and maintain perceptual stability over time. Here we consider the role of serial dependence in perceptual learning and its generalization in ASD where learning is often rigid and specific. Previous research has shown that high-functioning adults with Autism Spectrum Disorder (ASD) initially exhibit efficient learning in a standard texture discrimination task (TDT). However, when the target location was changed, these individuals experienced anomalously poor learning transfer (over-specificity). Interestingly, this over-specificity was eliminated in an experimental condition designed to reduce stimulus adaptation.

Objectives:

This study aims to investigate the effects of serial dependence during a TDT in high-functioning adults with ASD compared to matched controls, specifically examining how any differences between the groups relate to learning generalization or specificity.

Methods:

We reanalyzed data from a previous TDT study (Harris et al., Nat. Neurosci. 18, p1574, 2015), in which participants identified the orientation (vertical or horizontal) of a peripheral texture target while simultaneously performing a forced-choice letter discrimination task to maintain fixation. Two conditions were compared: (1) a 'standard' condition with consistent target presentations in all trials (10 ASD, 9 controls), and (2) a 'dummy' condition, where targetless trials were randomly interleaved with standard trials to reduce stimulus adaptation (10 ASD, 10 controls). The experiment spanned eight daily sessions, with the target location changed after the fourth session to test for learning generalization. Serial dependence biases were quantified using a linear mixed model, assessing the influence of prior N-back target orientation on current target judgments.

Results:

Both ASD and control groups exhibited response biases toward prior target orientations (significant up to seven trials back), with strongest biases when current targets were unreliable and prior targets were highly reliable, consistent with Bayesian perceptual models. For recent history (1-3 trials back), ASD observers showed approximately 30% less serial dependence compared to controls in both conditions. However, for more distant history (4-10 trials back), serial dependence in ASD observers remained lower under the 'standard' condition but matched control levels in the 'dummy' condition.

Conclusions:
