The dominance of the medical model in research has emphasized fixing the individual rather than considering broader social structures and contexts. With significant gaps in research around the strong links between emotional dysregulation and poor educational outcomes—particularly in autism, where dysregulation is being increasingly recognized.

Objectives: This study aimed to address gaps in the research, reframing traditional medical narratives by employing the neurodiversity paradigm. It used an everyday school setting (a specialist primary school for autistic children), promoting collaborative engagement among all stakeholders, including teachers, teaching assistants, and pupils. This was framed within a social model, a 'Community of Practice', to foster shared practices within specific contexts.

Methods: The study used a qualitative, mixed-methods approach. A focus group of teachers and teaching assistants discussed emotional regulation and dysregulation, exploring how regulation is built throughout a busy school day. Classroom observations provided real-time data on how dysregulation manifests and is managed through environmental adjustments, teacher interventions, structured routines, and physical movement. Additionally, three case studies focused on individual children, using innovative methods and adapted strategies to better understand their experiences and perspectives.

Results: The focus group data were analysed using thematic analysis, revealing key areas of consensus: Physical movement, predictability, and structure were identified as key strategies for fostering regulation; Identifying regulation and dysregulation were less dependent on external behaviours but more of a “felt state”, requiring teachers to have nuanced, flexible approaches; with teacher regulation and teamwork also essential. Classroom observations across three classes were analysed to establish patterns in practice, revealing three key aspects: Classroom environment management; Team organization and its impact and Children's participation and engagement, with differences noted between novel and familiar tasks.

The 'Child Voice' data, presented as three case studies, were analysed to identify linked issues around timetabling and task relatability.

Key findings emphasized the importance of purposeful movement in regulating children. This was evident both in lessons, where children had options to wander and opt out as a primary regulation strategy, and in planned movement sessions throughout the school week. Additionally, there was widespread use of prompting or modifying work to support already highly differentiated learning. It prompted reflection on potential misunderstandings of children's thought processes and feelings, leading to questions about mismatches in learning support.

Conclusions: Emotional regulation was found to be closely linked with purposeful physical movement and prompted understanding pupil experiences more deeply as a priority. Future research should explore the potential harms of misplaced expectations, especially those stemming from misunderstandings of attention and interest differences, which may contribute substantially to the dysregulation observed. Cultivating a 'Community of Practice' appears to be a promising approach to managing increasing workloads as well as supporting and creating meaningful change within this setting.

424.224 Multidisciplinary Intervention to Support Autistic Children during Long Term Epilepsy Monitoring

H. Barton¹, E. G. Newton², M. Wright³, N. Auer⁴ and M. Wojnaroski⁵, (1)Behavioral Health, Nationwide Children's Hospital, Columbus, OH, (2)Cortica, San Diego, CA, (3)Behavioral Health, Nationwide Children's Hospital, Colum, OH, (4)Nationwide Children's Hospital, Columbus, OH, (5)Nationwide Children's Hospital, Westerville, OH

Background: Children with autism spectrum disorder (ASD) are at increased risk for comorbid medical conditions, including epilepsy. Although epilepsy is often managed with medications, approximately 30-40% develop intractable epilepsy. Best practice for children with intractable epilepsy is a multiple day hospital admission with EEG and neuroimaging to determine other interventions to reduce seizures (Phase 1). These admissions can present unique challenges for autistic children due to communication delays, sensory aversions, and repetitive, self-injurious, or other disruptive behaviors. At our hospital, interviews with caregivers and providers identified similar challenges, along with related concern about the ability of autistic children to tolerate Phase 1 admission. Minimal research exists on evidence-based procedures to support children with ASD during EEG, and no known formal multidisciplinary programs exist. To fill this gap, we created an intervention program for children with ASD and intractable epilepsy, who were referred for Phase 1 admission.

Objectives: This presentation will describe the multidisciplinary development of an intervention program for children with ASD and epilepsy, components of the program, and results of a quality improvement (QI) project.

Methods: The intervention was developed and evaluated using QI methodology. Along with input from a multidisciplinary team (neurologists, nurse practitioners, nurses, child life specialists, EEG technicians), the authors developed a 3-tiered approach for child and family preparation utilizing a parent interview and behavior analytic principles. Individualized information about child needs for hospital admission was communicated to the inpatient team prior to admission. Behavior intervention, based on the child's needs, was implemented prior to admission by a psychologist or a Board Certified Behavior Analyst.

Results: From January 2020 to October 2024, 64 patients participated in the program. 73% were male, with an average age of 10.9 (range 2.6-18.9). 65% were white, 24% were black, 8% were biracial, and 2% were Asian.

The aim for the QI project was to increase the percentage of patients with ASD and epilepsy who participated in a comprehensive treatment program prior to Phase 1 admission, from 0% to 80%, by January 2021, and maintain through 2026. Initial baseline was 0% enrollment, as the program did not previously exist. 64 referred patients participated in the program (84%). 98% of patients enrolled were to complete all required medical procedures during Phase 1 admission. Caregiver behavior rating during admission were introduced in July 2024. Data regarding child disruptive behavior during admission, and caregiver perception of procedures, and caregiver empowerment was recently implemented, and available data will be included in the presentation.

Conclusions: This program highlights the need for and success of individualized multidisciplinary care for those with intractable epilepsy and ASD requiring epilepsy monitoring. This project is now standard of care at our hospital. Although autistic children with a comorbid medical condition may present with concerns or challenges for an evaluative medical procedure, it is possible for increased participation and caregiver satisfaction. Interventions such as ours which incorporate preparation, support, and multidisciplinary collaboration, allow for improved medical care and quality of life for autistic children and their families.

424.225 Nature Playgardens: A Six-Week Therapeutic Emotional-Behavioural Intervention Program for ASD Children and Their Caregivers

J. C. Wong^{1,2} and **T. Neo³**, (1)National University of Singapore, Singapore, Singapore, Singapore, (2)DEPT OF PSYCHOLOGICAL MEDICINE, National University Hospital, Singapore, SINGAPORE, Singapore, (3)Mind Science Center, National Univeristy of Singapore, Singapore, Singapore

Background:

Nature is powerful in improving the mental well-being of neurotypical children. A lack of affordable and accessible therapies for autistic children in their neighborhood, with evidenced based family-centered therapies and self-care programs for families with autistic children are common. There is a scarcity of studies conducted in tropical natural environments using validated clinical nature program protocols.

Objectives:

This study aimed to establish the usefulness of a nature-based clinical therapeutic intervention, consequently developing an accessible, replicable and validated program in the neighborhood children playgarden, that not only improves the emotional-behavioral difficulties of ASD children, but also reduces caregivers' stress and burden.

Methods:

A 6-week intervention program curated based on DIRFloortime® principles, carried out in specially designed Nature Playgardens, facilitated by trained professionals. Participant dyads (n=28) were boys aged 5-9yo diagnosed with ASD and their caregivers aged 21-80yo. The intervention consisted of 90-minute sessions of caregiver and facilitator assisted nature play, segmented into warm-up/cool down, child-led activities, collaborative activities. Caregivers were required to complete a training program by occupational therapists prior to the intervention. Study consisted of 4 time-points, pre (T0), mid (T1), post (T2), post 4-weeks (T3) intervention.

Child's psychosocial quality of life was measured using Pediatric Quality of Life Inventory (PEDsQL) at T0, T2, and T3. Emotional Regulation Checklist (ERC) – completed at T0 and T2 – consisted of 2 subscales testing for child's negative emotional reactivity and emotion regulation abilities. Caregiver's mental well-being was measured using the General Health Questionnaire (GHQ-12) at T0, T1, T2 and T3; caregiving burden was measured using the Burden Scale for Family Caregivers (BSFC-s).

All scales were scored by caregivers.

Results:

Linear Mixed Model Analysis controlling for age revealed at 95% CI:

Child participants' negative emotional reactivity (ERC) significantly decreased from T0 to T2, mean difference = -4.71, $p < .001$, CI (-6.31, -3.11).

Child's psychosocial quality of life (PEDsQL) significantly increased from T0 to T2 and T3. Mean difference (T2) = 5.96, $p = .004$, CI (1.98, 9.95). Mean difference (T3) = 6.82, $p = .001$, CI (2.84, 10.81).

Caregivers' mental well-being increased with a significant decrease in GHQ-12 scores from T0 to T0 to T2, mean difference = -2.03, $p = .046$, CI (-3.82, -.034).

Though there were no significant changes in caregiving burden, Pearson correlation revealed a significant negative relationship between caregiving burden and child's psychosocial quality of life at T2, $r(26) = -.42$, $p = .027$. Suggesting that with the child's psychosocial quality of life increases, caregiver's burden decreases.

Conclusions:

This study demonstrated the efficacy of a clinical nature-based therapeutic intervention in improving the emotional and social health of children with ASD. Child participants experienced a decrease in frequency of negative emotional reactions while experiencing an increase in psychosocial quality of life. This improvement in their child's quality of life was also found to simultaneously decrease caregiver's caregiving burden.

Caregivers also experienced an increase in overall psychological well-being after 6 weeks of intervention. Overall, the validation of this program provides families with ASD children an effective, accessible and affordable self-care intervention program.

424.226 Navigating Mathematics Education for Autistic Children: A Parental Insight

G. Yakubova¹, **T. Vyas²**, **M. Al-Dubayan³**, **W. Wu⁴**, **V. Y. Kang⁵** and **S. Gupta¹**, (1)Counseling, Higher Education, and Special Education, University of Maryland, College Park, MD, (2)University of Maryland, College Park, College Park, MD, (3)University of Maryland, College Park, MD, (4)University of Maryland at College Park, College Park, MD, (5)Counseling, Higher Education, and Special Education, University of Maryland at College Park, College Park, MD

Background: Autistic children often face unique challenges in learning mathematics, including sensory processing difficulties, communication barriers, and numerous other challenges. These challenges may affect their ability to understand math concepts and succeed in traditional classroom settings. Despite the critical role that parental support plays in the education of autistic children, scarce research has examined how parents perceive their involvement in their child's math education, their interactions with teachers, and the use of technology to support learning. To fill this gap, we explored parental perspectives on the mathematics education of their autistic children, with an emphasis on identifying common challenges, successes, and areas for improvement.

Objectives: The objective of this study was to qualitatively investigate the perspectives of parents on the mathematics education of their autistic children. In this study, we sought to understand how parents perceive their involvement in their child's math learning, their experiences with technology in math instruction, the quality of communication with teachers, and their expectations for their child's future academic success.

Methods: This exploratory study utilized semi-structured, in-depth interviews to gather qualitative data from 12 interviews of parents of autistic children currently attending k–12 schools in the U.S. Participants were recruited through network-based sampling using flyers distributed via social media, email listservs, and advocacy organizations. Individual interviews were conducted virtually using the Zoom platform, recorded, and transcribed for analysis. An inductive thematic analysis was applied to the transcripts to identify key themes, with inter-rater reliability conducted to ensure consistency in coding.

Results: Preliminary findings suggest that parents face significant challenges in supporting their autistic children's math education. Common issues include difficulty with word problems, the need for frequent practice to grasp math concepts, and sensory overload during mathematics classes. Parents with strong math backgrounds are able to provide after-school support, while those with less experience struggle to assist their children effectively. Access to technology also varies widely, with some parents actively seeking devices to support their child's learning. Many parents expressed frustration with the limited interaction and support they receive from teachers, citing concerns about whether the school's instructional methods are meeting their child's needs. Additionally, some parents emphasized the importance of providing their children with opportunities for inclusion in classroom settings, while also ensuring adequate support for individualized learning.

Conclusions: This study underscores the complexities faced by autistic children in learning mathematics and the challenges parents encounter in supporting their child's education. The findings highlight the importance of enhancing communication between parents and teachers, increasing access to technology, and fostering educational environments that are both inclusive and responsive to the individualized needs of autistic learners. These results suggest a need for future research and interventions that better support both parents and teachers in addressing the unique math learning challenges of autistic children.

424.228 Neuro-Strengths Based Support for Autism: From the Autistic Lens

S. Neustadt¹, S. Gallegos², K. Grabeel³, E. Kim², S. Golubock¹ and B. B. Braden¹, (1)Making Sense of Autism LLC, Denver, CO, (2)Arizona State University, Tempe, AZ, (3)Arizona State University, Phoenix, AZ, (4)College of Health Solutions, Arizona State University, Tempe, AZ

Background:

Autism spectrum disorder (ASD) presents complex challenges that traditional interventions often fail to address by solely focusing on deficit remediation, as opposed to a holistic approach that incorporates skills already present. Although ASD diagnoses are based on behavioral assessments, neuroscience research demonstrates that brain differences underlie those behaviors, which suggests that interventions informed by neurological understanding could offer more effective support. Despite these insights, many existing interventions still prioritize "normalizing" behaviors based on standardized assessment outcomes, which may not align with the unique neurological profiles and strengths of autistic individuals. This often leads to stress while learning and limited progress towards goals that are often not meaningful to the individual. A shift towards a strengths-based, neurobiologically informed approach could address limitations of current treatment paradigms and provide more tailored and effective interventions.

Objectives:

This study explores the feasibility and acceptability of the Neuro-Strength-Based Support for Autism (NSBSA) training provided to Speech-Language-Pathologists (SLP) and Occupational Therapists (OT) who serve autistic clients. We also evaluated whether therapists were able to shift their client's goal from deficit-focused to a strengths-based approach, and if their satisfaction in the goal-writing processes improved as a result.

Methods:

The NSBSA framework was developed by an autistic occupational therapist aiming to bridge the gap between research and practice by translating neuroscience findings into actionable strategies for practitioners. Participants included nine SLPs and seven OTs who participated in a 16-hour video-conference training program over 8 weeks. The training covered eight modules, including interpreting behaviors, sources of motivation, neuroscience research on inputs and self-awareness, and developing client-centered program goals. Feasibility was assessed through attendance and attrition rates, while acceptability was measured via post-intervention Course Satisfaction Survey. Pre- and post-intervention data were collected on participants' satisfaction with their goal-writing, measured on a Likert scale of 0 (No/Not at all), 1 (Some/Somewhat), and 2 (Yes/Very), and a knowledge assessment that evaluate their clinical reasoning in goal-writing practice.

Results:

Feasibility was high, with participants completing 7.29 ± 1.27 modules and attending 7.07 ± 1.21 Q&A sessions on average, with low attrition ($n=1$; 6%). Participants also reported high satisfaction and acceptability of the NSBSA training program, finding the content relevant to their practice (Table 1). Pre- to post-intervention assessments revealed significant improvements in both goal-writing satisfaction ($p < 0.001$) and goal-writing knowledge ($p = 0.005$).

Conclusions:

Preliminary findings indicate that NSBSA is a feasible and acceptable framework to improve autism service providers' experience and align therapeutic goals to motivations of autistic individuals. By leveraging strengths and neurobiological understanding, NSBSA offers a promising direction for traditional intervention models to evolve in a direction that can empower providers and reduce stress for autistic individuals. Importantly, the NSBSA framework can be applied to any existing autism intervention program to make them more attuned to unique neuro-profiles.

424.229 Neuroaffirming CBT for Autistic Adults: A Mixed-Methods Study Evaluating the Feasibility of Co-Production and Co-Facilitation

E. Matsuba¹, H. E. Monroe², A. Porthukaran³, L. Man⁴, Y. Lunsby⁵, A. Palikucin³ and D. Fanelli¹, (1)Department of Psychology, Boston Children's Hospital / Harvard Medical School, Syracuse, NY, (2)Azrieli Adult Neurodevelopmental Centre, Centre for Addiction and Mental Health, Toronto, ON, Canada, (3)Centre for Addiction and Mental Health, Toronto, ON, Canada, (4)Centre for Addiction & Mental Health (CAMH), Toronto, ON, Canada, (5)Adult Neurodevelopmental Services, Centre for Addiction and Mental Health, Toronto, ON, Canada

Background: Cognitive Behavioral Therapy (CBT) is an evidence-based intervention for reducing symptoms of anxiety and depression among autistic adults. However, there is a need for neuroaffirming interventions that are specifically adapted for autistic individuals. Others have cited the benefits of co-production and co-facilitation with autistic self-advocates, which integrates lived experiences alongside clinical interventions. Feasibility studies are necessary to inform future research examining effectiveness, however, none have assessed the feasibility of an autism-informed, co-produced, and co-facilitated CBT group.

Objectives: Using a mixed-methods approach, this study examined the feasibility of an adapted CBT group for autistic adults with co-existing mood and/or anxiety diagnoses in an outpatient clinic.

Methods: CBT groups for autistic adults (ages 20-25) with mood and/or anxiety diagnoses were conducted in an outpatient clinic using Mind Over Mood 2. Groups were facilitated by clinicians for 120-minutes/week over 8 or 13-weeks with 4-7 participants. Adaptions were made based on group feedback, current literature, clinical observations, and collaboration with an autistic self-advocate and included: increased structure and predictability, increased visuals and response options, increased communication modalities, supports for executive functioning, consideration of sensory needs, and the integration of autism-specific topics (e.g., alexithymia, autistic burnout). An autistic-self advocate was included as a co-facilitator of the third group. Feasibility was assessed using the key areas of focus from Bowen et al. (2009) framework. Qualitative feedback was collected using an anonymous survey and focus group. Limited-efficacy was assessed using questionnaires on symptoms of depression (PHQ-9) and anxiety (GAD-7). Data collection is ongoing, with an additional 12 participants expected by January 2025.

Results: The demand for adult autism services is high, with consistent referrals creating a long waitlist. Existing clinic infrastructure was sufficient for the successful implementation, integration, and expansion of the group. Adaptation was informed by multiple sources, as described above. Regarding practicality, the initial development process was time intensive (3-5 hours/week) but remitted for subsequent groups. Acceptability was high, as all participants who completed the survey agreed (n=2) or strongly agreed (n=6) that sessions were informative, helpful, and that they were satisfied. All participants would recommend the sessions to others. Participants commented that they “liked the autism specific stuff and the autistic co-facilitator’s experience” and “it was helpful to have flexibility and sensory accommodations”. Eleven participants completed pre- and post-intervention questionnaires for limited-efficacy testing. Results from the two-sample sign tests were non-significant for the PHQ-9 ($p>.05$) and the GAD-7 ($p>.05$), though 5 participants reported decreases in anxiety.

Conclusions: Neuroaffirming CBT was feasible across multiple key areas of focus. Autistic adults benefited from the autism-specific adaptations to the group structure and content. Further, the inclusion of an autistic co-facilitator fostered honest discussions and provided opportunities for group members to connect through shared experiences. Clinical changes were not detected, attributed in part to the small sample size and long-standing mental health concerns of the cohort. Clinicians are encouraged to involve autistic self-advocates as consultants, collaborators, and facilitators in a respectful, meaningful, and inclusive manner, to further document how manualized psychological interventions may be adapted and optimized.

424.230 Parent Involvement in Language Interventions for Autistic Students: A Systematic Review

J. Choi¹ and G. Y. Kim^{2,3}, (1)Ewha University, Seoul, Seoul, Korea, Republic of (South), (2)Baylor University, Lawrence, KS, (3)Educational Psychology, Baylor University, Waco, TX

Background: Parent involvement in the education of autistic students fosters a positive cycle of improvement for both students and families. By supporting learning at home, parents extend opportunities beyond those provided by professionals, improving students' progress in learning and building parents' confidence while reducing stress and isolation. As language and communication are key support areas for autistic students, parents can reinforce these skills across various contexts. Although the effectiveness of parent engagement and parent-mediated interventions are well-documented, there is limited research on their use with school-aged students. Thus highlighting the need for further exploration in this underinvestigated area.

Objectives: The purpose of this systematic review is to synthesize research on the impact of parent involvement in supporting language development for school-aged autistic students, and the following research questions guided the study:

RQ1. What are the characteristics of studies examining parent involvement in language interventions for autistic students?

RQ2. What are the characteristics of participants (i.e., parent, student, professional) on parent involvement in language intervention for autistic students?

RQ3. How are nonspeaking autistic students represented in studies on parent involvement in language interventions?

RQ4. How is the effectiveness of parent involvement in language interventions for autistic students reported in the literature?

Methods: The systematic review adhered to the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines (see Figure 1). Data were extracted and categorized into study characteristics, participant characteristics (students, parents, and professionals), reported language outcomes, and the representation of nonspeaking autistic students. Study quality was evaluated using the Cochrane Collaboration's Risk of Bias Tool for quasi-experimental designs and single-case designs. To ensure coding accuracy, two authors independently coded all included studies and calculated and reported interrater reliability.

Results: We included 7 RCT and 1 SMART design studies for review ($n = 8$). Most studies involved mixed-age groups (5-13 years old), and 66.7% focused specifically on children aged 9 and below. Non-speaking autistic students were included in only one study. Three studies reported the primary language of students and parents, while socioeconomic status was reported in just one. The types of language interventions varied across studies and were implemented by trained clinicians in most cases (87.5%), with no study involving parents as primary interventionists. Most studies were conducted in research institutes or hospital-based clinics (87.5%), with only one taking place in the family's home. Social communication was the most commonly targeted outcome across the included studies. Different parent teaching strategies were used, with feedback and rehearsal being used most frequently.

Conclusions: The findings of this review indicate that parent involvement in language interventions leads to positive developmental outcomes for autistic students. However, more research is needed to address the unique aspects of elementary school settings because the environmental factors specific to these settings may influence student outcomes.

424.231 Parent-Mediated and Paraprofessional-Mediated ABA: Effects on Goal Attainment and Adaptive Behavior

B. Pfingston¹, L. Sneed² and D. A. Samelson³, (1)Research Institute, Catalight, Walnut Creek, CA, (2)Research Institute, Catalight, Walnut Creek, CA, (3)Clinical Excellence, Catalight Foundation, Walnut Creek, CA

Background: Parent-Mediated applied behavior analysis (ABA) is an evidence-based intervention that focuses on building parenting skills to effectively implement behavioral procedures with their child to teach new skills as well as manage difficult behavior. Parent-Mediated ABA has been shown to produce positive outcomes for autistic children as well as their parents. In addition, parent-mediated ABA has several benefits compared to paraprofessional-mediated delivery models, including requiring less of a time commitment from families, and the ability for parents to use the skills they learn in treatment beyond the duration of the intervention. However, parent-mediated ABA is underutilized in community settings. This may be because, compared to the evidence base for traditional, paraprofessional-mediated models of ABA, there is comparatively less of a research base for parent-mediated ABA.

Objectives: We sought to expand the research base for parent-mediated ABA by comparing community-based parent-mediated ABA with a traditional, paraprofessional-mediated ABA intervention.

Methods: We analyzed quasi-experimental, retrospective clinical data of clients with ASD in either paraprofessional-mediated ($n = 197$) or parent-mediated ($n = 198$) ABA. Participants were youth with ASD (Mean Age = 6.40 years) who already participated in their respective intervention. Treatment type was not randomized; clients' parents chose the treatment modality in accordance with clinician recommendations. Outcome measures included adaptive behavior (as measured by the Vineland-III) and goal attainment (as measured by the Goal Attainment Scale) across three time points spanning 18 months.

Results: A two-way mixed ANOVA indicated no significant difference in the adaptive behavior composite nor the socialization, communication, and daily living skills subscales, either between groups or over time. A separate two-way mixed ANOVA showed significant differences in goal attainment between treatment conditions, across time, and with a significant interaction. Overall, the parent-mediated group had significantly higher goal attainment than the paraprofessional-mediated group, although all groups improved significantly over time. The interaction effect indicated that the parent-mediated group improved more, and more quickly, than the paraprofessional-mediated group.

Conclusions: These results suggest that parent-mediated ABA may be an acceptable alternative to paraprofessional-mediated interventions. In particular, parent-mediated ABA may be of particular use in skill acquisition, as exemplified by the progress made by clients in the parent-mediated group in goal attainment. One strength of this study is its large sample size. However, treatment conditions were not selected by random assignment; clients' parents were able to choose the treatment modality that best suited their needs. As such, more RCT evidence is necessary to confirm the effectiveness of parent-mediated ABA compared to its paraprofessional-mediated counterpart.

424.232 Peer-Mediated Intervention Using Lego®-Based Therapy in Brazilian Children with Autism Spectrum Disorder

L. O. Angelis¹, F. T. Orsati² and M. C. Teixeira³, (1)Universidade Presbiteriana Mackenzie, São Paulo, São Paulo, Brazil, (2)Instituto Inclusive Todos, São Paulo, São Paulo, Brazil, (3)Developmental Disorder Program, Mackenzie Presbyterian University, Sao Paulo, Brazil

Background: The LEGO®-based Therapy is a structured play-based intervention designed to promote social interactions within a natural play activity using Lego materials. The sessions involve collaborative LEGO® model building, in which each participant is assigned a distinct role—engineer, supplier, or builder—each responsible for different tasks. This role allocation is specifically aimed at fostering cooperation, enhancing communication, and encouraging problem-solving within the group.

Objectives: To verify the effects of LEGO®-Based Therapy in social interaction of children with autism spectrum disorder (ASD) in a afterschool setting. The objective was to compare a peer-mediated group, a specialist-mediated group, and a control group on a waiting list, to determine which group achieved the most significant gains.

Methods: Eighteen children with ASD from public schools in Embu das Artes, three neurotypical peers who served as mediators, aged between 5 and 8 years (neurotypical peers were matched by sex and gender with children with ASD), and one specialist, participated in the study. Prior to the intervention, the peer mediators underwent training in three role-playing sessions designed to prepare them for their role. The intervention consisted of 14 sessions, twice a week, each lasting 40 minutes, following structured LEGO®-based Therapy. The results were analyzed by video coding clips from all sessions, conducted by two independent judges. They checked the indicators of interaction skills acquired and the data compared pre, post and follow-up sessions to identify possible improvements in the stimulated behaviors by each group.

Results: The interobserver agreement was 86.3% (Kappa = 0.92 [95% CI 0.91-0.94]), classified as substantial or strong agreement. The specialist-mediated group showed an increase in the mean number of interactions from 1.01 to 12.93 ($W = 0.00$, $p = 0.03$; $d = 14.15$), as did the peer-mediated group, which increased from 0.73 to 13.27 mean of interactive behaviors ($W = 0.00$, $p = 0.03$; $d = 3.73$), both with large effect sizes. In contrast, the control group remained stable, with mean interactions ranging from 1.19 to 1.13 ($W = 12.50$, $p = 0.75$; $d = 0.11$), showing no effect size.

Conclusions: Both intervention groups demonstrated greater improvements compared to the control group. The most significant finding was that the structured LEGO®-based Therapy, when combined with peer mediation, can be an effective and low-cost strategy for enhancing interaction skills in children with ASD. This approach shows great promise as a tool for use in ASD interventions, highlighting the potential of peer mediation as an accessible and scalable resource for ASD therapy programs and in special education. These results support the integration of peer-mediated interventions into broader educational and therapeutic frameworks, particularly for promoting social and communication-based skills in children with ASD.

424.233 Perceptions of Cognitive Behavioral Therapy Among Autistic Adults

R. Garuda¹, J. A. Rankin², G. Flaherty³ and E. S. Brodtkin¹, (1)Psychiatry, Brodtkin Lab, Philadelphia, PA, (2)Psychiatry, University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA, (3)Department of Psychiatry, University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA

Background: Cognitive behavioral therapy (CBT) is useful for enhancing emotion regulation, making it an effective tool targeting social anxiety symptoms in autistic adults (Wenzel, 2017; Bemmer et al., 2021). The new social skills training intervention, Training to Understand and Navigate Emotions and Interactions (TUNE In), integrates 3 elements of CBT to reduce social anxiety: the thoughts feelings and behaviors log, anxiety thermometer, and automatic thoughts identification. Perception of helpfulness of these CBT elements has been related to efficacy of the intervention (Yarwood et al., 2021; Walsh et al., 2018). Given that, this study aims to evaluate the acceptability of the CBT elements in TUNE In through a qualitative interview, informing perceived efficacy.

Objectives: We aimed to qualitatively evaluate participants' perceptions of 3 CBT elements in TUNE In. We also sought to understand participants' previous experience and familiarity with psychotherapy and the elements of CBT.

Methods: Nineteen adult autistic participants without intellectual disability completed the TUNE In intervention. Fifteen of these participants completed an optional, post-TUNE In interview over Zoom. They were asked about past therapeutic intervention history (yes/no/maybe), past favorability (strongly disliked/disliked/neutral/liked/strongly liked) and efficacy (very poor/poor/fair/good/excellent) of CBT. They were asked to then rate the three CBT components on familiarity (not at all/slightly/moderately/very/extremely) and usefulness (not at all/slightly/moderately/very/NA), and if the component's level of focus (much less/less/same/more/much more) and presence (yes/no/maybe/NA) should change.

Results: We found that participants most commonly had prior experience with CBT, DBT, and General Talk therapy (refer to Table 1.0). Retrospectively, participants had a diversity of views on favorability of CBT, and a majority found it to be at least fair in efficacy (see Table 1.0). Most participants were also at least slightly familiar with all three CBT elements (ranging from 86.7% - 100% for the 3 elements). In the context of the intervention, most participants felt the 3 elements were at least slightly to extremely useful (73.3%-100%), wanted it to remain a part of TUNE In with at least the same amount of focus (53.3% - 66.7%), and a majority wanted all elements to remain in the intervention (73.3% - 80%). It should be noted that 26.6% of participants wanted less of the anxiety thermometer and 26.7% thought it was not at all useful (see Table 2).

Conclusions: In general, autistic adults tended to have a variety of therapeutic experiences, with a vast majority of the participants in this study having prior experience with CBT (Benevides et al., 2020). Unsurprisingly, they were all also generally familiar with the 3 CBT elements assessed here, found all 3 elements mostly useful, and wanted the elements to remain in the intervention with a similar level of focus. These results reflect the acceptability of CBT for addressing the social anxiety symptoms that many autistic adults experience, and the importance of including these elements in later iterations of TUNE In (Bemmer et al., 2021). In the future, we will recruit a larger cohort of participants to better understand the preferences and experiences of autistic adults in TUNE In.

424.234 Pilot RCT to Compare a Home-Based Tailored Cognitive Behavioral Therapy for Insomnia (CBT-I) Versus Web-Based CBT-I to Improve Sleep in Caregivers with Insomnia in the Context of Caring for an Autistic Child with Insomnia

M. C. Souders¹, A. Kearney², A. Amoah³, A. Kim⁴, E. Magland⁵, R. Eikov³ and J. Pinto-Martin³, (1)407 Trail West, Philadelphia, PA, (2)psychiatry, The Children's Hospital of Philadelphia, Philadelphia, PA, (3)Nursing, University of Pennsylvania, Philadelphia, PA, (4)Psychiatry, The Children's Hospital of Philadelphia, Philadelphia, PA, (5)University of Pennsylvania, Philadelphia, PA

Background:

Autism spectrum disorder represents one of the most perplexing neurobiological differences with a prevalence of 1 in 36 children. Lifelong challenging and distinctive behaviors often associated with ASD may have a significant impact on caregivers' mental health and family functioning, including the ability to develop and maintain healthy sleep routines for themselves and their child.

Objectives: To determine the acceptability and feasibility of a RCT utilizing a web or home-based CBT for Insomnia intervention implemented by nurses to improve sleep of a caregiver and autistic child.

We will examine caregiver and child sleep parameters and daytime behaviors pre and post intervention.

Methods:

40 caregivers/child dyads will be recruited from The Children's Hospital of Philadelphia. Caregivers must be 18 years or older and children must be 3-17 years old with confirmed ASD diagnosis. Each must meet criteria for insomnia. The modified CBT-I is a 6 week intervention that includes 1) A one hour education session developed by the Autism Treatment Network, Sleep Tool Kit; 2) Identifying positive evening routines, developing a visual schedule and implementing ecological changes, 3) Introducing a calming module with 12 soothing activities as suggestions to be incorporated into the bedtime routine and 4) Developing a bedtime protocol pairing irresistible sleepiness with going into the bedroom (stimulus control). Each dyad will be randomized into either the web or home-based intervention after education visit. At baseline and 8 weeks follow up, participants will complete sleep measures including one week Fitbit data, sleep diaries, sleep questionnaires and behavioral measures including, CBCL, PHQ-9, GAD-7, parent efficacy scale. An acceptability survey will be completed at week 8.

Results:

To date, 27 dyads have enrolled in the study. Caregivers N= 6 fathers and N= 20 Mothers and 1 Paternal grandmother. Children N=5 female, N=1 transgender. N= 21 male, mean age of caregivers 44 yo, mean age of child 7.5 years old. 66.7% white and 33.3 % Minority. To date Caregivers have found the study acceptable (Lickert scale of 1-7 with 7 =strongly agree) in terms of randomization 6/7 , assessment of sleep problems 7/7, communication with nurses 7/7, frequency of visits 6/7, tailoring CBT for themselves and their child 7/7.

Conclusions:

We will determine acceptability and feasibility, summary statistics calculated from survey.

Using linear mixed-effects modeling, sleep measures will be assessed prior to and following the intervention. We will test for differences in characteristics of caregivers and children whose symptoms improve, stay the same, and worsen over time. T-Tests will be used. This data will support a larger RCT with the Department of Defense funding opportunity through the Congressionally Directed Medical Research Program. This Autism Research Program focuses on improving lives of those living with ASD.

424.235 Pilot Randomized Controlled Trial of Mindful Time, a Novel Telehealth Mindfulness-Based Intervention for Autistic Adolescents and Their Caregivers

N. L. Matthews¹, **M. Mitchell²**, **H. Honda¹**, **A. Malligo³**, **S. Boyd¹**, **B. A. Pagni^{3,4}** and **B. B. Braden⁵**, (1)Southwest Autism Research and Resource Center, Phoenix, AZ, (2)Southwest Autism Research & Resource Center, Phoenix, AZ, (3)Arizona State University, Tempe, AZ, (4)New York University, New York, NY, (5)College of Health Solutions, Arizona State University, Tempe, AZ

Background: There is a need for accessible psychosocial interventions for autistic youth with co-occurring mood symptoms. Research suggests that mindfulness-based interventions (MBI) may be a valuable method for reducing internalizing symptoms in autistic adults (Forbes & Miller, 2023). Less is known about MBIs for autistic adolescents. This study examined MINDful TIME (Mindfulness-based Intervention for NeuroDiverse Teens: Telehealth Instruction, Mobile-app Enhanced), a novel group-based telehealth intervention for autistic adolescents and their caregivers.

Objectives:

- 1) Examine feasibility and acceptability of MINDful TIME.
- 2) Compare change in adolescent depression, anxiety, and mindfulness between treatment (Tx) and delayed treatment control (DTC) groups.
- 3) Explore whether treatment-related improvements were maintained at 2-month follow-up.

Methods:

Participants in this hybrid feasibility and pilot parallel randomized controlled trial were 42 adolescent-parent dyads. Randomization was stratified by adolescent age, biological sex, and race/ethnicity. Tx participants (n = 21) attended eight weekly group meetings conducted through Zoom, during which they learned mindfulness strategies and habit formation techniques to establish a regular mindfulness practice. DTC participants (n = 21) completed an 8-week wait period prior to beginning the program. Participants in both groups completed a follow-up visit 2-months after program exit (n = 34).

Feasibility was assessed using attendance and fidelity of implementation checklists. Acceptability was measured using teen- and parent-report acceptability questionnaires. At each timepoint, parents completed the Children's Depression Inventory (CDI-2) and Multidimensional Anxiety Scale for Children (MASC-2). Adolescents completed the Child and Adolescent Mindfulness Measure (CAMM).

Results:

The program was implemented with fidelity (90.28-96.25%) and 90% of Tx dyads completed the program. Participants attended > 90% of sessions and reported high acceptability. There was a significant effect of group on the combined dependent variables (CDI-2, MASC-2, and CAMM positive change scores from baseline to program exit) when controlling for baseline values (Pillai's Trace = .217, $F(3, 32) = 2.95$, $p = .047$, $\eta_p^2 = .22$). Reported in Table 1, follow-up univariate tests indicated that Tx adolescents showed greater improvement in depression symptoms at program exit than DTC. There was not a significant difference in MASC-2 change scores. However, there was a significant treatment group by biological sex interaction ($F(1, 34) = 4.22$, $p = .05$, $\eta_p^2 = .11$) with Tx females demonstrating a larger improvement in anxiety symptoms than DTC females ($F(1, 34) = 4.24$, $p = .05$, $\eta_p^2 = .11$). The univariate test for CAMM was approaching significance with a medium effect size, suggesting that Tx participants may have increased levels of mindfulness relative to DTC. Analyses examining maintenance of treatment-related gains in the full sample indicated significant or approaching significant improvements for all three variables at program exit and maintenance of treatment-related gains at 2-month follow-up (see Figure 1).

Conclusions:

Findings indicate feasibility, acceptability, and preliminary efficacy of MINDful TIME for improving depression symptoms in autistic adolescents and maintenance of treatment-related gains at a 2-month follow-up. We also found potential sex-specific effects on adolescent anxiety, which should be examined in future studies. Findings warrant future examination of MINDful TIME to support mental health in this population.

424.236 A Comparison of Implementation Strategies for Training Community Providers in a Statewide Rubi Parent Training Initiative

D. Swain¹, R. Torres², K. Grubb³, D. M. Tagavi³, N. Goldfeder⁴, M. Houchell¹, M. Siegel⁵ and K. Bearss⁶, (1)Developmental Pediatrics, University of Colorado Denver - School of Medicine /Children's Hospital Colorado, Aurora, CO, (2)Seattle Children's Hospital, Seattle, WA, (3)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (4)MaineHealth, Portland, ME, (5)Boston Children's Hospital, Boston, MA, (6)Psychiatry and Behavioral Sciences, Department of Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA

Background: Community mental health providers receive little training in evidence-based practices for autistic youth and often refer families to specialty clinics with long waitlists (Maddox & Gaus, 2019). One scalable approach to addressing this clinical need is through community provider training in the implementation of parent training programs, which are empirically supported, time-limited, and cost-effective. The Research Unit on Behavioral Interventions (RUBI) program is a parent training program for families of autistic children with quality-of-life impacting behaviors, including meltdowns, aggression, and transition difficulties. RUBI has been found to be acceptable to parents, reliably delivered by trained therapists, and effective in reducing challenging behaviors when evaluated under ideal conditions (i.e., efficacy trials). The current study details a statewide effort to build community provider capacity to serve autistic youth and their families through training in the RUBI Parent Training program. Providers were offered one of three training pathways: 1) access to on demand webinars, 2) participation in a live two-day training, or 3) ECHO RUBI training.

Objectives:

- 1) Explore baseline differences in provider-level factors across training modalities
- 2) Examine immediate and long term (6-month follow-up) impact of training modality on provider knowledge of behavioral principles and RUBI self-efficacy
- 3) Determine provider and training level predictors of gains in knowledge and self-efficacy

Methods: Providers who enrolled in a statewide training effort of the RUBI Parent Training program between October 2022 and October 2024 and consented to research are included in the analyses. Providers completed (1) a demographic questionnaire at baseline, and (2) questionnaires on self-efficacy and knowledge of behavioral principles at baseline, end of training, and 6-months post-training.

Results: Out of the 318 community providers who enrolled in a statewide training for the RUBI Parent Training program, 129 consented to participation in the study (30.6%), with 67 completing pre-, post-, and 6-month assessments to date. A majority of providers are female (83.8%), White (90.8%) and hold graduate degrees (59.2% Masters or higher). Provider education level and sex significantly varied across training modality, with higher rates of providers with graduate level training choosing On-Demand training (75%) compared to the other training options (50% and 52.6%). Additionally, 93% of Live training participants were female compared to 70.8% of ECHO participants. Provider knowledge of behavioral principles and self-efficacy improved significantly from baseline to endpoint across all three training modalities, with no direct effect of training type. There were no significant changes in knowledge of behavioral principles or self-efficacy from Endpoint to 6-month follow-up. Moderator analyses will focus on the impact of training type and provider type on changes in provider knowledge and self-efficacy.

Conclusions: Implementation research provides the opportunity to understand how best to help community providers learn to implement evidence-based treatments, such as RUBI. Community providers across all training modalities demonstrated significant gains in behavioral knowledge and self-efficacy that maintained 6-months post training. Discussion will include a review of barriers to training and implementation approaches that facilitate training of behavioral health providers to improve clinicians' comfort and knowledge related to the implementation of RUBI.

424.237 Predictors of Parental Attendance in an Online Rubi-Based Behavior Support Program

H. W. Kent¹, K. N. Drapalik², D. J. Magin³, E. Davis⁴, M. Rinaldi² and K. V. Christodulu², (1)Center for Autism and Related Disabilities- University at Albany, Albany, NY, (2)Center for Autism and Related Disabilities/University at Albany, Albany, NY, (3)Center for Autism and Related Disabilities/University at Albany, Albany, NY, (4)Center for Autism and Related Disabilities, Albany, NY

Background:

The COVID-19 pandemic prompted the adaption of many evidence-based interventions for caregivers of autistic individuals to be delivered in a virtual format. These online versions of parent-mediated interventions for children with autism spectrum disorder (ASD) provide promising results by reducing barriers to participation, with caregivers finding them comparable to in-person programs (de Nocker & Toolan, 2021; Corona et al., 2021). Recent literature, regarding the efficacy and acceptability of telehealth adaptations, primarily cites caregiver and child outcome measures in combination with attendance and attrition rates (de Nocker & Toolan, 2021). However, there is a gap of research investigating predictors of parental attendance in telehealth delivered parent-mediated interventions for ASD.

Objectives:

To explore this question, we investigated how levels of parenting stress, autism symptomology, and severity of non-compliant behaviors predict attendance in an online Research Units in Behavioral Intervention-based behavior support program (RUBI; Bearss et al., 2015).

Methods:

31 caregivers of children 5-13 years old, diagnosed with ASD completed the Parenting Stress Index Short Form, Fourth Edition (PSI-4 SF; Abidin, 1995), the Social Responsiveness Scale, Second Edition (SRS-2; Constantino, 2012), and the Home Situation Questionnaire-Autism Spectrum Disorder (HSQ-ASD; Chowdhury et al., 2016) prior to beginning the eleven-week program. Throughout the program, session attendance was collected and recorded.

Results:

To examine if there was a relationship between session attendance and parenting stress, autism symptomology, and severity of non-compliant behaviors, three linear regression models were evaluated. The SRS-2 total score ($F(1, 25)=.906, p=.351, R^2=.036$), the PSI-4 SF total stress score ($F(1,30)=.028, p=.869, R^2=.001$) as well as the HSQ-ASD total severity score ($F(1,30)=.037, p=.850, R^2=.001$) were all not significant predictors of program attendance.

Conclusions:

These findings suggest that parenting stress, autism symptomology, and severity of non-compliant behaviors were not related to program attendance in a virtual parent-training program. However, due to the small sample size, the study was limited in its power to detect an effect. Future studies may replicate these analyses with a larger sample size to determine which factors may be associated with program attendance and participation.

424.238 Preliminary Feasibility, Acceptability, and Efficacy of the Competence in Romance and Understanding Sexual Health (CRUSH) Curriculum for Autistic Adults

J. L. Vanderburg¹, A. Sharma², M. Armstrong³, E. Quin⁴, E. Pereida⁵, D. Kang⁶, D. W. Pantalone⁷ and S. Faja⁸, (1)Developmental Behavioral Pediatrics, University of Oklahoma Health Sciences Center, Oklahoma City, OK, (2)Boston Children's Hospital, Brookline, MA, (3)Labs of Cognitive Neuroscience, Boston Children's Hospital, Boston, MA, (4)Boston Children's Hospital Labs of Cognitive Neuroscience, Brookline, MA, (5)Developmental Medicine, Boston Children's Hospital, Boston, MA, (6)Harvard University, Cambridge, MA, (7)Psychology, University of Massachusetts Boston, Boston, MA, (8)Boston Children's Hospital, Harvard, Boston, MA

Background:

Autistic adults identify sexual health as their top unmet healthcare need, including (1) forming healthy sexual relationships and (2) reducing the potential for sexual victimization. To address this need, we conducted a literature review and mixed methods needs assessment resulting in the development of the CRUSH curriculum. Targeting the unique needs of autistic adults, CRUSH is a group-based intervention that facilitates learning new information, increasing motivation and self-efficacy, and developing behavioral skills. CRUSH targets pragmatic language in the context of discussing sexual health constructs as an underlying factor that contributes to learning, self-efficacy, and effective behavior.

Objectives:

Primary goals were examining the feasibility (successful completion of session content and retention across the 20-week intervention) and acceptability (favorable evaluation of content and format). A secondary goal focused on examining initial changes in pragmatic language, knowledge, self-efficacy, and behavior.

Methods:

Participants were eight autistic adults (2 women, 5 men, 1 transgender individual) aged 18-30 with cognitive abilities in the borderline range or above ($FSIQ > 70$). Two facilitators led the CRUSH groups plus participants received 1:1 coaching to individualize content. We assessed pragmatic language, accuracy of sexual health vocabulary, self-efficacy with sexual health behaviors, and behavioral changes at baseline, mid-intervention (10 weeks), and post-testing.

Results:

CRUSH was highly feasible, with all eight participants completing the 20-week curriculum and returning for post-testing. Further, the CRUSH facilitators were able to complete the curriculum content during the intervention period. Acceptability was positive, and group members appreciated the review and synthesis of the previous week's content, the use of visual content and interactive activities, and explicit directions about social aspects of relationships, like flirting. Topics reported as especially important were sex and gender identity, identification of potential partners, consent, and "Sex Ed 2.0." Pragmatic language (defining sexual health terms) improved from baseline to post-testing; group members used less slang, $F(2,12) = 4.5$, $p = .05$, $h_p^2 = 0.43$, and vulgarity, $h_p^2 = 0.07$, with large and medium effects, respectively. Participants had a more accurate sexual health vocabulary as the curriculum progressed, $h_p^2 = 0.15$ (medium effect). They reported feeling more comfort with their current sex life, $h_p^2 = 0.16$, getting and using birth control, $h_p^2 = 0.15$, and more confidence being sexually assertive (e.g., saying "no"), $h_p^2 = 0.13$. Behaviorally, participants reported more efficient and collaborative sexual health decision making, $h_p^2 = 0.06$, and, qualitatively, one participant—who had asked what it means to have a crush on someone at the beginning—was in a relationship by the end. They said, "I have a girlfriend now, which is nuts, and I was actually able to initiate most of that relationship."

Conclusions:

Preliminary investigation of the CRUSH curriculum showed promising initial results, suggesting that it is feasible and acceptable to autistic adults. Results suggest post-intervention changes in pragmatic skills in discussing sexual health, information, motivation, self-efficacy, and behavior relative to baseline. Additional evaluation of curricula like CRUSH that are tailored for the sexual health and relationship needs of autistic adults are needed to address critical gaps in healthcare.

424.239 Project Forward: Internships Focusing on Support for Self-Determination Improve Career Prospects for Autistic College Graduates

H. Wang¹, J. Wong², C. Yeh³ and Y. Lin¹, (1)Department of Special Education, National Tsing Hua University, Hsinchu, Taiwan, Taiwan, (2)Department of Special Education, National Tsing Hua University, HsinChu, Taiwan, Taiwan, (3)Department of special education, National Tsing Hua University, Hsinchu, Taiwan, Taiwan

Background: Autistic college graduates in Science, Technology, Engineering, and Mathematics (STEM) are equipped with valuable work skills and professional training to obtain employment in reputable industries. However, due to their social challenges, autistic individuals often cannot obtain employment in line with their professional abilities and are disadvantaged in the competitive job market. With insufficient life experience and career exploration, most autistic college graduates struggle with self-determination, which is critical in enabling autistic individuals to identify their strengths, career aspirations, and effective career-based pathways. Work experience increases autistic individuals' practical skills, helping them gain meaningful employment. However, most employment services target individuals with profound disabilities. Little research thus far has developed supportive internship programs tailored for autistic college graduates with a higher potential to obtain competitive employment.

Objectives: Project FORWARD seeks to develop a supportive internship program in Taiwan that integrates self-determination-focused support and internship opportunities in STEM industries. We examined autistic individuals' career perspectives before and after participating in the supportive internship program.

Methods: We created competitively-paid internship opportunities for autistic college graduates through partnerships with two Taiwanese semiconductor companies. We recruited applicants from eight colleges, providing individualized training in resume writing and job interviews. Eligible autistic individuals then participated in official interviews and obtained a two-month, fully-paid internship. Two hours of employment support were provided weekly during the internship. The employment support involved group discussions focused on the workplace challenges faced by participants, using self-determination strategies to guide and facilitate problem-solving while enhancing their workplace adaptation skills. We conducted semi-structured interviews to understand autistic individuals' career perspectives before and after the internship. Thematic analysis was used to examine participants' narratives about work. Data triangulation and peer debriefing were undertaken to ensure the trustworthiness of the findings.

Results: In total, 14 autistic college graduates participated in Project FORWARD and received resume and interview training (*mean age* = 24.5; *SD* = 2.74). Five individuals successfully matched appropriate internship positions. Nine participants were on the waiting list. All participants exhibited idealized self-concepts toward employability and vague career expectations before entering internships. Individuals who completed the internship shared that they gained a more realistic understanding of work through emerging in the workplace. Instead of blaming external environmental barriers, interns developed concrete action plans to improve their social competencies to fit into the workplace culture. Additionally, interns recognized the gaps between their current abilities and job demands in STEM industries, leading to clearer career plans to enhance their soft skills and professional abilities for future jobs. By contrast, participants on the waiting list hold career perspectives similar to their pre-internship views after two months.

Conclusions: Our study demonstrates a successful model for developing college-company collaborations and creating a supportive internship program in STEM industries. We found that self-determination-focused support with workplace immersion helps autistic individuals adapt to the work environment, develop concrete action plans for job preparation, and establish clear career goals. Our findings suggest that tertiary educators strive to connect with local companies and create more internship opportunities for autistic college graduates.

424.240 Provider Perceptions of Incorporating Special Interests When Treating Autistic Youth

B. Jeyanayagam¹, L. Moskowitz², A. Drahotá³, C. M. Kerns¹ and M. D. Lerner⁴, (1)Department of Psychology, St. John's University, Queens, NY, (2)Department of Psychology, Michigan State University, East Lansing, MI, (3)University of British Columbia, Vancouver, BC, Canada, (4)A.J. Drexel Autism Institute, Drexel University, Philadelphia, PA

Background: "Special interests" are an important facet of an autistic person's identity and can enhance well-being (Grove et al., 2018). Incorporating special interests into interventions has the potential for positive change in a variety of outcomes (Harrop et al., 2019). Further, leveraging or capitalizing on an individual's special interest through incorporating it into treatment is an adaptation that has been recommended for autistic youth when using CBT to treat anxiety (Kerns et al., 2017), parent training for disruptive behaviors (McNeil et al., 2018), and increasing social motivation and meaningful social interaction (Vismara & Lyons, 2007). However, it is unclear to what extent community providers actually use (or are even aware of) this strategy in usual care.

Objectives: This study sought to examine community providers' perceptions of their use, the usefulness, and the evidence-base for incorporating special interests when treating autistic youth.

Methods: 674 community-based providers who reported working with autistic youth (aged 7-22) participated in the Usual Care for Autism Study (UCAS; Wainer et al., 2017). Providers who rated (on a 4-point scale) that they were somewhat to very familiar with the therapeutic strategy of 'incorporating special interests' were asked to report their frequency of use, perceived usefulness, and perceptions of how strongly research supports use of this strategy for treating anxiety, externalizing behaviors, and social skills in autistic youth. Repeated-measures ANOVA with a Greenhouse-Geisser correction was used to compare differences across treatment target.

Results: 68.2% of providers reported familiarity with 'incorporating special interests' into treatment. There were significant differences in provider ratings of the frequency of use, $F(1.791,404.687)=18.9, p<.001$, perceived usefulness, $F(1.323,272.510)=4.72, p<.05$, and perceived research support, $F(1.842,279.915)=12.5, p<.001$, for incorporating special interests to treat the different outcome variables. Pairwise comparisons with a Bonferroni adjustment suggest that 'incorporating special interests' is most frequently used by providers when teaching social skills, following by treating externalizing behaviors, and used least frequently when treating anxiety ($p's<.05$; Figure 1A). Similarly, providers believe that there is stronger research support for 'incorporating special interests' to address social skills than externalizing behaviors ($p<.05$) and anxiety ($p<.001$; Figure 1C). Notably, approximately 25-30% of participants indicated a lack of knowledge regarding the research base for incorporating special interests to treat anxiety, externalizing behaviors, and social skills (Table 1). Post hoc tests did not elucidate differences between perceived usefulness by treatment target.

Conclusions: Although most providers reported familiarity with this strategy, the substantive minority of providers unfamiliar with the potential utility of 'incorporating special interests' into treatment highlights the need to investigate provider characteristics associated with this unfamiliarity; and for subsequent training and education of neurodiversity-informed adaptations to treatment. Further, most community providers familiar with this strategy reported frequent use, particularly when teaching social skills, and perceived this to be a somewhat to very useful strategy for treating various outcomes. Yet, the results also suggest a gap in knowledge regarding the evidence base for this strategy, particularly for treating anxiety and externalizing symptoms, underscoring the need for future research on the efficacy, effectiveness, and dissemination of this strategy.

424.241 Robot-Assisted Training Enhances Emotion Recognition in Cantonese-Speaking Children with Autism Spectrum Disorder (ASD) in Audio-Only Contexts

M. Li¹, Z. Li², S. Chen³, X. Chen⁴, Y. Zhang⁵, A. Chan¹, T. Tang⁵ and Z. Tian³, (1)*The Hong Kong Polytechnic University, Hong Kong, Hong Kong*, (2)*Chinese and Bilingual Studies, The Hong Kong Polytechnic University, Hong Kong, Hong Kong, Hong Kong*, (3)*The Hong Kong Polytechnic University, Hong Kong, Hong Kong, Hong Kong*, (4)*The Hong Kong Polytechnic University, Hong Kong, Hong Kong, Hong Kong (China)*, (5)*The Hong Kong Polytechnic University, Hong Kong, Hong Kong, Hong Kong*

Background: Children with Autism Spectrum Disorder (ASD) frequently experience challenges in interpreting emotional cues, which can adversely affect their social interactions and communication abilities. Recent studies have integrated robot-assisted training into interventions for ASD, demonstrating positive outcomes in enhancing social skills across various domains. However, research examining the effects of training on the perception of different domains (speech and music) and the integration of modalities (audio-only and audio-visual) remains relatively limited. Additionally, there is a scarcity of research conducted on native Cantonese-speaking trilingual children with ASD.

Objectives: The present study aims to examine the effects of robot-assisted training on emotion recognition across domains (speech and music) and modality (audio only and audio visual) children with ASD. It particularly assesses the efficacy across audio-only and audio-visual presentations. The stimuli include four types: music-only, speech-only, music with dynamic facial expressions, and speech with dynamic facial expressions. The research questions are:

- (1) Does robot-assisted training significantly enhance emotion recognition across different domains and modalities for children with ASD?
- (2) Are there differences in the effectiveness of training for emotion recognition between the audio-only and audio-visual modalities?
- (3) Will the training effects demonstrate emotion-specific differences across domains and modality?

Methods: This study examined the effects of robot-assisted training on emotion recognition in Cantonese-speaking children with ASD. Twenty-seven children with ASD (mean age 9.74 ± 1.50 years, IQ 110.63) and twenty-seven neurotypical (NT) controls (mean age 9.85 ± 1.46 years, IQ 106.07) were recruited. Two participants from the NT group were excluded as outliers. Autistic children participated in two 150-minute robot training sessions, where a robot displayed speech and music conveying six emotions — anger, fear, happiness, sadness, surprise, and tenderness — along with corresponding facial expressions with facial parameters extracted from videos of human actors. Both ASD and NT groups completed auditory-only and audio-visual emotion recognition tasks before and after training for both music and speech domains. Emotion recognition proficiency was analyzed using a mixed-effects logistic regression model.

Results: (1) Significant enhancements in emotion recognition were found in the audio-only settings for both speech and music domains, with autistic participants showing considerable improvement in the accuracy. (2) In audio-only modality, all emotions except “sadness” exhibited significant improvements after training. (3) Although integrating visual cues with audio stimuli generally enhances the performance of participants with ASD across most emotions, training outcomes indicated that individuals with ASD benefited more from audio-only modalities, especially for emotions “anger” in music stimuli and “tenderness” in speech stimuli. In the audio-visual modality, the training did not yield significant positive outcomes for either speech or music.

Conclusions: The research explored the robot-assisted training effects on emotion recognition in children with ASD across different domains and modalities. The results demonstrated that training sessions significantly enhanced emotion recognition in audio-only modality. The absence of significant improvements in the audio-visual modality may be attributed to a “ceiling effect” in emotion recognition accuracy among children with ASD, where their performance did not significantly differ from that of their NT peers.

424.242 School Services That Facilitate Employment Success for College Students with Autism Spectrum Disorders

J. Wong¹, Y. Lin² and E. E. Chen^{3,4}, (1)*Department of Special Education, National Tsing Hua University, HsinChu, Taiwan, Taiwan*, (2)*Department of Special Education, National Tsing Hua University, Hsinchu, Taiwan, Taiwan*, (3)*Interdisciplinary Program of Education, National Tsing Hua University, Hsinchu, Taiwan, Taiwan*, (4)*Department of Educational Psychology and Counseling, National Tsing Hua University, Hsinchu, Taiwan, Taiwan*

Background: Obtaining competitive employment is the final goal for every college student. However, even with the appropriate competency and work skills, autistic young adults are significantly less able to obtain employment than their neurotypical peers. If they are able to secure employment, autistic adults are often in positions that are inadequate with respect to their education levels. To address this issue, school services have become essential in helping college autistic students transition to the workforce. In Taiwan, the Ministry of Education has injected 6.66 million USD yearly for tertiary educators to provide educational services fostering vocational success for college students with disabilities. Tertiary educational institutions in Taiwan are required to develop individual support plans (ISPs) for students with disabilities, and often offer various additional career services as well. However, little research thus far has explored which services successfully support college autistic students in obtaining employment.

Objectives: We sought to identify the school services that best support autistic young adults in their career development and to investigate what factors outside of school could predict the employment status of autistic young adults.

Methods: We surveyed college autistic students to investigate what career services they obtained in school. Prior to data collection, we conducted semi-structured interviews with 24 school teachers at college disability resource centers, 20 college autistic students, and 20 parents of autistic young adults. The survey questions were developed based on the interview results, and then reviewed by four external experts. To ensure content validity, we conducted a pilot test with seven autistic young adults and three neurotypical individuals before finalizing the survey accordingly. In the end, the survey contained three main sections: demographics, background information, and school services to assist student's career development.

Results: In total, 112 college autistic students completed the survey (age mean (SD) = 21.7 (2.8); Male = 81.3%). Most participants (97.3%) had received the basic school services (e.g., ISPs) required under Taiwanese law. However, over a third of (37.5%) students were unaware of the additional career services provided by their university. Among the school services provided, internships arranged by the university were the only significantly effective service to promote employment, controlling for participant age and education level. By contrast, the basic school services did not predict employment outcomes. Furthermore, acquiring the skills for independent commuting enabled autistic young adults to enter the workplace successfully. In particular, motorized mobility (e.g., driving cars and riding scooters) was a stronger predictor of positive employment outcomes than non-motorized mobility (e.g., biking).

Conclusions: Our study demonstrates the importance of job immersion for college autistic students in obtaining employment. Through these opportunities to experience actual workplace culture, autistic students may be able to transition and adjust to a career more easily. Additionally, motorized mobility allows for students to access these opportunities on their own, further fostering their sense of independence. Our findings suggest that local businesses, perhaps with governmental support, should work with universities to ensure that internships are available not only for neurotypical college students but their autistic peers as well.

424.243 Sensory-Friendly Dental Care: Results from a Randomized Controlled Crossover Trial Adapting the Dental Environment to Improve Care for Autistic Children

L. I. Duker (Stein)¹ and J. Polido², (1)Chan Division of Occupational Science and Occupational Therapy, University of Southern California, Los Angeles, CA, (2)Children's Hospital, Los Angeles, Los Angeles, CA

Background: Many autistic children experience poorer oral health and greater oral care challenges compared to neurotypical peers; research suggests these are associated with sensory over-responsivity. It is important to identify innovative solutions to improve the dental care experience for autistic children, as well as enable dentists to successfully perform standard clinic-based procedures for this population.

Objectives: To determine if a sensory adapted dental environment (SADE) reduces physiological and behavioral distress in autistic children undergoing dental cleanings, compared to a regular dental environment (RDE). Quality of care, cost, and satisfaction were also examined.

Methods: This randomized controlled crossover trial was conducted at a pediatric dentistry clinic in a large urban children's hospital. Autistic children 6-12yrs underwent two dental cleanings 6mo apart (1 each in SADE and RDE) in a randomized and counterbalanced order. Visual, auditory, and tactile stimuli were modified in the SADE. Outcomes included: physiological stress (electrodermal activity); behavioral distress (dentist-report and coding of video-recordings); resource utilization metrics as cost proxies (duration, staffing); quality of care (scored intraoral photographs), and child/parent satisfaction (1-5pt Likert scale). Mixed effects regression models were performed to assess physiological/behavioral distress; multivariate linear regressions and repeated-measures ANOVA assessed cost and quality measures, respectively.

Results: Autistic children (n=162) had a mean age of 9.16 years and were primarily male (84%), Hispanic (72%), and with expressive language abilities equal to or less than a four-year-old (66%). Significantly lower physiological stress and video-coded behavioral distress were found in SADE vs. RDE (all $p < .05$), suggesting decreased sympathetic activity and increased relaxation during care in the SADE. Findings also support that physiological stress was predictive of behavioral distress during the dental cleaning; age, IQ, and expressive communication moderated the intervention's success. No significant differences were found in cost or quality measures for SADE vs. RDE. High satisfaction was reported by caregivers (M=4.6/5) and children (M=4.2/5) for care in the SADE, with parents stating that the SADE improved child experience (M=4.4/5).

Conclusions: Identifying innovative solutions to enhance oral care is critical for autistic children. This is the first large-scale study, to our knowledge, to examine the efficacy of a SADE to improve dental care for autistic children. Dental cleanings performed in a SADE can be provided at the same quality as in an RDE for autistic children with no additional treatment-related costs, but with greater satisfaction and decreased physiological and behavioral distress. Use of a SADE is relatively inexpensive, scalable, and easy to implement with minimal training. The use of a SADE for children with special health care needs and/or dental fear/anxiety has recently been added to the American Academy of Pediatric Dentistry's List of Behavioral Guidance Best Practices.

424.244 Social Improvements in Autistic Teens: Behaviorally Coded & Computational Linguistic Analysis of Conversation Skills

A. R. Bordofsky¹, T. W. Vernon², C. Faulk³, L. J. Fulop³, Z. Williams⁴, S. Cho⁵ and J. Parish-Morris¹, (1)UC Santa Barbara, Santa Barbara, CA, (2)UCSB Koegel Autism Center, Santa Barbara, CA, (3)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (4)Vanderbilt University, Nashville, TN, (5)Linguistic Data Consortium, University of Pennsylvania, Philadelphia, PA

Background: Autistic adolescents often experience vulnerabilities in social communication and challenges with establishing desired social relationships with others (Martínez-González et al., 2022). Social skills interventions such as the Social Tools And Rules for Teens (START) program aim to improve social competence and motivation in autistic adolescents and reduce autism-related social communication difficulties (Vernon et al., 2018). Recent advances in computational linguistics, machine learning, and large language models highlight the potential of these tools for objectively quantifying improvements in social function over time. In this study, we use computational linguistics, or computer-assisted analysis of the verbal profiles of autistic adolescents to characterize and objectively assess social growth in autistic adolescents participating in a randomized controlled trial (RCT).

Objectives: The first aim of this study is to evaluate the use of computational linguistics as an effective outcome measure for a completed RCT of the START Program. The second aim of this study is to explore whether linguistic markers of social communication success differ by speaker (male and female) and interlocutor context (same-sex vs. opposite-sex conversations).

Methods: Participants were 35 autistic adolescents (12-17 years old) with verbal IQs greater than 70. The treatment group was composed of 16 participants and the waitlist control group included 19 participants (35 total). Participants attended weekly 90-minute sessions focused on a variety of social skills for 20 weeks. 421 five-minute conversations between adolescent participants and 140 young adult social partners were collected at intake, 5 weeks, 10 weeks, 15 weeks, 20 weeks (post), and follow-up (40 weeks). Conversations were analyzed using (a) behavioral coding for selected social behaviors (i.e. questions asked, positive affect, minimal encouragers, and eye contact) and (b) computational linguistics including text-based metrics, acoustic features, and conversation-based metrics.

Results: Analysis of START RCT outcome data revealed significant Group $\times$ Time treatment effects for overall social impression ratings and multiple verbal and nonverbal social behaviors, including questions asked ($p=.035$), listening behaviors ($p<.001$), eye contact ($p=.003$), and positive facial expressions ($p=.009$). Compared to waitlist controls, analyses also revealed that START participants experienced significant improvements in parent endorsed social communication skills (SSIS-parent, $p<.001$), autism symptoms (SRS-2, $p<.001$), and teen self-endorsements (SSIS-self $p=.011$). Preliminary linguistic analyses showed that adolescents who participated in the START Program produced more friend-related words, second-person pronouns, and saw increased stability in their voices post-intervention. Linguistic analyses are ongoing and will be complete by May 2025.

Conclusions:

Behavioral coding and preliminary computational linguistic analyses both yielded evidence of increased reciprocal interest/engagement (i.e. question asking, friend-related word use, second-person pronoun use) and enhanced overall comfort (i.e. positive affect, increased voice stability) after participation in the START Program. This overlap suggests that the use of computational linguistics may be effective for measuring improvements in social outcomes and highlights the potential for this tool to be used to tailor interventions to the unique needs of autistic individuals.

424.245 Depression and Anxiety Symptom Change during Psychological Therapy for Autistic Clients: Evidence from National Healthcare Records in England

R. T. Pender¹, C. El Baou², L. Crane³, R. Saunders⁴, A. Spector², J. Stott⁵, A. John⁶, M. Richards⁷, E. O'Nions³, J. Buckman⁷ and S. Pilling²,
(1)Division of Psychology and Language Sciences, University College London, London, United Kingdom, (2)University College London, London, United Kingdom, (3)University of Birmingham, Birmingham, Birmingham, United Kingdom, (4)Research Department of Clinical, Educational & Health Psychology, University College London, London, London, United Kingdom, (5)University College London, London, London, (6)UCL, London, England, United Kingdom, (7)University College London, London, United Kingdom

Background: Autistic people appear less likely to benefit from currently-recommended mental health treatments. Intervention development and adaptation is hampered by a lack of knowledge regarding whether subgroups of autistic people differ in their degree of risk, and what characterises subgroups of autistic people who respond differently to interventions.

Objectives: This study aimed to be the first to 1) identify trajectories of depression and anxiety symptoms during routine psychological therapy for autistic people, 2) describe the characteristics of groups that followed particular symptom trajectories, and 3) calculate the odds of following different types of symptom trajectory, based on pre-treatment risk factors.

Methods: Sessional anxiety and depression symptom scores for N=7,175 autistic individuals accessing National Health Service Talking Therapies for anxiety and depression (NHS TTad) services between 2012-19 across England were drawn from a linked, national healthcare record dataset (MODIFY). Growth Mixture Modeling (GMM) is a data-driven statistical approach that identifies relatively homogeneous subpopulations within heterogeneous data, resulting in distinct longitudinal trajectories. GMM models were estimated for depression (Patient Health Questionnaire-9) and anxiety (Generalised Anxiety Disorder-7) symptom severity change over eight psychological intervention sessions. Latent trajectory classes were described in relation to demographics (gender, age, ethnicity) and pre-treatment clinical variables (psychotropic medication, long-term health condition, Intellectual Disability and functioning - Work and Social Adjustment Scale).

Results: Seven different anxiety trajectories, and five depression trajectories were observed. Groups showed stable, improving or deteriorating symptoms during treatment. Trajectories became clearly distinct by the third treatment session. Lower pre-treatment global functional impairment was associated with likelihood of following trajectories defined by initially severe depression and anxiety symptoms that improved during treatment, relative to trajectories showing limited improvement in severe clinical ranges [OR(95%CI) = .91(.86 - .96); .93(.89-.97)]. Lower pre-treatment impairment in social leisure activities was associated with likelihood of either rapid or gradual anxiety improvement, compared with a trajectory showing limited improvement in the severe clinical range [OR(95%CI) = .76(.69 - .83); .85(.78-.93)]. Identifying as belonging to an ethnically-minoritised group was associated with increased likelihood of deteriorating anxiety symptom trajectories during treatment compared with trajectories showing limited improvement in severe or moderate clinical ranges [OR(95% CI) = 2.66(1.24-5.68) 3.83(1.34-10.96)]. Female gender, older age, presence of an Intellectual Disability diagnosis and psychotropic medication use were associated with likelihood of following trajectories showing limited improvement, in mild or moderate clinical ranges.

Conclusions: Pre-treatment impairment in global functioning and social leisure was associated with lower odds of benefiting from mental health intervention. Belonging to an ethnically-minoritised group was associated with higher odds of deteriorating anxiety during treatment. Findings highlight the value of examining early change in treatment response, and identifying individuals at risk of poorer outcomes before treatment has begun. After the third treatment session, clinicians could identify a likely change trajectory and consider adapted or augmented intervention if there is no improvement. Interventions should be adapted on the basis of individuals' cultural backgrounds and autism. Augmented intervention approaches that address social and functional impairment may be promising in improving treatment outcomes for autistic people.

424.246 Social Skills Improvements in Autistic Youth: A Pilot Study of the Superflex Curriculum and Minority Status Differences

K. Walker¹, A. S. Nahmias² and M. D. Lerner³, (1)Stony Brook University, Stony Brook, NY, (2)AJ Drexel Autism Institute, Drexel University, Philadelphia, PA, (3)A.J. Drexel Autism Institute, Drexel University, Philadelphia, PA

Background: Social differences, a well-established autistic trait (APA, 2013), may influence interpersonal relationships, academic achievement, and psychological well-being (Silveira-Zaldivar et al., 2021), with evidence showing that Black and Latino autistic children experience greater social isolation than their White peers (Azhad et al., 2017). Certain interventions may be less effective for minority groups due to cultural mismatches, highlighting the need for culturally responsive approaches to maximize their impact (Smith et al., 2011). The Social Detective/Superflex (SD/S) curriculum series is a social skills intervention that is widely disseminated across school and clinic settings and is endorsed by professionals (Yadlosky, 2012). While recent efforts have been made to enhance the inclusivity of SD/S (e.g. updating materials to better reflect diverse groups), the impact of children's minority status on changes in social skills from the SD/S remains unexplored.

Objectives: This pilot study examines the impact of minority status on social skills outcomes across SD/S. We predicted that caregivers of children from a minority background would report less change compared to caregivers of White Non-Hispanic children.

Methods: As part of a larger study, seven autistic children (Table 1) participated in SD/S, which met weekly for 20 weeks at a university laboratory. Caregivers' reported child demographic information (e.g., age, sex, race/ethnicity) and pre- and post-intervention social skills (Social Skills Improvement System Social Skills subscale (SSIS), child use of SD/S vocabulary). Pre- and post-intervention social skills scores were compared using t-tests. Linear regression was conducted to assess the influence of minority status on changes in social skills, controlling for age and sex.

Results: Parent-reported social skills (SSIS and child use of SD/S vocabulary) significantly improved from pre- to post-SD/S (*p-values* < 0.035; Table 1). Minority status significantly predicted changes in social skills (i.e., minority children experienced less improvement), controlling for age and sex, on the SSIS ($B = -16.00, p = 0.007$ (Figure 1)) and in report of children's use of SD Vocabulary ($B = -1, p < 0.001$), but not Superflex Vocabulary ($B = -0.25, p = 0.85$).

Conclusions: Caregivers reported significantly improved social skills outcomes for autistic children that participated in SD/S. However, children from a minority background experienced less improvement in social skills (SSIS and Social Detective Vocabulary) compared to their White peers. Interestingly, minority status did not predict changes in Superflex Vocabulary use. This difference may result from recent updates to the Superflex materials, which are more current and potentially more culturally responsive than those of Social Detective. However, further research with larger and more diverse samples is necessary, as the disparity may indicate SD/S curriculum does not fully account for cultural norms and communication styles, leading to less effective implementation and parental lower perceived gains in social skills. This study is limited by its small sample size and single-group pre-post design, highlighting the need for further with larger samples and randomized experimental designs. Recognizing minority status differences underscores the importance of considering racial/ethnic factors in social skills interventions, guiding future adaptations of SD/S to be more effective for diverse autistic youth.

424.247 Solution-Focused Brief Therapy for Autistic Young Adults

L. Minner¹, J. Hong¹, C. Lewin¹, A. P. L. Yu², C. Franklin¹ and S. Magana¹, (1)Steve Hicks School of Social Work, The University of Texas at Austin, Austin, TX, (2)Steve Hicks School of Social Work, University of Texas at Austin, Austin, TX

Background:

Autistic adults often face significant challenges in accessing appropriate behavioral health interventions, which can lead to increased mental health difficulties, including anxiety, depression, and suicidality. Despite the clear need, there is a notable gap in research on evidence-based behavioral health strategies tailored specifically for autistic adults. Solution-focused brief therapy (SFBT), with its strengths-based and goal-oriented framework, holds promise as a viable intervention for this population. However, little research has explored the efficacy of SFBT in autistic adults. For this study, we adapted the SFBT protocol based on clinical expertise and lived experience and piloted it with autistic adults.

Objectives:

For this analysis, our aim was to examine the feasibility and acceptability of the SFBT. Specifically, whether participants can be recruited and engaged in all sessions; and the usefulness of the intervention to them.

Methods:

We convened a team of researchers, social work clinicians who had experience working with autistic adults, students, and an autistic adult researcher to adapt the SFBT protocol. We worked with a community organization that serves autistic young adults to recruit five participants. Participants were four female and one male, and their ages ranged between 18 and 29 years old. We conducted four-weekly individual SFBT sessions with five autistic adults, followed by 45-to-60-minute post-intervention interviews that included open-ended questions. Using a phenomenological approach, we explored participants' overall experiences, helpful or challenging aspects, and suggestions for improvement through semi-structured interviews. Three interviews were audio-recorded and transcribed verbatim; two were manually transcribed. Thematic analysis identified key themes, supported by participants' direct quotes. An audit trail documented the entire analytic process to ensure rigor.

Results:

All five enrolled adults participated in pre and post interviews, and all four therapy sessions, demonstrating strong feasibility. Thematic analysis revealed four key themes: lessons learned by participants, helpful aspects, challenging aspects, and improvement suggestions. Participants reported positive experiences with SFBT, describing sessions as "helpful", "hopeful", and "made me feel happy". Lessons they learned included feeling empowered, stronger motivation to practice independent living skills, and deeper insights into their identities as autistic individuals. Participants expressed a desire to pursue changes in various life domains, including career, hobbies, and social circles. Participants identified helpful aspects as follow: Opportunities to reflect on self-identity, breakdown of the goal into smaller achievable tasks, and a strength-based approach that draws on participant's existing resources. Challenging aspects included difficulty understanding questions, inability to address structural issues, and logistical challenges, such as time constraints and transportation difficulties. For future improvements, participants suggested increasing the number of sessions, implementing more structured goals, and adopting a more individualized approach incorporating their special interests.

Conclusions:

Our study found that SFBT holds potential to be a viable intervention for autistic adults. SFBT's strength-based and goal-oriented framework was found to support the participants' exploration of self, a necessary step in effective mental health support. Further research is needed to examine the effectiveness of SFBT with this population.

424.248 State of the Science on Peer-Facilitated Interventions for Autistic People

L. Graham Holmes¹, C. J. Crompton², A. Newson³, R. Calderon⁴ and E. F. Rothman⁵, (1)Silberman School of Social Work, Hunter College, CUNY, New York, NY, (2)Centre for Clinical Brain Sciences, University of Edinburgh, Edinburgh, UNITED KINGDOM, (3)University of Oregon, Eugene, OR, (4)University of Texas at Dallas, Richardson, TX, (5)Occupational Therapy, Boston University, Sargent College, Boston, MA

Background:

Autistic people report high rates of unmet support needs. Some autistic adults find it difficult to connect with non-autistic supporters, who may have little education about or hold stigmatizing views of autism. Several studies suggest that autistic people learn well from other autistic people and benefit from hearing their experiences reflected and sharing information and solutions to common issues. Peer-facilitated interventions (PFIs) are provided by a person with lived experience with a condition and can include outreach, skill building, health coaching, case management, system navigation, or psychoeducation. PFIs could be a promising innovation for addressing the support needs of autistic people.

There is a large body of evidence for the effectiveness of PFIs for people in recovery from substance use disorder or mental health challenges. They are widely used across the mental health and veterans' health systems and considered an essential mental health service by the World Health Organization. PFIs have been shown to reduce inpatient hospitalization, substance use, social isolation, model community living, enhance social networks, and improve adherence and participation in treatment for non-autistic people.

Objectives:

To date, it is not clear whether PFIs are feasible, acceptable, or effective for autistic people. Some providers have expressed uncertainty about whether PFIs could be effective for autistic people. The objective was to review research on PFIs for autistic people and make recommendations for future research and practice.

Methods:

Using PRISMA guidelines, we conducted a scoping review of the English-language, peer-reviewed published articles on PFIs for autistic people of all ages. PFIs were defined as those in which at least one autistic person delivered the intervention to other autistic people, and an autistic facilitator was chosen based on their lived experience or autistic characteristics being expected to contribute to the efficacy of the intervention versus for other reasons such as proximity (e.g., in peer-mediated interventions in special education settings). Both formative research and tests of interventions were included.

Results:

We identified 4,157 studies, removed duplicates, and screened the remaining 1,561 studies. Of the articles reviewed, 15 met criteria for inclusion (see Table 1). Of these, 5 were formative research to inform development of a PFI, 9 were evaluations of PFIs and 2 were both formative and evaluation. All used community-engaged methods with autistic people in an advisory capacity (n=6) or engaged in co-production (n=9).

Intervention targets were diverse, including social or communication (n=9), improving mental health (x=2), improving cognition or executive function (n=1) or other targets (n=3) with secondary targets focused on well-being or quality of life for several studies. The intervention studies reported preliminary evidence of feasibility and efficacy. Both intervention studies and formative research reported a high degree of acceptability of PFIs.

Conclusions:

PFIs are a promising approach for meeting the needs of autistic people in a cost-effective, accessible, and acceptable manner and can be eligible for Medicaid reimbursement. Research gaps include stronger trial methods using comparison groups, methods for training and supervision of peer support specialists, and implementation of PFIs across different settings.

424.249 Study Retention in School-Based Autism Intervention Research: Factors Related to School Provider Attrition

L. Hayutin¹, A. Losh¹, L. DeVries², C. Middleton¹, S. Nickles³, K. Pickard⁴, L. G. Klinger⁵ and J. Reaven⁶, (1)University of Colorado Anschutz Medical Campus, Aurora, CO, (2)University of Colorado School of Medicine, Aurora, CO, (3)CU Anschutz, Denver, CO, (4)Emory University School of Medicine, Marcus Autism Center, Atlanta, GA, (5)TEACCH Autism Program; Psychiatry, UNC TEACCH Autism Program, Chapel Hill, NC, (6)Psychiatry, University of Colorado Anschutz Medical Campus, Aurora, CO

Background: An estimated 40% of autistic youth develop co-occurring anxiety (van Steensel et al., 2011), which can negatively impact experiences at school, with peers, and at home (Reaven et al., 2020). Schools are viewed as an important resource for identifying and addressing anxiety in autistic students (Adams et al., 2019); however, school providers often feel underequipped (Reyes et al., 2022), strained (Kerr & Brown, 2016), and in need of specific resources (Kester & Lucyshyn 2019). Despite evidence of a desire for training in evidence-based anxiety interventions for autistic youth, attrition is high in the field of special education and school providers face barriers (e.g., high burnout) to implementing EBPs (Billingsley & Bettini, 2019; Suhrheinrich et al., 2021). The current study explores characteristics of interdisciplinary school providers (ISPs) who withdrew from a school-based comparative-effectiveness trial, to determine potential barriers to ISP participation, which can inform future implementation research.

Objectives: Examine differences between ISPs who remained versus withdrew from a comparative effectiveness trial, including measures of stress and burnout, leadership support and implementation climate.

Methods: Interdisciplinary elementary and middle school providers (N=128) were enrolled in an ongoing cluster randomized controlled type 1 hybrid-effectiveness trial comparing the effectiveness of two school-based anxiety interventions, *Zones of Regulation* (ZOR; Kuyper, 2011) and *Facing Your Fears in School* (FYF-S; Reaven & Blakeley-Smith, 2024) for autistic students (Table 1). ISPs were degreed providers in any discipline working with autistic students (e.g., school psychologists; special educators). ISPs completed the following: Emotional Exhaustion subscale of the *Organizational Social Context Questionnaire* (Glisson et al., 2008), *Implementation Leadership Scale* (Aarons et al., 2014), and *Implementation Climate Scale* (Ehrhart et al., 2014), were randomly assigned to ZOR or FYF-S, and completed program-specific training. Post-training, ISPs were asked to deliver the assigned program to a small group of autistic students. Timing and reason for ISP study drops were tracked. Due to uneven group sizes, Welch t-tests were used to assess significant differences between ISPs who withdrew (N=27) and those who remained (N=101).

Results: See Figure 1 for reported reasons for study dropout. Welch t-tests revealed a significant difference in years of experience ($t(44.96)=7.42$, $p<.01$) between ISPs who dropped (mean=6.06 years; SD=6.11) and those who remained (mean=10.12 years; SD=8.15). There was also a significant difference in burnout ($t(21.87)=5.20$, $p<.05$) between ISPs who dropped (mean=12.5; SD=3.31) and those who remained (mean=10.42; SD=3.65). There was no significant difference between ISPs in their reported implementation climate or leadership.

Conclusions: Consistent with the literature (Suhrheinrich et al. 2021) ISPs were more likely to drop out from the study when they had fewer years of experience and higher levels of stress and burnout. Implementation climate and leadership did not differ between groups. These findings suggest that working to reduce stress and burnout among school providers and providing increased support for early career school professionals may help remove barriers for successful inclusion in research that could help inform evidence-based interventions (Locke et al., 2024a; Locke et al., 2024b).

424.250 Summer Program for Asian Autistic Youth: Program Development and Examination of Initial Efficacy and Social Validity
V. Y. Kang¹, E. Safarha², J. E. Kim³, M. Mann⁴, H. Lu⁴, A. La⁵, S. Awasi⁶ and S. Joo⁶, (1)Counseling, Higher Education, and Special Education, University of Maryland at College Park, College Park, MD, (2)University of Maryland at College Park, College Park, MD, (3)University of Maryland, College Park, MD, (4)Chinese Culture and Community Service Center, Rockville, MD, (5)Speech Garden, Rockville, MD, (6)University of Kansas, Lawrence, KS

Background: Asian autistic youth is growing yet no studies explored this population. During summer break, autistic youth and families often experience isolation and stress due to lack of community-based programs. While there is some research on summer programs for autistic youth, the program component and outcomes may not be generalizable to Asian communities who come from collectivistic culture.

Objectives: The study addressed the following research questions. 1. What are the characteristics of the Asian autistic youth who participate in a 6-week long summer program? 2. How do they engage in social interaction and discussion during the program? 3. How do parents perceive the social validity of the summer program?

Methods: The summer program was a 2 hour/week, 6-week long program that supported emotion regulation, sportsmanship, interpersonal skills, conversational skills, and friendship skills through literacy, arts, board game, gross motor game, and free play. Each staff member was assigned with two youths to provide behavior support. 19 youth and 10 staff participated in the program. 13 parents/14 youth consented to participate in the surveys/interviews. Youths' age ranged from 5-12 years and were predominantly bilingual Asians. A pre-program survey was completed by the parent. Staff collected data on youth behaviors during the social activities and discussion. Parents completed the Treatment Acceptability Rating Scale and an interview to evaluate the social validity of the program after the last session. Descriptive analysis was conducted with the demographics, youth behaviors, and parent questionnaires. Two coders engaged in iterative coding of interview transcripts to identify emerging themes.

Results: The Asian autistic youth had moderate levels of autism based on the Autism Symptoms Dimensions Questionnaire (M=2.93 out of 5) and the quality of their peer relationship was low based on the Parent-reported Peer Relations Questionnaire (M=32.3 out of 80). The greatest changes in youth behavior were (1) sharing an idea (M=21.9%, of the time W1 to 40%, W5); and (2) making comments to a peer/staff's idea (M=16.5%, W1 to 29%, W5). The frequency of social skills showed greatest improvement after staff's verbal/gestural prompt (M=62, W1 to 85.5, W5). 72% parents believed the program aligned with children's goals. 57% believed the program made long-term positive impact. Parents shared, "This kind of opportunity is rare. It is beneficial for children who feel comfortable in a small group.", and "It gives us [parents] a little bit of a break.", "It was great that this was specifically for special needs kids ... It helped with social behavioral skills." and "We come from different cultures, different ways of raising your kids We're all in the US, but in our homes, we might be slightly different."

Conclusions: Summer program for Asian autistic youth is rare and beneficial for both youth and parents. Future research could explore cultural adaptation of the program to create more inclusive and meaningful social interaction opportunities. Measurement/assessment of youth behaviors during sessions could be standardized to evaluate the impact of the program on youth outcomes.

424.251 Supporting Hygiene and Social Safety through a Parent-Led Sexual Health Education Program for Autistic Youth
L. DeVries¹ and C. Middleton², (1)University of Colorado School of Medicine, Aurora, CO, (2)University of Colorado Anschutz Medical Campus, Aurora, CO

Background: While most youth experience some difficulties adapting to the changes of their bodies during puberty, autistic youth may face heightened challenges in understanding and addressing hygiene needs and social demands that arise in the teenage years (Corona et al., 2016). Parents are well-positioned to provide coaching on topics related to the teenage years to their children; however, there are limited resources for caregivers of autistic youth (Cosgrove et al., 2024) and providers often neglect puberty-specific challenges (Larson et al., 2021). Although two of the most important topics for parents include caring for changing bodies and social safety (Nichols & Blakeley-Smith, 2009), there is little research examining specific parent goals in this area and support needs. Moreover, it is relatively unknown if parent-led programming can yield greater independence in these areas. It is important to understand which hygiene and social safety skills are most important for parents at the time of program delivery as this will allow interventions to be better tailored to parent needs.

Objectives: The main goal of the present study was to examine the most common pre-intervention parent goals. An exploratory goal was to determine if there were individual changes in hygiene skill acquisition pre-post intervention for a small subsample of participants.

Methods: The present subsample includes nine parents of cisgender male youth between the ages of 10-18 ($M = 12.05$ years). Parents were participating in a larger, randomized controlled trial comparing a novel parent-led sexual and reproductive health education (SRE) program, Birds & Bees, to a widely available SRE resource guide. Only parents randomized to receive Birds & Bees complete the Parent Goals interview, a brief 20-minute interview to identify individualized goals from a pre-determined list of possible outcomes, modeled after Goal Attainment Scaling (GAS; Ruble et al., 2012). Parents indicated the level of support their child needed for each skill area and rated their top three goals for their child pre and post intervention (see Table 1 for scoring). Complete data will be available by December 2024.

Results: Youth in the sample showed the most independence with wearing undergarments and oral hygiene. They showed the least independence with deodorant use. See Figures 1 and 2 for top priorities related to hygiene and social safety, respectively. Post intervention, a third of teens showed greater independence in at least one of the following areas: Deodorant use, Shaving, and Oral Hygiene. Over half of participants at post reported increased conversations regarding social safety and utilizing additional strategies (e.g., resources, teaching skills, etc). Complete results are forthcoming.

Conclusions: Functional outcomes are important to include in newly developed interventions, particularly when youth are the target of the intervention, but are not directly involved in the delivery. Results indicated that parents have many overlapping concerns in SRE skill development and even if youth are independent in the specific skill, the quality and frequency of use is important to parents. Based on a small subsample, there are some changes to youth independence in hygiene skill acquisition from pre to post intervention.

424.252 Supporting Inclusion and Belonging for Autistic Students: A Pilot Study of a Peer Educational Program in the Early School Years

S. Carstensen-Sinha¹, S. Thompson-Hodgetts², H. M. Brown³, S. Manilall⁴ and J. DuVal¹, (1)Faculty of Rehabilitation Medicine, University of Alberta, Edmonton, AB, Canada, (2)Occupational Therapy, University of Alberta, Edmonton, AB, Canada, (3)Educational Psychology, University of Alberta, Edmonton, AB, Canada, (4)Edmonton Catholic Schools, Edmonton, AB, Canada

Background: Social inclusion and belonging are fundamental to well-being. Autistic students are at high risk for experiencing social exclusion, which negatively impacts their learning and well-being. Educational interventions aimed at increasing classmates' understanding of autism might support inclusion and belonging.

Objectives: Through this feasibility and pilot study we: (1) co-designed a feasible (time, training, cost), peer-focused, educational intervention intended to improve peer understanding, engagement and inclusion of autistic students, and (2) evaluated outcomes of the intervention on (a) peer engagement between autistic and other students, and (b) perceptions on inclusion, operationalized as belonging, acceptance, and valuing of autistic students.

Methods: Two classes of students at two different elementary schools participated. A weekly, 40 minute intervention was completed with each class over three weeks. Each session consisted of reading a book with a diversity awareness theme, a facilitated discussion, and a related creative activity. Interventions were led by the researcher, an occupational therapist who also has an autistic child. As such, her personal stories were also integrated into discussions with students and activities. The discussions covered general awareness of diversity, how autistic and non-autistic people can work together, and finding common ground. Photographs of student work were collected. Semi-structured interviews were completed with classroom teachers ($n=2$), educational assistants ($n=3$) and selected students ($n=10$). The interviews were recorded, transcribed and, along with students' work and reflexive memos, were analyzed through a process aligned with reflexive thematic analysis.

Results: Preliminary themes include: (1) *Good citizen vs. good friend* - students' intentions shifted from a charity and service mindset to one of connection; (2) *"That's just autism"* - students began to understand autistic behaviour as just another way of being, and began to more positively reframe their perceptions of their autistic peers; (3) *Permission to address the "elephant in the room"* - students felt that the intervention gave them permission to talk frankly about autism, which allowed them to develop a fuller understanding of their autistic peers; (4) *"I thought it was just me"* - through an exploration of diversity, students discovered that many (non-autistic) peers felt "different" in one way or another. Acknowledgement of the universality of these feelings led to new and more authentic social connections across the class as a whole, (5) *Lived experience as an active ingredient* - students discussed the researcher's personal stories frequently during the interviews, and (6) *"I could use that"* - staff developed new skills and approaches to support community development and inclusion in their classrooms that they planned to use in the future.

Conclusions: A short educational intervention with peers supported a shift in attitudes and understanding towards autistic peers and each other in an inclusive elementary classroom. The influence of the intervention on the experience of belonging for autistic students was less apparent. Lived experience may be a key component of interventions that target attitude and behaviour change.

424.253 Teachers' Experiences Implementing Time2Connect As a Strategy to Build Positive Relationships with Autistic Students

O. E. Hughes¹, G. Vecsey², A. Eisenhower³, J. Blacher² and N. Hamsho², (1)University of Massachusetts Boston, Boston, MA, (2)Department of Psychology, University of Massachusetts Boston, Boston, MA, (3)School of Education, University of California, Riverside, CA

Background: Student-teacher relationships characterized by warmth and open communication promote students' social integration, emotional and behavioral adjustment, and academic engagement (McGrath & Van Bergen, 2015; Losh et al., 2022). However, relationships between autistic students and their teachers are often characterized by low levels of closeness and high levels of conflict (Blacher et al., 2014, Zee et al., 2020). There is a need for feasible strategies to improve such relationships.

Objectives: As part of a larger autism-focused professional development (PD) program, *Smooth Sailing*, teachers were taught to engage in Time2Connect (T2C) sessions, short (3-10 min), one-on-one interactions with a focal autistic student during the school day. T2C incorporates evidence-based strategies to promote positive student-teacher relationships and is child-led, non-directive, and communicates teacher enthusiasm about the students' interests. The purpose of this study is to understand teachers' experiences using T2C. We examined (1) teachers' implementation of T2C strategies, including their frequency and maintenance, (2) teachers' perspectives of the feasibility and acceptability of implementing T2C, and (3) teachers' perspectives of the benefits of T2C.

Methods: Twenty-one teachers participated with an autistic focal student in their classroom (29% teachers of color, 62% students of color). Teachers taught general education classes in kindergarten (76%), first grade (5%), or second grade (19%) in MA (29%) or CA (71%). Teachers were asked to implement T2C sessions 3-5 times/week during their participation in the larger 4-week PD program; their frequency of usage during the program and their maintenance of T2C sessions after the program was monitored through teacher-report surveys (Aim 1). Throughout the program, teachers reported on T2C's feasibility and acceptability (Aim 2) and answered open-ended questions about how their student responded to T2C and what they learned about the student (Aim 3). We conducted a thematic analysis of the open-ended responses.

Results: All teachers implemented T2C sessions (mean: 9.45, range: 1-50), at an average of 3 sessions per week (range: 1-10). All teachers reported fully or partially using the learned strategies (following the child's lead, descriptive commenting, and shared enthusiasm) and 97-100% of teachers reported fully or partially avoiding directives, academic instruction, and asking questions. 76% of teachers reported avoiding questions to be a challenging T2C strategy to implement.

For feasibility and acceptability, all teachers rated T2C as helpful and effective and 90% of teachers agreed or strongly agreed T2C helped them get to know their student. Some teachers (40%) found it difficult to schedule T2C sessions, yet, all teachers planned to continue to implement T2C with the focal student and other students. Preliminary thematic analysis showed T2C provided opportunities for students to show more of themselves and allowed teachers to develop a more nuanced appreciation of their students' strengths. After T2C, teachers noted improvements in the students' comfort in the classroom. Full analyses are ongoing.

Conclusions: Results suggest T2C is a promising approach for K-2 general education teachers to get to know their autistic students, recognize their students' interests and strengths, and to ultimately reduce conflict and promote closeness between autistic students and their teachers.

424.254 Teaching Autistic Students Using Robot Assisted Instruction

P. LaCava, *Rhode Island College, Providence, RI*

Background: Technology-Aided Instruction has been rated as an evidence-based practice for autistic students (Steinbrenner et al., 2020). Following technological advances, there have been increased investigations using robot assisted interventions (Kumazaki et al., 2020). Robot instruction leverages autistic preferences, desire for predictability, repetition, etc., while increased engagement and short-term improvement of several skills has been noted as an intervention outcome (Gómez-Espinoza et al., 2024; Holeva et al., 2022). Despite these successes and technology's potential, well known barriers exist. These include minimal intervention length, small sample size, lack of standardized implementation, focus on clinic settings, etc. (Santos et al., 2024; Yuan et al., 2021).

Objectives: This exploratory study is the first step in a multi-phase project. Our study objectives are to 1) determine the feasibility and effectiveness of using a robot assisted curriculum with autistic students in school settings, and 2) understand stakeholders' perceived implementation successes and challenges.

Methods: Over a 6-month period, we implemented a mixed methods approach in a public school in Southern New England. We collected observation data on the conversation skills of 7 autistic students (ages 6-13) across a multiple baseline design. We collected descriptive data to track participant use of the Robokind robot (Milo) and curriculum (conversation skills module) including engagement, time used, quiz scores, etc. A facilitator guided students through lessons using Milo and an iPad. Qualitative interviews were conducted with students, families, and teachers at the conclusion of the study.

Results: Students used Milo for an average of 17 minutes per weekly session while lessons averaged 6 minutes. While most students increased conversation skills from baseline to intervention phases, no causal relationship between variables was observed. Feedback from stakeholders was mixed with generally positive comments. While most students enjoyed using Milo, one student withdrew from the study due to boredom.

Conclusions: Robot assisted instruction was observed to be feasible in a school setting as it took minimal time and facilitator training, and students were rated by observers as typically highly engaged. All stakeholders were very willing to try this technology in a school setting. While promising, more research is needed to address limitations. In the next phase of this project, a rigorous single case design will be implemented with a more diverse student population.

424.255 6-Month Follow-up Outcomes of CBT Practices in Treating Anxiety in Autistic Children

K. Sung and **J. Wood**, *Human Development & Psychology, University of California Los Angeles, Los Angeles, CA*

Background:

Anxiety is a common co-occurring challenge among autistic children that often interferes in several domains including home, school, social settings, and daily living. While both standard and adapted practices of cognitive behavioral therapy (CBT) are found to be efficacious in addressing anxiety among autistic children, adapted CBT practices have been shown to be more efficacious in reducing anxiety levels, as well as in addressing emotion regulation, social communication, and adaptive functioning. At present, less is known about the longer term outcomes of both standard and adapted CBT practices in supporting anxious autistic children.

Objectives:

The present study is a secondary data analysis of a multi-site randomized clinical trial that compares the longer-term outcomes of adapted and standard CBT practices in addressing clinically significant anxiety and social communication challenges among autistic children through the following questions: 1) Does adapted CBT produce superior outcomes to standard CBT at the 6-month follow-up? and 2) Do both groups (i.e., standard and adapted CBT) maintain treatment outcomes from post-treatment to 6-month follow-up?

Methods:

In the original study, volunteer participants ($N = 167$), between the ages of 7 and 13, and their families were recruited from 3 cities in the US, and were randomized to receive 16 weekly sessions of adapted CBT, standard CBT, or treatment as usual. Participants randomized to adapted CBT or standard CBT were administered follow-up measures 6 months following active treatment.

The Pediatric Anxiety Rating Scale (PARS; RUPP, 2002), an independent evaluator clinician-rated scale, was used to measure anxiety. The Social Responsiveness Scale–Second Edition (SRS-2; Constantino & Gruber, 2005), a parent-reported scale, was used to measure social communication challenges. Both measures were administered at baseline, mid-treatment, post-treatment, and 6-month follow-up.

In line with the primary data analyses, general linear mixed models (GLMMs) were utilized to compare the longer-term outcomes of both adapted and standard CBT in addressing anxiety and social communication challenges from baseline to 6-month follow-up, as well as the stability, from post-treatment to 6-month follow-up.

Results:

Condition (i.e., adapted CBT, standard CBT) was significantly associated with the outcome variable on the scale for anxiety, PARS ($b = 0.297$, $SE = 0.141$, $t = 2.082$, $p = .037$, 95% CI [0.017, 0.571]), as well as the scale for social communication, SRS-2 ($b = -0.148$, $SE = 0.066$, $t = -2.259$, $p = .025$, 95% CI [-0.278, -0.019]). There were no significant differences between conditions from post-treatment to 6-month follow-up in the scales for anxiety and social communication ($p = .441-.519$).

Conclusions:

While both groups (i.e., adapted CBT, standard CBT) demonstrated lower levels of anxiety and social communication challenges during the 6-month follow-up, adapted CBT outperformed standard CBT on both scales, suggesting the potential advantages of a modular-based, personalized CBT approach in addressing the specific challenges experienced by anxious autistic children.

424.256 The Effectiveness of an Adapted Psychological Intervention for Depression for Autistic Adults: The Autism Depression Trial (ADEPT-2)

A. Russell¹, K. Cooper², D. Dagnan³, B. Ingham⁴, P. E. Langdon⁵, N. Wiles⁶, D. Rai⁷, D. Kessler⁸, J. Horwood⁹, A. X. Realpe⁸, C. Metcalfe⁸, L. Cotton⁹, J. Thorn¹⁰ and M. Vazquez Morales⁹. (1)Centre for Applied Autism Research, Psychology, University of Bath, Bath, UNITED KINGDOM, (2)Department of Clinical, Educational and Health Psychology, University College London, London, London, United Kingdom, (3)Community Learning Disability Services, Cumbria, Northumberland, Tyne and Wear NHS Foundation Trust, Workington, Cumbria, United Kingdom, (4)Cumbria, Northumberland, Tyne & Wear NHS FT, Newcastle upon Tyne, Tyne and Wear, (5)University of Birmingham, Birmingham, West Midlands, United Kingdom, (6)Centre for Academic Mental Health, University of Bristol, Bristol, Bristol, United Kingdom, (7)Population Health Sciences, Bristol Medical School, University of Bristol, Bristol, United Kingdom, (8)University of Bristol, Bristol, United Kingdom, (9)Bristol Trials Centre, University of Bristol, Bristol, Bristol, United Kingdom, (10)Bristol Medical School, University of Bristol, Bristol, Bristol, United Kingdom

Background: Autistic people are disproportionately affected by depression. Evidence based psychological treatments for mild-moderate depression include low intensity cognitive behavioural therapy (CBT). Low intensity CBT for depression ordinarily comprises provision of evidence-based information with support from a therapist and is widely available in the UK healthcare context. However, it was not developed specifically for autistic people who can experience difficulties accessing standard psychological treatments. A low-intensity CBT intervention (Guided Self-Help: GSH) was developed in collaboration with autistic advisors (Russell et al., 2020). A pilot RCT demonstrated GSH was acceptable and feasible and warranted further investigation in respect of effectiveness.

Objectives: This study reports the results of a two parallel group multi centre pragmatic randomised controlled trial (RCT) (ISCRTN 17547011) conducted in UK statutory healthcare services investigating the effectiveness of GSH.

Methods: To test effectiveness, 266 Autistic adults (≥ 18 years) eligible and consenting to participate in the study were randomised to GSH or Treatment as Usual (TAU). TAU was described as NHS support for depression and is carefully characterised during the study. Randomisation was stratified according to baseline Beck Depression Inventory (BDI-II) score, trial centre and anti-depressant medication. Participants randomised to GSH were provided with intervention materials and offered 9 individual sessions delivered remotely with a therapist coach who had received training in the intervention. All participants are followed up at 16-, 32- and 52-weeks post-randomisation. The primary outcome is the BDI-II score at 16 weeks. Secondary outcomes include self-report measures of depression, anxiety, work and social adjustment, quality of life, patient rated global outcome and health and social care resource use. A public and patient involvement and engagement (PPIE) group are involved in the design, conduct and reporting of the study.

Results: The RCT has recruited above target (266/243 (109%). Thirteen participants withdrew from the study to date. Of 132 participants allocated to GSH, 109 (82%) completed the intervention. Follow-up rates at 16 and 32 weeks are 89% and 80% respectively with final follow-up of 52 weeks currently at 80%. We will report on the primary intention-to-treat analysis comparing BDI-II scores at the 16-week follow-up between the groups as allocated

Conclusions:

The results of this study will help us to understand if evidence-based psychological interventions adapted for autistic people can be effective when delivered in routine care. Issues relevant to implementation will be considered based on the findings.

424.257 The Effects of Internalizing Symptoms on Adolescent Outcomes of the PEERS® Intervention

M. K. Guell¹, K. A. Willar², A. Haendel³, A. Arias⁴, S. Pleiss⁵ and A. V. Van Hecke¹, (1)Psychology, Marquette University, Milwaukee, WI, (2)Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Stanford, CA, (3)Marquette University, Milwaukee, WI, (4)University of California, Santa Barbara, Santa Barbara, CA, (5)Goldfinch Neurobehavioral Services, Eden Prairie, MN

Background: The Program for the Education and Enrichment of Relational Skills (PEERS) is effective at improving social skills of autistic youth. However, few studies have examined the suitability of PEERS for youth with comorbid mental health concerns. Research suggests that autistic youth are highly likely to have co-occurring disorders (Simonoff et al., 2008), especially internalizing disorders, such as anxiety and depression (Greenlee et al., 2016; Hudson et al., 2019; Van Steensel et al., 2011). Comorbid internalizing disorders are linked with poorer social skills in autistic youth (Ambrose et al., 2021).

Objectives: This study explores the effects of internalizing symptoms (IS) on outcomes of the PEERS intervention by examining the relationship between IS and 3 composite outcome variables (i.e., social awareness, social interaction, social communication) before and following the intervention.

Methods: 61 autistic youth ages 11–17 ($M=13.54$, $SD=1.31$; 86.89% male) who completed the PEERS program were included in the analysis. Caregivers completed the Child Behavior Checklist (CBCL; Achenbach, 2001), Social Responsiveness Scale (SRS-2; Constantino & Gruber, 2012), Social Skills Improvement System (SSIS; Gresham & Elliott, 2008), Test of Adolescent Social Skills Knowledge (TASSK; Laugeson et al., 2009), and Social Communication Questionnaire (SCQ; Rutter et al., 2003).

Meaningful Grouping, which uses non-statistical methods to group variables based on the interpretation of variables' meanings, was used to create composite outcome variables (Song et al., 2013). This allows outcome measures assessing similar domains to be grouped, allowing for a broader understanding of changes in social functioning. Composite outcome variables were calculated using the average of z-score transformations of the standardized original scores produced by each of the variables comprising the composite (see Table 1 for groupings).

Results: Paired-samples t-tests examined changes between pre- and post-intervention timepoints for three composite variables. All showed an increase from pre- to post-treatment, indicating improvement in social skills (Awareness: $t(51)=-9.38$, $p<.001$; Cohen's $d=1.30$; Interaction: $t(51)=-5.36$, $p<.001$; Cohen's $d=.74$; Communication: $t(51)=-5.08$, $p<.001$; Cohen's $d=.70$).

Hierarchical regression was conducted to predict participants' awareness, interaction, and communication at pre- and post-treatment. If indicated, covariates (e.g., gender, IQ, autism severity, medication status) were included in the first step, and IS (CBCL Internalizing Problems) was included in the second step of the model for pre-intervention analyses. When examining post-treatment outcomes, pre-intervention composite scores were included in the first step of the models. Complete results of the hierarchical regression models can be found in Table 2.

At pre-intervention, IS was a marginal predictor of awareness, whereas at post-intervention, it was non-significant. For interaction, IS was a significant predictor at pre-intervention, but only a marginal predictor at post-intervention. Lastly, IS was not a significant predictor of communication at either timepoint.

Conclusions: Findings indicate that the composite variables are sensitive to change between timepoints. Although IS did predict pre-treatment social interaction, it did not consistently predict social functioning following the intervention. As such, higher levels of IS do not appear to interfere with youth's ability to access and utilize the PEERS curriculum. Future work will examine the PEERS program with youth with confirmed diagnoses of internalizing disorders.

**424.258** The Feasibility of Non-Specialist Health Workers Delivering a Social Communication Intervention in New Delhi (India) Delivered in a Community Setting.

M. .¹, V. Rana², M. Verma³, **G. Divan⁴**, C. A. Taylor⁵, J. Green⁵ and V. Vajaratkar⁶, (1)Sangath India, New Delhi, Delhi, India, (2)Sangath, New Delhi, Delhi, India, (3)Sangath, Goa, Goa, India, (4)Child Development Group, Sangath India, New Delhi, India, (5)University of Manchester, Manchester, United Kingdom, (6)Sangath, New Delhi, India

Background:

Autism Spectrum Disorder (ASD), is a developmental disorder with a prevalence of 1 per cent in India. Hence there are over two million young children with autism requiring support, the majority of whom lack access to evidence-based care. The UK's Pre-school Autism Communication Therapy (PACT) has been shown to be effective and was adapted and expanded for use by non-specialists as the Parent Mediated Autism Social Communication Intervention for Non-Specialist Plus (PASS Plus). The PASS component, employs video feedback of naturalistic play to assist parents in creating a supporting social communication environment around their autistic child. The Plus component, supports other related concerns. The COMPASS (Communication-centered Parent-mediated treatment for autism spectrum disorder in South Asia) trial aimed to embed an effectiveness evaluation in New Delhi, India, by training health system frontline workers to deliver the intervention between December 2019-October 2023.

Objectives:

To evaluate the feasibility of non-specialist health workers delivering a social communication intervention for ASD in New Delhi (India) delivered in a community setting.

Methods:

A total of 261 children with ASD, aged 2 to 9 years, were randomized after recruitment from two government hospitals in New Delhi, India. Among them, 130 children were allocated to the intervention arm. The intervention was delivered by 7 Accredited Social Health Activists (ASHAs) and 10 project-based workers with similar characteristics which included a lack of exposure to childhood disability. The non-specialists received 7-day training followed by an internship period with practice cases. On achieving competency via a knowledge and skills assessment, these counsellors delivered cases within the trial. Families were offered 12 communication sessions, with Plus modules to address coexisting concerns based on felt need. All cases were tracked for a range of measures and counsellors received both individual and group supervision.

Results:

Descriptive analysis of the delivered sessions showed that 65% of families completed 12 sessions; 11% families received less than 3 sessions, 18% families received between 3 to 7 sessions, 7% families received between 8 to 11 sessions. The majority of sessions 77% were delivered in-person, followed by virtual delivery for 20% sessions, while 3% sessions were conducted in hybrid mode. Out of the total 1214 sessions, 7 health system frontline workers, the ASHAs delivered 39% sessions, while 10 project-based workers delivered 61% sessions. The average number of sessions being delivered by per ASHA being ~79 and the average number of sessions being delivered by project-based counsellors being ~74. 4 tranches of fidelity were conducted, with a total of 98 sessions being evaluated for treatment fidelity. 90% of sessions passed on the fidelity measure.

Conclusions:

The COMPASS trial adds to the evidence of the feasibility of task sharing a complex autism intervention to lay health workers in India. The intervention showed adaptability to various modes of delivery and the same this adaptation to the pandemic did not have any negative impact on its completion rate.

424.259 The Influence of Parental Stress on Outcomes of a Social Skills Intervention

C. M. Lee¹, S. Frank² and R. L. Hudock³, (1)Department of Pediatrics, University of Minnesota - Twin Cities, Minneapolis, MN, (2)Department of Pediatrics, University of Minnesota, Minneapolis, MN, (3)University of Minnesota, Minneapolis, MN

Background: Parental stress is a recognized risk factor for adverse child outcomes (Crum & Moreland, 2017), including the development of aggression and disruptive behavior (Theule et al. 2010), internalizing problems (Mäntymaa et al. 2011), compromised emotional coping (Cappa et al. 2011), and impaired social cognition and competence (Guajardo et al. 2009). Parental mental well-being is known to impact intervention outcomes for children with autism spectrum disorder (ASD), particularly in programs with a strong parent-implemented component (Shine & Perry, 2010; Kasari et al., 2015). Previous studies suggested that participating in a parent-assisted social skills program (Program for the Education and Enrichment of Relational Skills, PEERS®; Laugeson and Frankel 2010) reduced the parenting stress associated with adolescent mood and social isolation (Corona et al., 2019); however, the influence of parental stress on adolescents' intervention outcomes remains unexplored.

Objectives: Examining how parental stress influences adolescents' outcomes after participating in a 16-week, parent-assisted social skills intervention (PEERS).

Methods: Forty-five adolescents (5 females; mean age 14.23 years $\pm$ 1.87) and their parents/caregivers who completed the PEERS program were included. Adolescents completed pre- and post-intervention questionnaires to assess social, emotional, and behavioral challenges (Youth Self-Report, YSR). Parents/caregivers completed parallel measures to report their child's internalizing and externalizing problems (Child Behavioral Checklist, CBCL) and their stress level related to parenting (Stress Index for Parents of Adolescents, SIPA) across five domains (i.e., adolescent concerns, parent concerns, adolescent-parent relationship, total parenting stress, and life stressors) before and after the intervention. Linear regressions were used to examine if parental stress moderated intervention effects.

Results: Parents reported significant reductions in adolescents' somatic complaints ($F = 4.73$, $p = 0.02$), social problems ($F = 5.78$, $p = 0.018$), and aggressive behaviors ($F = 4.14$, $p = 0.045$) following the intervention (Table 1). Parental stress levels before the group intervention significantly moderated some treatment effects. Specifically, parents who endorsed greater stress related to their teens' moodiness/emotional lability ($\beta = -0.254$, $p = 0.026$) and delinquency/antisocial behaviors ($\beta = -0.284$, $p = 0.041$) observed less improvement in teens' somatic complaints. Additionally, caregivers who reported greater stress related to their life restrictions ($\beta = -0.264$, $p = 0.003$), social alienation ($\beta = -0.585$, $p = 0.004$), incompetence/guilt ($\beta = -0.388$, $p = 0.023$), and overall parenting stress ($\beta = -0.067$, $p = 0.003$) endorsed less improvement in teens' somatic complaints. Less stress on the relationship with their partner is associated with greater improvement in teens' somatic complaints ($\beta = -0.365$, $p = 0.012$) and aggressive behaviors ($\beta = -0.282$, $p = 0.007$). Interestingly, no significant relationship was found between parental stress and changes in social problems as measured by the CBCL (Table 2).

Conclusions: Parents within our sample reported significant improvements in their adolescents' somatic complaints, social problems, and aggressive behaviors following their participation in the PEERS program. Parent stress moderated changes in somatic complaints and aggressive behavior, but not social problems, suggesting stress may hinder treatment outcomes. Further research is needed to explore how parental stress interacts with social skills interventions to optimize outcomes for adolescents.

**424.260 The Psychological Impact of Leisure and Rehabilitation Activities in Children with Autism: A Delphi Approach**

E. Grossi, Autism Research Unit, Villa Santa Maria SCS, Tavernerio, Como, Italy

Background:

Emotional well-being and happiness have received little attention in the field of autism. When we focus on well-being, we often do so from a negative perspective, that is, the lack of functioning that is assumed to play a key role in ensuring a good quality of life. The leisure-rehabilitation programs offered to children and adolescents with autism convey different kind of psychological responses and have an intrinsic power to influence the emotional pattern in different ways.

Objectives: To define how different types of rehabilitation programs can be expected to influence the psychological response of children and adolescent affected by autism.

Methods:

We applied the Delphi procedure during a workshop with 18 expert therapists (12 females- 6 males), with at least 10 years' experience in pediatric neuropsychiatric rehabilitation, specifically in autism. A two-round Delphi study was conducted in accordance with the Guidance on Conducting and REporting DELphi Studies (CREDES) with the aim of achieving consensus regarding the appropriateness of 12 types of leisure-rehabilitation activities (Dance therapy, Dramatherapy, Exercising in the gym, Exercising in the swimming pool, Individual sports, Team sports, Indoor climbing, Music play, Outdoor visits to common life environments, Outdoor visits to museums, Outdoor visits to parks and gardens, Writing your life story) in inducing seven types of psychological responses: Emotional engagement, Social engagement, Cognitive engagement, Physical engagement, Just fun, Sense of adventure, Sense of novelty.

Each participant could vote from 0 (complete lack of appropriateness) to 10 (maximum of appropriateness), where 5 means doubtful. Kappa statistics tested interrater reliability.

Results:

We observed as expected an improvement of agreement with the second Delphi round (mean K from 0.36 to 0.39). The activities with the highest potential for each psychological response were indoor climbing for physical engagement, for sense of adventure and for sense of novelty; team sports for social engagement and for fun, dramatherapy for emotional engagement, writing your life story for cognitive engagement. The top five activities with the highest overall impact (mean overall score > 7) were in decreasing order: indoor climbing, team sports, outdoor visits to common life environments, exercising in the swimming pool, and dramatherapy.

Conclusions:

The analysis of judgement made through a Delphi method showed that the twelve leisure-rehabilitation activities may act in different way on seven types of psychological responses. This varied potential allows modulating in clinical practice the combination of activities to the specific needs of the subject in the best way maximizing the potential benefit of rehabilitation.

424.261 The Role of Gender in Social Goal Setting and Achievement for Autistic Youth in PEERS® for Adolescents

K. L. Fisher¹, E. A. Laugeson² and C. T. Moody³, (1)UCLA Semel Institute for Neuroscience and Human Behavior, UCLA PEERS Clinic, Los Angeles, CA, (2)UCLA Semel Institute for Neuroscience and Human Behavior, UCLA PEERS® Clinic, Los Angeles, CA, (3)UCLA Semel Institute for Neuroscience and Human Behavior, University of California Los Angeles, Los Angeles, CA

Background: PEERS® for Adolescents, an evidence-based relational skills program, has been shown to reliably result in improvements in participants' social communication, engagement, and skills knowledge on standardized measures (Laugeson et al, 2009; Zheng et al., 2021). Further, preliminary research has shown that adolescents are more satisfied with their individualized goals following PEERS® (Fisher et al., 2024), reinforcing the social validity of the program in addressing the unique priorities of participants in line with the neurodiversity movement (Pellicano & den Houting, 2022), examining the role of gender in PEERS® program outcomes, research findings suggest that male and female adolescents benefit similarly on standardized measures (McVey et al, 2017). However, less is known about the role of gender in social goal identification and achievement. Research has demonstrated gender differences in social behavior, with autistic females generally showing stronger social communication skills and engaging in more camouflaging behaviors than autistic males (Wiskerke et al., 2018; Wood-Downie et al., 2021). Given this, it is possible that autistic female adolescents may identify different types of social goals or apply social skills differently, affecting social goal achievement in social skills programming.

Objectives: The current study aimed to examine gender differences in participant's social goal identification and achievement during an evidence-based social skills program, PEERS® for Adolescents.

Methods: Fifty-four adolescents ($M_{age}=14.2$, $SD=1.9$; 66.7% male; 51.9% White) identified 2–3 social goals during the first week of PEERS® (T1) and rated their satisfaction with each goal on a 7-point Likert scale from “very dissatisfied” to “very satisfied.” Goals were classified into six types: conversational skills, making friends, deepening friendships, conflict resolution, social confidence, and other. Participants later rated their satisfaction with their individualized goals 8-weeks into the program (T2) and during week 16, after completing the program (T3).

Results: There was no significant difference in the type of goals endorsed by males and females, $\chi^2(5)=4.96$, $p=.421$; however, quantitatively the most commonly endorsed type of goal for males was related to making friends (28%) while the most common goal type for females was deepening friendships (40.5%). Collapsing across gender, a repeated measures ANOVA revealed significant improvements in goal satisfaction over time for the full sample, $F(1.7,208.5)=190.52$, $p<.001$. Further, pairwise comparisons indicated significant improvement between each time point, $p<.001$. After including gender in the repeated measures ANOVA, there was a non-significant interaction between the effects of gender and time, $F(1.7)=0.33$, $p=.68$.

Conclusions: Overall, findings suggest that PEERS® for Adolescents participants were significantly more satisfied with their individualized goals after the program, further emphasizing the validity of PEERS® for autistic youth. When examining the role of gender, findings suggest that males and females report similar rates of improvements in satisfaction with their social goals over the course of PEERS® for Adolescents. This finding further supports previous literature that both male and female participants benefit from PEERS® (McVey et al, 2017). Given high co-occurrence of gender diversity and autism (Dewinter, De Graaf, & Beeger, 2017), future research should examine PEERS® program response among gender-diverse autistic adolescents.

424.262 The Social Tools and Rules for Schoolchildren (STARS) Program: A Pilot Investigation for Autistic Children

K. M. Russell¹, D. Anderson², J. Beck³, R. Netz³ and T. W. Vernon⁴, (1)UC Santa Barbara, Santa Barbara, CA, (2)University of California, Santa Barbara, Santa Barbara, CA, (3)University of California Santa Barbara, Santa Barbara, CA, (4)UCSB Koegel Autism Center, Santa Barbara, CA

Background: Developing friendships is critical for school-aged children, as peer relationships play an important role in one's personal well-being (Rose et al., 2022) and prevent social isolation and loneliness (Hartup, 1996). The Social Tools And Rules for Schoolchildren (STARS) Program is an adaptation of the existing teen-based START group program (Vernon et al. 2016) reimagined to increase social skills and connections for school-aged children on the autism spectrum. This program combines a 10-topic social curriculum with an immersive experiential learning emphasis encompassing unstructured peer socialization and play periods to provide a supportive, strength-based natural context for social experimentation and skill building.

Objectives: The aim of this study was to conduct a multiple baseline trial of the Social Tools And Rules for Schoolchildren (STARS) program in a clinic setting. Specifically, we assessed the preliminary efficacy, feasibility, and social validity of the STARS program through parent reported and behavioral observation measures of the children's social communication skills and enjoyment of the program to inform the likely success of a future effectiveness trial. It was hypothesized that child participants' social skill use would significantly increase and would report high social validity after participating in the program as demonstrated via behavioral data and parent reports. It was also hypothesized that the research team would find the STARS program feasible to run in the clinic setting.

Methods: Participants were three children with autism aged 7, 8, and 10 and their parents. Inclusion criteria included the use of full sentence phrases to communicate, a verbal IQ ≥ 70 , and verification of their autism diagnosis. Participants were diverse across genders (2 males, 1 female) and racial and ethnic identities (White and Hispanic/Latinx; Native American and Hispanic/Latinx; Asian and Non-Hispanic/Latinx). The bi-weekly STARS program consisted of an individual therapeutic check-in, group discussion and practice of 10 social skill topics, group activity, group socialization and play time, and an individual checkout. Pre intervention data was collected 2 weeks before the program began and post intervention data was collected 3 weeks after the program ended. Behavioral data on engagement, initiations, and responses were collected across multiple baseline timepoints, during every STARS session, and at post intervention. A social skill use measure (SSIS) was also collected at intake and post and social validity ratings were collected at post.

Results: Behavioral observation results indicate that social skill use improved for all three participants following participation in STARS (See figures 1, 2, and 3). For fidelity, adherence to the session protocol was 96.67% and the mean attendance was 93.33%. Overall, social validity ratings were moderately high for two participants. SSIS scores indicated generalization of social skill use increases for two participants (mean change = 5.67, SD = 3.4).

Conclusions: Results show promise for the STARS model in improving social communication skill use in autistic children. The model was found to be feasibly run within a clinic setting. These results warrant explorations into adapting the model for use in the schools and replications with larger cohorts of school-aged participants.

424.263 The Social Validity of TEACCH Practices in South Korean Educational Settings

J. Park¹, S. Y. Kim², S. Kim³ and S. Y. Kim⁴, (1)Duksung Women's University, Dobong-gu, Seoul, (2)Duksung Women's University, Dobong-gu, Seoul, Korea, Republic of (South), (3)EL seeds center(EL child development research), Sungnamsi, Gyeonggi-do, Korea, Republic of (South), (4)Korea University, Seongbuk-gu, Seoul, Korea, Republic of (South)

Background: Although TEACCH has been recognized for its effectiveness in improving learning outcomes for autistic individuals across cultures (Virues-Ortega et al., 2013), research and practical application in South Korea have been limited. Examining social validity by stakeholders who actually implement the intervention is crucial to determine that TEACCH is feasible, culturally appropriate, and effective for the target population; however, the social validity of TEACCH practices has not been closely examined either within South Korea or internationally.

Objectives: This study aimed to examine the social validity of applying TEACCH practices in South Korean educational settings, particularly for autistic school-aged children and preschoolers.

Methods: A total of 13 Korean stakeholders participated in this study (10 females, age range: 26-49 years), including five special education teachers, five therapists, and three parents, all working with or caring for autistic children aged 3 to 10. Participants' educational levels consisted of one high school graduate, one with an associate degree, six with bachelor's degrees, three with master's degrees, and two with doctoral degrees. All participants completed the TEACCH online workshop organized by the University of North Carolina at Chapel Hill. Semi-structured interviews were conducted both before and after the workshop: pre-workshop interviews inquired about participants' experiences with environmental structuring and TEACCH, while post-workshop interviews focused on opinions about the effectiveness of TEACCH for autistic children in South Korea. Data were analyzed using content analysis to identify key themes related to the social validity of TEACCH in South Korea.

Results: A total of three themes—current practices of structuring the environment, TEACCH-related experiences, and perspectives about TEACCH—were identified from the pre-workshop interviews, while one theme, perspectives on the use of TEACCH in Korea, was identified in the post-workshop interviews. Tables 1 and 2 present the sub-themes, categories, and exemplary quotes identified in the pre- and post-workshop interviews, respectively. The pre-workshop interviews revealed that most participants structured the environment for autistic individuals predominantly using visual methods. For those not structuring the environment, reasons included environmental constraints (e.g., limited space) or individual characteristics that made it unnecessary. Many participants had some experience learning about TEACCH. All participants who had experience with TEACCH found it helpful, but concerns were raised regarding its effectiveness depending on the individual characteristics of autistic children. The post-workshop interviews revealed mixed perspectives on TEACCH. Participants who viewed TEACCH as effective reported that it was well-suited to the characteristics of autistic individuals and facilitated skill acquisition. Others saw TEACCH as only partially effective, considering the complexity of tasks and diverse environments. Concerns related to practical challenges, such as limited space and time for implementation were mentioned.

Conclusions: The social validity of TEACCH for school-aged and preschool-aged autistic children in South Korea revealed mixed results, with some expressing positive views while others had concerns. We plan to follow up after a month to explore the long-term social validity of the program. Future studies are needed to develop specific strategies for implementing TEACCH in the Korean educational system, taking into account cultural differences and variations in educational structures.

424.264 Therapist-Driven Adaptations to an Individualized Mental Health Intervention for Autism (AIM HI) Delivered Via Telehealth

B. Abundis¹, T. S. Munro¹, L. Brookman-Frazee², A. S. Lau³ and A. Jobin⁴, (1)California State University San Marcos, San Marcos, CA, (2)Psychiatry, University of California, San Diego, La Jolla, CA, (3)Psychology, University of California Los Angeles, Los Angeles, CA, (4)California State University, San Marcos, San Marcos, CA

Background: Research supports the use of telehealth for supporting autistic individuals (Ellison et al., 2021). Further, adaptations to evidence-based interventions (EBI)—when delivered in community settings—are common (Lau et al., 2017; Stirman et al., 2013) and may serve to increase EBI feasibility or fit to novel modalities. Characterization of adaptations for telehealth can increase access to high quality interventions. An Individualized Mental Health Intervention (AIM HI) is an EBI for school-age autistic children with co-occurring mental health needs (Brookman-Frazee et al., 2022), but research has not evaluated AIM HI delivered via telehealth.

Objectives: This study aims to (1) characterize therapist-driven adaptations to AIM HI when delivered via telehealth, and (2) evaluate the perceived feasibility of AIM HI by providers who learned AIM HI in a telehealth modality.

Methods: This study analyzes data from a Hybrid Type 3 implementation-effectiveness trial testing implementation strategies paired with autism EBIs in youth mental health settings to characterize therapist-driven adaptations to AIM HI via telehealth. The sample consisted of mental health therapists enrolled in the trial who completed at least 80% of the 6 month AIM HI training process ($n = 20$) and delivered AIM HI via telehealth. Most were female (80.0%) and had a Master's degree (75.0%). Providers received AIM HI training, including introductory workshops, ongoing coaching/consultation, and case-specific feedback by expert trainers. Post (6 month) training data are reported, including therapist report of adaptations and perceived intervention feasibility.

Results: Most participants (50.0%) delivered AIM HI via computer, laptop, or tablet, or in combination with phone (25.0%). Most (52.6%) reported adapting AIM HI for their client/family to a great or very great extent. Mean ratings were in the moderate range for integration of components from other treatments ($M (SD) = 2.93 (1.16)$; scale = 1-5), lengthening/extending pacing ($M (SD) = 2.85 (1.22)$), adjustment to how components were presented/discussed ($M (SD) = 2.71 (1.21)$), and modification to intervention materials ($M (SD) = 2.25 (1.25)$). Providers also reported applying AIM HI strategies to novel populations ($M (SD) = 2.53 (1.34)$). Infrequently reported adaptations were shortening pacing or skipping/adjusting component order. Providers delivering AIM HI via telehealth reported it was feasible ($M (SD) = 4.09 (.77)$; scale = 1-5).

Conclusions: This study highlights prevalent adaptations during telehealth delivery of AIM HI. The percent of providers reporting adaptations were similar to those reported in research examining adaptations for in-person delivery (Dyson et al., 2019). Reported adaptations were largely fidelity-consistent, representing consistency with the AIM HI protocol and aligned to strategies for individualizing the intervention to specific clients.

These findings may also indicate modifications particularly relevant to the telehealth format (e.g., modifying materials for computer/tablet), which may be relevant to other autism or mental health interventions being modified for telehealth. Finally, the findings suggest that delivery of AIM HI via telehealth is feasible, which can increase access to evidence-based approaches for autistic youth with co-occurring mental health needs. Future research should evaluate the effect of these adaptations on intervention fidelity and youth mental health outcomes.

424.265 Therapist-Reported Adaptations to an Individualized Mental Health Intervention for Autism (AIM HI) Delivered in School-Based Settings

T. S. Munro¹, B. Abundis¹, L. Brookman-Frazee^{2,3}, A. S. Lau⁴ and A. Jobin^{3,5}, (1)California State University San Marcos, San Marcos, CA, (2)Psychiatry, University of California, San Diego, La Jolla, CA, (3)Child and Adolescent Services Research Center, San Diego, CA, (4)Psychology, University of California Los Angeles, Los Angeles, CA, (5)California State University, San Marcos, San Marcos, CA

Background: Community therapists' adaptations to evidence-based interventions (EBI) are common and may serve to improve feasibility and fit of EBIs to different service delivery contexts (Lau et al., 2017; Stirman et al., 2013). Many EBIs for autistic youth with co-occurring mental health needs were developed for and tested within clinic-based settings. However, youth often receive mental health services with schools, and limited research has evaluated how EBIs are adapted to fit this context (Sturm & Kasari, 2023). An Individualized Mental Health Intervention (AIM HI; Brookman-Frazee et al., 2010) is a parent-mediated and child-focused intervention to reduce challenging behaviors for school-age children with autism and co-occurring mental health needs in publicly-funded mental health services. Evidence supports its effectiveness in clinic- and school-based services (Brookman-Frazee et al., 2022). This study leverages data from a Hybrid Type 3 implementation trial testing implementation strategies paired with autism EBIs in children's mental health settings to characterize therapist-reported adaptations to AIM HI within school-based mental health services.

Objectives: This study aims to (1) characterize therapist-reported adaptations to AIM HI by school-based mental health providers, and (2) evaluate the feasibility and intentions to use AIM HI within school-based services.

Methods: The sample consisted of school-based mental health therapists enrolled in the AIM HI TEAMS trial who completed at least 80.0% of AIM HI training ($n = 25$). The majority of the sample was female (64.0%) and had a Master's degree (88.0%). Primary disciplines included Marriage and Family Therapy, Social Work, School Psychology, and Mental Health Counseling. All providers received 6 months of training in AIM HI, including didactic workshops and ongoing coaching/consultation for approximately 6 months with case-specific feedback and performance monitoring via video and material review by expert coaches/trainers. Data are reported from the post (6 month)-training questionnaire, which included therapist-reported adaptations when delivering AIM HI, and feasibility and intentions to continue using the intervention.

Results: Overall, 50.0% of school-based providers reported adapting AIM HI for their client/family to a great or very great extent. The most frequently reported adaptations were lengthening/extending pacing (33.4%), integrating components from other treatments (29.1%), and applying AIM HI strategies to novel populations (25.0%). Also common was the involvement of other people in the child's care (e.g., teachers). Providers reported minimal adaptations to the order of the AIM HI protocol steps, and they rarely reported shortening or skipping components. Providers reported high levels of feasibility and intentions to continue delivering AIM HI.

Conclusions: Therapists reported a variety of fidelity-consistent adaptations when delivering AIM HI in school settings. They also found AIM HI feasible and fitting for the school-based context. Adjusting pacing to fit services delivered within the school day may be particularly relevant to school-based delivery, especially when involving caregivers in care. Tools for supporting school-based providers in involving other people in the youth's care, and for integrating other approaches, may also be important. In addition to examining the impact on youth outcomes and intervention fidelity, next steps include comparing adaptations for school- and non-school-based mental health providers.

424.266 Understanding Homework Practice of Skills Taught during a Cognitive-Behavioral and Mindfulness Based Program

J. A. Rankin^{1,2}, G. Flaherty³, R. Rasty⁴, R. Garuda⁵, J. Carmona⁶, G. Di Giovanni⁶ and E. S. Brodtkin³, (1)Psychiatry, University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA, (2)Honors College, Ball State University, Muncie, IN, (3)Department of Psychiatry, University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA, (4)The University of Pennsylvania, Philadelphia, PA, (5)Psychiatry, Brodtkin Lab, Philadelphia, PA, (6)University of Pennsylvania, Philadelphia, PA

Background: Few social functioning programs exist for adults. TUNE In (Training to Understand and Navigate Emotions and Interactions), a 17-week cognitive behavioral and mindfulness program, was developed at the University of Pennsylvania to support social functioning in autistic adults by addressing social anxiety (component 1), social skills and cognition (component 2), and skill generalization (component 3).

Objectives: The goal of the present study was to assess participant completion of assigned homework throughout the program, what influenced homework completion, and how homework completion was associated with changes in social functioning scores.

Methods: Overall, 20 participants completed TUNE In as part of a larger randomized control trial. Participants completed the Social Responsiveness Scale (SRS-2) self-report, as a measure of social functioning, prior to starting TUNE In and after each of the 3 components. In addition, participants reported preferences (ie., how helpful and useful different skills were) on various elements within each component via a qualitative interview. Participants' homework completion, practicing five different mindfulness-based exercises (Warm-Up Stretches, Mindful-Walking, Sitting, Standing, and Listening Exercises) taught during component 1, was tracked during component 2 via weekly logs where participants indicated how often they practiced each exercise daily.

Results: Overall, participant SRS-SR scores significantly improved after the first component of the TUNE In ($t(16) = 2.57, p = .02$), while responses to the subsequent two components, component 2 ($p = .11$) and component 3 ($p = .42$), varied. There was a significant correlation between how helpful participants found the exercise and the amount of homework practice for only one of the five mindfulness exercises (walking exercise; $r = .73, p < .01$). Post-Component 1 SRS scores were inversely correlated with Amount of Homework Practice across all exercises (controlling for baseline SRS; all $r = -.66, p = .01$). This suggests that those who showed greater response to component 1 of TUNE In on the SRS-SR, subsequently practiced these exercises (at home) more going forward. Exploratory analyses revealed that prior experience in a group-format organization (e.g., sporting, social, or artistic) significantly predicted the amount of homework practice among participants overall ($t(15) = 2.31, p = .04$) and the amount of practice of 3/5 exercises specifically (Walking, Listening, and Standing; all $t(12) > 2.79, p < .02$). The mean amount of exercises practiced after component 1 was three times greater among those with experience in group-format organizations before (average total exercises practiced: 75.80 vs 26.17).

Conclusions:

Overall, mindfulness exercises were particularly effective elements within TUNE In, a multifaceted program to support autistic adults socially. While their qualitative reporting on how helpful certain exercises were did not correspond to how much they practiced these exercises in the future, how helpful these exercises were quantitatively (ie., as captured by the SRS-2) did relate to how often participants practiced these exercises in the future. Moreover, having prior experience with group-activity formats was associated with how much participants practiced these exercises, suggesting that prior experience in group activities may be a meaningful variable in response to support programs.

424.267 Using Linguistic Analysis to Measure Clinical Intervention Outcomes Among Autistic Youth

C. Faulk¹, A. R. Bordofsky², L. J. Fulop¹, Z. Williams³, T. W. Vernon⁴, J. Parish-Morris¹ and S. Cho⁵, (1)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (2)UC Santa Barbara, Santa Barbara, CA, (3)Vanderbilt University, Nashville, TN, (4)UCSB Koegel Autism Center, Santa Barbara, CA, (5)Linguistic Data Consortium, University of Pennsylvania, Philadelphia, PA

Background: Autism is characterized by challenges in social communication as well as repetitive and restricted patterns of behavior. Given autism's heterogeneous nature, an efficient way to characterize individual participants is needed to tailor intervention efforts. There is a growing number of evidence-based interventions designed to target social skills in autistic individuals, bringing along a critical need for methods to granularly and objectively measure clinical outcomes. Previous studies have examined linguistic differences in autism (Parish-Morris et al., 2016) and the potential to use them as part of an assessment tool for clinical outcomes and a digital phenotyping toolkit. The START Program is an intervention for transition-age youth, designed to target social communication by providing an opportunity to practice conversational skills. An RCT of this intervention was previously conducted and validated, imparting a sample well-suited for linguistic analysis.

Objectives: To assess whether key clinical outcomes can be measured using computational linguistic analysis, validated by gold-standard human annotation.

Methods: Adolescents aged 12-17 years with a confirmed diagnosis of autism were recruited to participate in the START RCT, and randomly assigned to "START" or "waitlist" groups. START participants (N=35 teens, 11 female) completed two five-minute "get to know you" conversations with unfamiliar neurotypical confederates, one male and one female per session. These conversations were recorded at intake and at weeks 5, 10, 15, 20 (post-intervention) and 40 (follow-up). Waitlist participants also completed conversations at intake and 20 weeks, then enrolled in the START program. Conversations were systematically coded by trained raters to identify verbal and nonverbal behaviors related to social inquiries, minimal encouragers, eye contact, and positive facial expressions. Prior analysis of outcome measures and behavioral coding revealed significant interactions between group and time, indicating positive treatment effects in the START group (Vernon, 2018). Linguistic analyses are complete for 16 conversations from 8 participants (4 START, 4 waitlist, half female) at intake and 20-weeks. Audio was manually transcribed by trained annotators. Conversational features were analyzed using an in-house Python script to identify features such as turn-taking rates (Cho et al., 2023). Language features (word valence, frequency, etc.) were extracted using LIWC software (Boyd, 2017). Acoustic features of participants' voices were analyzed using Covarep (Degottex, 2014) and openSmile (Eyben, 2010).

Results: Compared to pre-trial conversations, START participants produced significantly more second-person pronouns ("you": $p < 0.001$) and friend-related words ($p = 0.007$). These changes differed significantly from waitlist participants ("you": $p = 0.05$, friend: $p = 0.03$). START participants' voices also became more stable (lower SD of amplitude: $p = 0.01$, lower average zero crossing rate: $p = 0.001$) compared to both post-intervention and compared to waitlist participants (SD amplitude: $p = 0.025$, zero crossing rate: $p = 0.07$).

Conclusions: Social skills intervention outcomes can be captured using linguistic and speech features extracted from automated analysis pipelines. Final analyses will include 421 conversations at all study time points. Examining outcomes across the intervention duration could aid in identifying areas of strength and weaknesses for each individual, and inform future smart-design clinical trials that actively re-assign participants based on key treatment response metrics.

424.268 Viewpoints on Barriers and Facilitators to Physical Activity Among Autistic Adults

V. N. Duong¹, J. McVeigh¹, E. Quested¹ and C. Thompson², (1)Curtin School of Population Health, Curtin University, Perth, Western Australia, Australia, (2)Curtin School of Allied Health, Curtin University, Perth, Western Australia, Australia

Background: Insufficient physical activity (PA) among autistic adults is a growing concern due to its association with increased risks of obesity, diabetes, and cardiovascular diseases. However, information about the barriers and facilitators to PA participation among this population is limited.

Objectives: This study aimed to investigate the viewpoints on factors influencing PA from the perspectives of autistic adults.

Methods: Q-methodology, a research method that studies people's subjective opinions by having them rank-order statements, revealing patterns through statistical analysis, was used to examine the viewpoints of autistic adults, their parents, and health professionals on PA among autistic adults. Forty-one statements on PA's barriers and facilitators were developed based on previous studies and input from autistic community advisors. Forty-one participants, including 29 autistic adults (M age = 32.0 SD = 6.8), eight mothers of autistic individuals (M age = 39.3, SD = 4.8) and four health professionals (M age = 31.5, SD = 6.76), sorted each statement onto a normally distributed sorting grid on a continuum of "least like how you think" (ranking value: -6) to "most like how you think" (ranking value: +6). Sorts from participants underwent varimax-by-person centroid factor analysis to identify the viewpoints. This statistical method clusters similar ranking patterns based on correlations, revealing distinct groups of shared perspectives or viewpoints among participants.

Results: Four viewpoints were identified: 1. Difficulty maintaining PA due to inherent autistic traits despite available resources; 2. A lack of social support and negative PA perception; 3. Social, behavioural control and financial barriers; and 4. A need for tailored PA programs.

Conclusions: The results suggest that autistic adults experience the common barriers to participating in PA observed in the neurotypical population. However, autistic adults also face unique barriers to participating in PA related to their neurodivergence (e.g., hypersensitivity and social differences, motor coordination). A lack of understanding and support for their unique needs contributes to negative PA experiences and perceptions, which could reduce their motivation for PA. However, autistic adults expressed interest in tailored PA programs and social support. Future intervention design should consider creating appropriate PA settings, providing social support, and personalised strategies to improve autistic adults' PA experiences and participation.

424.270 "Finding Some Sisters": An Initial Evaluation of an Autistic-Led Peer Support Program for Newly Diagnosed Autistic Women

A. Tint¹, C. Alexander-Arias², L. Barker², H. E. Monroe², T. Kelly², B. Mistry³, P. Owusu⁴, D. Mosleh³, Y. Lunskey³, H. Y. Lin², S. Gruszecki⁴, J. Rovet⁴ and Y. Hamdan⁵, (1)Psychology, University of Calgary, Calgary, AB, Canada, (2)Azrieli Adult Neurodevelopmental Centre, Centre for Addiction and Mental Health, Toronto, ON, Canada, (3)University of Toronto, Toronto, ON, Canada, (4)Centre for Addiction and Mental Health, Toronto, ON, Canada, (5)Azrieli Adult Neurodevelopmental Centre, University of Toronto, Toronto, ON, Canada

Background: Autistic women are frequently underrecognized early in life and go on to receive their autism diagnoses in adulthood, which often carries negative mental health repercussions. Despite a high need for mental health services, a lack of post diagnostic support is consistently noted as a source of distress for late diagnosed Autistic women. There is growing recognition of the benefits of peer support amongst Autistic youth and adults. However, there is a lack of evidence for peer support programs tailored to the needs of newly diagnosed Autistic women.

Objectives: This study aimed to: 1) evaluate the feasibility and acceptability of an Autistic-led virtual peer support program for newly diagnosed Autistic women; 2) assess limited efficacy through changes in participants' mental health, social connectedness, and Autistic identity; and 3) explore participants' experiences in the program.

Methods: Recognizing insights from Autistic women are essential in designing effectively tailored supports, this study used participatory methods throughout program development and evaluation. Inclusion criteria for program participants included: 1) receiving a clinical autism diagnosis in the 8 months prior to start of the study; 2) identify as a woman; 3) English proficiency; 4) 18 years of age or older; 5) able to participate independently in the virtual program. The 8-session program included psychoeducation on various aspects of autism, neurodiversity, and sex/gender-based concerns identified during the coproduction process. Each session also allowed for the sharing of participants' perspectives and experiences. Feasibility was assessed by session attendance and completion rates (i.e., attended 75% of sessions). Acceptability was assessed through a post-program satisfaction questionnaire. Limited efficacy testing was assessed via pre- and post-program surveys measuring wellbeing, Autistic identity, and social connectedness. Participants also completed post-program semi-structured interviews. Data analysis is ongoing. Pre- and post-changes will be analyzed using descriptive statistics and paired-sample t-tests. Qualitative analysis is guided by an inductive reflexive thematic analysis through processes of familiarization, coding, and theme development. Analytic summaries are currently being refined with a team of self-advocates, researchers, and trainees.

Results: A total of 18 Autistic women participated in the program ($n=15$ completed pre and post questionnaires; $n=17$ completed individual interviews). Participants' attendance was strong ($M_{\text{sessions}} = 7.0$, $SD = 1.23$) with an 88.8% completion rate, demonstrating initial feasibility. Participants were satisfied with the program (100% agree/strongly agree that they would recommend the program to other Autistic women), including the virtual format (87.5% agree/strongly agree the online sessions were convenient and easier to attend than in-person sessions), indicating high levels of acceptability. Qualitatively, participants identified a number of positive outcomes such as new skill development, enhanced wellbeing, and increased sense of community. Participants highlighted that peer-support programming created unique opportunities to develop positive Autistic identities by connecting, learning, and sharing in a safe, Autistic-led environment.

Conclusions: Results to date provide preliminary support for the feasibility, acceptability, and limited efficacy of a novel Autistic-led virtual peer support program for newly diagnosed Autistic women. Findings can inform future programming to meet the underserved needs of newly diagnosed Autistic women.

424.272 An Assessment of the Potential for Adoption of XR Technologies to Improve Academic Outcomes for Autism Spectrum Disorder Learners.

A. Dedekind, Private, Cape Town, Western Cape, South Africa

Background: The 4th industrial revolution is changing the way we live and work in fundamental ways. New breakthrough technologies are creating new forms of revenue and value that enable and improve our daily lives Schwab (2016).

The acceleration of these new technologies is creating mounting pressure on the workforce of the future, and there is much discussion on the latent readiness of the educational sector Kosko et al. (2021) and Education 4.0 policies and strategies to generate the relevant skills and talent necessary for the future Collins et al. (2023).

In South Africa the Autism Spectrum Disorder community remains disenfranchised from the talent pool due to a lack of relevant academic opportunities Pillay et al. (2022), facing choices of mainstream schooling with a focus on academic standards but a challenging learning context, or, special schooling environments which cater more readily to their environmental needs, however these focus on life and coping skills rather than academic growth Keen et al. (2016).

Objectives: Research question: To what extent are XR technologies being considered by educators to improve the learning experience and outcomes for autistic children?

We focus on *virtual reality*, *augmented reality*, and *mixed reality* with the following objectives:

1. To understand levels of awareness of XR technologies within South African educators (of ASD learners).
2. To assess their (SA Educators of ASD learners) understanding of the potential of XR technologies to impact the learning experience and learning outcomes of ASD students.
3. To assess whether they would consider adopting extended realities technologies within their teaching practices.
4. To make recommendations to educators and the technology industry to enable the adoption of XR technologies for educational purposes.

Methods: Thirteen qualitative semi structured interviews were conducted within a six week period using non-probability sampling. We explored current levels of awareness and usage of extended realities (XR) technologies and we utilised the Unified Theory of Acceptance and Use of Technology 2 (UTAUT2) model Venkatesh et al. (2012) to understand the factors that influence the consideration and adoption of extended realities technologies by special needs educators in the Western Cape, South Africa, for application to the ASD learning context.

Results: Current levels of awareness and usage of XR technologies was low, with little exposure in social media, the most prolifically used source of continuous learning for the participants. However, once exposed to the technologies in the form of presentation and discussion, 85% of the participants in the study believed that XR technologies could positively impact the ASD learning experience and were willing to embrace the technology where relevant (dependent on the learner) and with a balanced approach to use with due consideration for the risk of over reliance on the technology.

Conclusions: Given the openness of the participants and their collaborative partnerships with the parents of ASD children to explore new possibilities for ASD intervention, the opportunity exists for further research. We propose an experimental longitudinal study to test the use of XR technologies for positive impact on the ASD learning experience and academic outcomes.

424.273 A Randomized Control Trial on the Effectiveness of Improvisational Music Therapy for Autistic Children. Baseline Findings.

A. Kovalova¹, A. Jaschke², C. Howlin³, J. W. Pool⁴, D. M. Greenberg⁵, I. Pallás-Ferrer⁶, E. Merriam⁵, C. Brushwood⁵, R. Atkinson⁴, K. Hayden⁴, C. Moore⁴, C. Allison⁷, H. Odell-Miller⁴ and S. Baron-Cohen⁷, (1)Department of Psychiatry, Autism Research Centre, University of Cambridge, Cambridge, Cambridgeshire, United Kingdom, (2)Department of Psychiatry, University of Cambridge, Cambridge, Cambridgeshire, United Kingdom, (3)School of psychology, Trinity College Dublin, Dublin, Ireland, United Kingdom, (4)Anglia Ruskin University, Cambridge, Cambridgeshire, United Kingdom, (5)University of Cambridge, Cambridge, Cambridgeshire, United Kingdom, (6)University of Cambridge, Cambridge, United Kingdom, (7)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, Cambridgeshire, United Kingdom

Background:

Improvisational music therapy is a promising intervention for autistic children who often encounter difficulties in social communication and high levels of anxiety. Previous studies on music therapy for autism have shown mixed results partly due to limitations in outcome measures. This trial aims to use more sensitive tool that measures change in social communication and a broader range of assessments to capture post-intervention changes more effectively. The study is ongoing, and we have currently randomized 123 autistic children. We will have baseline data on all 200 children by April 2025, and will present the baseline findings at INSAR.

Objectives:

The primary aim of this trial is to examine whether improvisational music therapy can improve social communication in autistic children aged 7-11 years. Secondary objectives include assessing the impact of music therapy on adaptive behaviour, anxiety, and well-being. Additionally, subgroup analyses based on verbal ability (minimally verbal, phrase-speaking, and fluent speakers) will be conducted.

Methods:

This randomized controlled trial (RCT) involves 200 autistic children from various UK schools who will be recruited between November 2023 and April 2025. Participants are randomly assigned to receive either 12 weeks of improvisational music therapy or support as usual. The trial followed an assessor-blind, pragmatic two-arm cluster design. Baseline data are collected before randomization, and follow-up assessments will be conducted at 13 weeks (T1) and 39 weeks (T2). Music therapy is administered twice weekly (30 minutes per session) by a registered and specialised music therapist. Various improvisational techniques are employed to engage a child and in turn enhance social communication skills. The primary outcome is the change in social communication, measured by the Brief Observation of Social Communication Change (BOSCC). The secondary outcome measures include: (1) Parent reported anxiety scale for youth with ASD (PRAS-ASD) (2) Young Child Outcome Rating Scale, for wellbeing (YCORS), (3) Strengths and Difficulties Questionnaire (SDQ); and (4) Vineland Adaptive Behaviour Scale (VABS). (5) The Children's Communication Checklist-2 (CCC-2) is completed to evaluate pragmatic speech with fluent speakers only. (6) The Music Engagement Scale (MES); and (7) Assessment of the Quality of Relationship (AQR) are used to evaluate the child-therapist relationships using video-analysis of music therapy sessions. Demographic information is collected using the Wechsler Abbreviated Scale of Intelligence (WASI-II), Music at Home Questionnaire (M@H), Children's versions of the Empathy Quotient (EQ) and Systemizing Quotient (SQ). This randomized control trial is registered with the NIH U.S. National Library of Medicine: <https://classic.clinicaltrials.gov/ct2/show/NCT06016621>, clinicalTrials.gov Identifier: NCT06016621.

Results:

By April 2025, we will have randomized the full sample of 200 autistic children. Linear and multiple regression analysis will be conducted to show inter and intra variability between the two groups and the three study arms. Verbal ability may be used as potential predictor for levels of social communication as well as the secondary outcomes

Conclusions:

Baseline findings will allow us to explore potential predictors and mediators of social communication outcomes, laying the foundation for assessing the effectiveness of music therapy.

424.274 Feasibility and Preliminary Efficacy of Community Autism Peer Support (CAPS) Program Targeting Community Functioning in Young Autistic Adults

W. Song¹, L. Shea¹, J. Gifford¹, C. Carlton², L. Tomczuk³, J. Reese⁴, J. Ventimiglia¹, A. Clarke⁵, K. Kaplan⁶, S. Nonnemacher⁷, M. Y. Wong⁸ and M. Salzer⁹, (1)A.J. Drexel Autism Institute, Drexel University, Philadelphia, PA, (2)AJ Drexel Autism Institute, Drexel University, Philadelphia, PA, (3)A.J. Autism Institute, Drexel University, Philadelphia, PA, Philadelphia, PA, (4)Drexel University, Philadelphia, PA, (5)Philadelphia, PA, (6)University of Delaware, Newark, DE, (7)NASDDDS, Washington DC, DC, (8)Drexel University, Policy and Analytic Center, A.J. Drexel Autism Institute, Philadelphia, PA, (9)Temple University, Philadelphia, PA

Background: There is a lack of peer support interventions delivered by autistic individuals themselves, and little research has been conducted to examine these emerging services from the perspective of those with lived experience. Recognizing the national and urgent need for service development and delivery for autistic adults, a steering committee – including autistic adults, family members, peer specialists, researchers, service providers, and policymakers - developed the Community Autism Peer Support (CAPS) program. Based on existing peer support models, the CAPS program includes features such as goal-oriented activities and individualized support plans that allow peer specialists to tailor the program to each person's needs and interests.

Objectives: To investigate the feasibility and preliminary efficacy of the CAPS program – a peer support service designed for autistic individuals, targeting community functioning in young autistic adults.

Methods: Participants were autistic adults aged 18 to 30 with a formal autism diagnosis and challenges in one or more major life areas (social, school, work, self-maintenance). They were randomly assigned to either receive CAPS services delivered by trained peer specialists for up to 12 months or to continue with their usual services. Intervention participants met regularly with peer specialists to discuss goals, challenges, resources, progress, and action steps. All results were assessed at the 3-month follow-up. Feasibility and acceptability were assessed using semi-structured qualitative interviews. Fidelity was assessed using service data, progress notes, and qualitative interviews. Relationships between the peer specialists and participants were assessed by the Working Alliance Inventory (WAI) and IPS Core Competencies Scale (IPSCCS).

Results: Of 102 autistic adults assessed for eligibility between Mar 2023 and Aug 2024, 40 were randomized to the CAPS intervention (n=20) or control (n=20) groups (Table 1). Qualitative data at 3-month from a total of 16 intervention participants regarding their perceptions and responses to the intervention supported feasibility and provided important insights to guide future trials (Table 2). WAI (M=3.15, SD=0.49) and IPSCCS scores (M=3.96, SD=0.67) indicated high levels of agreement and positive relationships between participants and peer specialists. For fidelity, more than half the participants received full points on at least seven out of 10 service delivery criteria that are viewed as essential components of the CAPS program. Preliminary efficacy data will be presented in detail for INSAR. Methodological challenges to designing and implementing a randomized controlled, clinical trial with a new service in partnership with providers in the community settings included (1) difficulty recruiting/hiring trained peer specialists at the beginning of the trial, (2) lack of experiences in delivering peer support services or work experiences in general among peer specialists, and (3) staff/supervisor turnover and engagement.

Conclusions: CAPS is one of the first autistic-delivered peer support interventions for autistic young adults. There is evidence showing that the CAPS program is a feasible and acceptable service for autistic young adults in the community setting. However, evidence supporting the preliminary efficacy of this model is limited. We will discuss challenges and potential solutions to conducting an RCT in the community setting based on our experiences.

Poster Session

May 2nd, 2025, 12:30 PM - 1:30 PM - Hall 4A

425.275 Verbal Comprehension and Applied Theory of Mind Competence Mediate the Prediction of Explicit Theory of Mind Knowledge on Social Functioning in Children with Autism Spectrum Disorder: A Two-Year Follow-up Study

Y. T. Yu^{1,2}, **K. L. Chen**^{2,3,4}, **C. H. Lin**⁵ and **C. L. Hsieh**^{1,6,7}, (1)School of Occupational Therapy, College of Medicine, National Taiwan University, Taipei, Taiwan, (2)Department of Occupational Therapy, College of Medicine, National Cheng Kung University, Tainan, Taiwan, (3)Department of Physical Medicine and Rehabilitation, National Cheng Kung University Hospital, College of Medicine, National Cheng Kung University, Tainan, Taiwan, (4)Institute of Allied Health Sciences, College of Medicine, National Cheng Kung University, Tainan, Taiwan, (5)Department of Psychiatry, Chi Mei Medical Center, Tainan, Taiwan, (6)Department of Occupational Therapy, College of Medical and Health Science, Asia University, Taichung, Taiwan, (7)Department of Physical Medicine and Rehabilitation, National Taiwan University Hospital, Taipei, Taiwan

Background:

Children with autism spectrum disorder (ASD) face significant challenges in social functioning, which are influenced by theory of mind (ToM) and verbal comprehension. ToM can be categorized into explicit knowledge and applied competence. While most research has focused on explicit ToM knowledge, the crucial impact of verbal comprehension on social functioning is often underestimated. Additionally, the reliance on cross-sectional designs may limit our understanding of how these dynamics evolve over time. Addressing these gaps can deepen our understanding of the mechanisms underlying social functioning in children with ASD and facilitate the development of more effective, targeted interventions.

Objectives:

This study aimed to investigate whether applied ToM competence and verbal comprehension mediate the prediction of explicit ToM knowledge on social functioning over a two-year period in preschool to school-aged children with ASD.

Methods:

A total of 123 children diagnosed with ASD (106 boys) participated in this study, completing an initial assessment (T1: January 2015 - October 2018) and a follow-up (T2: May 2017 - November 2020), approximately two years apart. At T2, the children were aged 5 to 14 years (mean = 8.6, SD = 1.7). Consistent procedures were followed at both assessments. Standardized tasks and questionnaires were applied to assess children's social functioning, verbal comprehension, explicit ToM knowledge, and applied ToM competence. A mediation analysis model (Figure 1) was used to determine if explicit ToM knowledge could predict social functioning and to explore how this predictive relationship is influenced by applied ToM competence and verbal comprehension.

Results:

The mean scores for the 123 children with ASD showed no significant differences between T1 and T2, except for ToMTB ($t_{(122)} = 3.1, p < .05$) and ToMI-2-C ($t_{(122)} = 6.9, p < .05$). The mediation analysis (Figure 1) revealed that scores on explicit ToM knowledge significantly predicted social functioning scores (total effect, effect size = 0.48; 95% CI: 1.38 to 3.00), with applied ToM competence and the verbal comprehension serving as key mediators (the serial indirect effect, pathway $a1 \times a3 \times b2$, effect size = 0.14; 95% CI, 0.03 to 0.24). Additionally, explicit ToM knowledge also predicted applied ToM competence over a 2-year period (parallel indirect effects, pathways $a2 \times b2$, effect size = 0.14; 95% CI = 0.01 to 0.31).

Conclusions:

This two-year study investigates how ToM influences social functioning in children with ASD. The findings show that applied ToM competence and verbal comprehension act as key mediators linking explicit ToM knowledge to social functioning. Furthermore, explicit ToM knowledge is foundational, as it predicts applied ToM competence and social functioning. Therefore, interventions should prioritize enhancing explicit ToM knowledge before adapting them to the child's verbal comprehension abilities to improve social outcomes.

425.276 The Interplay of Sociability, Social Cues Processing and Theory of Mind: Insights from Williams Syndrome

A. Key¹ and D. Jones², (1)Dept. of Pediatrics, Emory University School of Medicine, Atlanta, GA, (2)Vanderbilt Kennedy Center, Vanderbilt University Medical Center, Nashville, TN

Background: Williams syndrome (WS) is often considered to be the opposite of autism because of the distinctive phenotypic features of high sociability and increased visual attention to faces. Yet, compared to neurotypical peers, individuals with WS experience difficulties maintaining social relationships and interpreting social situations. They are also less successful on theory of mind tasks.

Objectives: This study used behavioral and neural measures in young adults with WS to examine their ability to effectively integrate and interpret multiple social cues. We hypothesized that basic perceptual abilities would be intact, while higher-order cognitive processes needed for accurate interpretation of social information would be less efficient compared to the neurotypical peers.

Methods: 27 adults with WS ($M = 28.36 \pm 7.43$ years) and 30 neurotypical controls ($M = 25.52 \pm 7.35$ years) completed a novel visual two-alternative forced-choice "Mind Reading" task that involved identifying a preferred object based on a combination of co-occurring facial cues (positive vs. negative emotional expressions; gaze direction toward vs. away from the target item) displayed by unfamiliar young adult faces. Event-related potentials (ERP) in response to faces and objects characterized neural processes supporting task performance. Temporal principal components analysis identified time windows corresponding to the perceptual (N170), attentional (P3), and affective (LPP) processing of social (faces) and nonsocial (objects) stimuli.

Results: Although objectively less accurate than the neurotypical peers, participants with WS successfully identified preferred vs. not preferred objects (M accuracy > 70%) when corresponding positive and negative facial emotional expressions were paired with the gaze directed toward the target item. However, they performed at chance level when the correct response required disengaging from the direction of the gaze, with greater decrement in performance observed for participants with lower IQ. ERPs revealed no group differences in the neural responses indexing face perception and no evidence of increased salience of social stimuli in WS. Contrary to the findings in the neurotypical peers, ERP responses to target objects in participants with WS were not significantly modulated by gaze direction, less sensitive to the facial emotion context, and reflected no extended processing beyond the initial affective evaluation. Biological sex differences did not affect the results.

Conclusions: The pattern of similarities and differences between the WS and neurotypical groups indicates that successful utilization of social information requires the ability not only to perceive but to integrate multiple facial cues (e.g., emotional expression and gaze direction) and to engage higher-order cognitive abilities needed to accurately interpret indirect social signs (e.g., averted gaze). The current findings support the idea that increased social interest may not be sufficient for optimal social-pragmatic functioning and therefore have implications for the design of interventions targeting social competence in neurodevelopmental disorders.

425.277 Adaptive Profile Changes from Toddler to School Age in Children with Low & Moderately Low Adaptive Skills in Autism Spectrum Disorder (ASD) and Its Implications for Functional Goal Making

D. Jain¹, J. Bhat² and S. Iyer³, (1)Developmental Paediatrician, Shishu Child Development & Early Intervention Centre, Ahmedabad, Gujarat, India, (2)Narendra Modi Medical College, Ahmedabad, Gujarat, India, (3)School of Arts and Sciences, Ahmedabad University, Ahmedabad, Gujarat, India

Background: In ASD, the core deficits of social communication delay and restricted/repetitive behaviour patterns can impair adaptive functioning, i.e., Skills the child needs to function in day-to-day life. As adaptive demands increase with age, understanding how adaptive skills evolve helps in modifying interventions and adjusting social environments.

Objectives: This study examines adaptive level trajectories in different domains & sub-domains from toddlerhood to school age, in children with low and moderately low adaptive skills and their implications for functional goal-setting.

Methods: The study included 483 children aged 2–12 years, with mild-to-moderate CARS-2-ST scores, from urban, middle-to-upper socio-economic backgrounds, with at least one parent holding a graduate-level education. Adaptive skills were assessed using the Vineland-3 scale. Non-parametric tests were used for statistical analysis.

Results: 65% of the children had low and 35% moderately low adaptive levels with 81.3% male and 18.7% females. Gender was not significantly associated with the results.

Overall adaptive level standard score (SS) was negatively correlated with age ($p < 0.001$), with 1.28 unit decrease in SS for 1 unit increase in age. For communication and motor domains, the correlation between age and adaptive level changes was not significant. In ADL (activities of daily living) and socialization domain, there was a negative correlation ($p < 0.001$) with 1.90 unit decrease in ADL and 1.88 decrease in social skills for each unit increase in age.

In sub-domains, for receptive language, gross and fine motor skills the association between age and domains was not significant. There was a negative correlation, for expressive and written language with a decrease of 0.11 (expressive) and 0.12 (written) units with 1 unit increase in age. Personal & community ADL skills also decreased with age (0.09- personal, 0.37- community). All three sub-domains of the socialization domain (interpersonal, play, coping) were negatively correlated with age (0.31/0.66/0.33 unit decrease for each unit age increase).

Low Adaptive Group: Overall, communication, receptive language, and gross motor skills improved across age. ADL and socialization domain, expressive language, personal and community ADL skills, interpersonal, play/leisure, and coping skills declined with age. Motor and fine motor domain variations were not significant.

Moderately Low Group: Overall, communication and fine motor skills improved, and the adaptive level of play/leisure skills decreased over age. All other domains and sub-domain changes were not significant. Written language peaked in the 3.1–6 years for both low and moderately low groups.

Conclusions: Overall, communication and motor adaptive levels were stable from toddler to school age, while ADL and socialization skills decreased. Moderately low adaptive levels showed improvement or stable trajectories for all domains, except the play/leisure domain. Low adaptive level showed improvement in communication, receptive and motor domain, but decline in all parameters of socialization domain, ADL skills, and expressive language. The impact of environmental factors and cognitive abilities on adaptive skills needs to be evaluated. The distinct adaptive level changes, emphasize the need for customized interventions and changes in social environments, including schools, to promote better functional independence in children with ASD.

425.278 Impact of Diagnostic Disclosure and Stigma on First Impressions Formed By Autistic and Non-Autistic Adults

E. Groves¹, L. Hite¹, E. Dixon², S. B. McCullough³, E. Zane³ and R. B. Grossman¹, (1)CSD, Emerson College, Boston, MA, (2)University of Bath, Boston, MA, (3)Communication Sciences and Disorders, James Madison University, Harrisonburg, VA

Background: Literature suggests that diagnostic disclosure improves how autistic individuals are perceived by non-autistic raters (Sasson & Morrison, 2017), but the impact of diagnostic disclosure may be mitigated by the amount of autism stigma raters hold (Morrison et al., 2019). Research in other marginalized groups suggests that internalized stigma negatively influences within-group social perceptions (Misra et al., 2021), but there have been no investigations into how internalized stigma of autistic raters influences first impression formation of autistic and non-autistic individuals.

Objectives: Analyze the autism stigma of autistic and non-autistic raters and investigate how stigma and diagnostic disclosure influence first impressions formed of autistic vs non-autistic adolescents.

Methods: We gathered 48 video clips of autistic and non-autistic adolescents aged between 12 and 17 mimicking sentences originally produced by non-autistic adolescents. Half the videos were accurately labeled with the adolescent's neurotype, i.e. "this individual has an Autism diagnosis" or "this individual has no diagnosis", the other half were unlabeled. Autistic ($N=120$) and non-autistic ($N=141$) adult raters watched each video and used slider bars to provide their first impressions by indicating agreement with seven statements (e.g. "How likely is it that this person is likable") (Sasson et al., 2017). After watching all videos, raters also completed a scale measuring autism stigma (Gillespie-Lynch et al., 2015) and another scale measuring impression management, i.e. participants' motivation to inhibit prejudiced reactions (Dunton and Fazio, 1997).

Results: A two (rater neurotype) by two (video neurotype) by two (disclosure) repeated measures ANOVA with stigma and impression management as covariates revealed no main effects for rater neurotype ($F(1, 257) = .92, p = 0.34$), video neurotype ($F(1, 257) = .001, p = .98$), or disclosure ($F(1, 257) = .09, p = 0.760$). There was, however, a significant interaction between video neurotype and disclosure ($F(1, 257) = 5.53, p = .02$). Post-hoc pairwise comparisons showed no significant effect of disclosure for autistic videos (7.74 [95CI-2.64, 18.11], $p = .143$), but significantly more favorable ratings for non-autistic videos following disclosure, compared to videos without disclosure (20.87 [95CI 12.61, 29.14], $p < .001$). Additionally, autistic participants reported significantly higher anti-autism stigma than non-autistic participants ($F(1, 261) = 33.03, p < .001$) and there was a three-way interaction between video neurotype, disclosure, and stigma score ($F(1, 257) = 3.94, p = .048$), indicating that stigma may influence first-impression formation differently depending on neurotype. There was no significant group difference in impression management ($F(1, 261) = 3.24, p = .073$), indicating that autistic and non-autistic individuals have similar motivations to inhibit prejudiced reactions.

Conclusions: Findings imply that disclosing the absence of a diagnosis may improve perceptions of non-autistic adolescents while disclosing an autism diagnosis may not affect ratings for autistic adolescents. Autistic raters exhibited more stigma than non-autistic raters, providing some insight into internalized stigma within the autistic community. Given the three-way interaction between stigma, disclosure, and neurotype of the person being rated, these findings suggest that efforts to reduce anti-autism stigma should also include autistic individuals.

425.279 An Idiographic Exploration of Masking in Autistic Adults

M. Somerville¹ and **S. E. MacPherson²**, (1)*Psychology Department, University of Edinburgh, Edinburgh, United Kingdom*, (2)*Department of Psychology, University of Edinburgh, Edinburgh, United Kingdom*

Background:

Masking is a frequently reported behaviour in autistic people referring to the use of strategies to conceal autistic traits in social interactions. Previous research has examined masking on the group level through thematic analysis and quantitative methods and identified links with mental health.

Objectives:

This study explores the lived experience of masking and mental health using an idiographic approach and focus on the unique experiences of individuals.

Methods:

Semi-structured interviews were used to gather data. To make the process inclusive to different communication needs, the interviews were conducted online or in-person according to participant preference. Each participant participated in two interviews lasting one hour each. Data were analysed through the idiographic approach of interpretive phenomenological analysis..

To enhance the validity of the results and ensure that the lived experience of the participants is captured accurately, a process of member checking was undertaken. Following data analysis, participants received a plain English summary of the interpretation of their interviews and were given the opportunity to comment on this summary, identify anything they disagree with, and add additional information. These new data points were integrated into the final analysis.

Results:

All participants reported that they held a complicated relationship with masking. For many participants masking served a vital protective function, acting to shield them from the discrimination commonly experienced by autistic people. However, these same participants reported that masking had severe detrimental consequences to their mental health including depression, anxiety, and low self-esteem. For these participants a complex cost-benefits analysis was applied when deciding whether or not to mask – weighing up the benefits of being shielded from discrimination versus the downstream effect masking had on their mental health. Several participants reported that extensive masking since childhood had left them uncertain about many aspects of their own identity, as they struggled to know what was authentic and what was part of the mask. Several of these participants additionally described the process of unmasking as a journey of discovery and exploration wherein they were starting to uncover their real selves. A number of participants shared that their autistic traits were just one aspect of their identity that was subject to masking. Different participants reported masking their gender identity, mental illness, and their nationality. The common thread among these participants was that any aspect of their identity that was marginalised by society was masked as an act of self-protection.

Conclusions:

The study contributes to the growing understanding of masking through centring the voices of autistic people. A complicated relationship between masking and mental health was uncovered as choosing to mask was detrimental to long-term mental health but also acted to shield participants from experiencing discrimination and the consequences thereof. Identity also emerged as a core construct to be considered in discussions of masking. Masking strategies were not uniquely applied to participants' identity as autistic people, but also other aspects of their identity that were marginalised in society and that might make them vulnerable to discrimination.

425.280 Are Adults with Autism (really) Better at Estimating the Thoughts of Others with Autism?

H. De Laet¹, **A. D. Nijhof²** and **J. R. Wiersema²**, (1)*Faculty of Psychology and Educational Sciences - Ghent University, Ghent, Belgium*, (2)*Department of Experimental Clinical and Health Psychology, Ghent University, Ghent, Belgium*

Background: While prevailing theories suggest that social interaction difficulties are inherent to individuals with autism, the theory of the double empathy problem (Milton, 2012) proposes that these difficulties arise from a mismatch between different neurotypes. The theory predicts more challenging communication between individuals with and without autism, but better communication among individuals with autism. Although qualitative studies on the experiences of individuals with autism seem to support this theory, experimental studies testing the theory are largely lacking.

Objectives: The goal of this study is to test whether adults with autism are better at estimating the thoughts of others with autism than of those without autism.

Methods: 109 adults (55 with autism) took part in an empathic accuracy task, where they watched videoclips of two individuals interacting. Whenever the videoclips was paused, they had to estimate the thoughts of the individuals in the videoclips. To create the videoclips, five dyads – each consisting of one adults with autism and one without autism - were filmed while they got to know each other (unstructured situation) and figured out the rules of a game (structured situation). Directly after, the filmed persons wrote down the thoughts they had while interacting with the other person. Crucially, the participants watching the final videoclips were unaware of the diagnosis of the person in the video. After data collection, four independent raters rated the accuracy of each estimated thought (of the participant watching the video) by comparing them to the original thought (of the person in the video).

Results: In contrast to our hypothesis, adults with autism were not better at estimating thoughts of another adult with autism. Instead, adults with autism were generally less accurate compared to individuals without autism in estimating thoughts of others irrespective of diagnosis.

Conclusions: Our findings do not support the theory of the double empathy problem and are not in line with previous reported experiences of individuals with autism, warranting further investigation

425.281 Are Autism Knowledge, Contact, and Identification Associated with Rapport in Real-World Interactions Among and between Autistic and Non-Autistic Adults?

R. Calderon¹, **S. J. Foster²**, **C. Wilks³**, **M. Dodd⁴**, **D. Ropar⁵**, **S. Fletcher-Watson⁶**, **C. J. Crompton⁷** and **N. J. Sasson¹**, (1)*University of Texas at Dallas, Richardson, TX*, (2)*Psychology, University of Texas at Dallas, Richardson, TX*, (3)*University of Edinburgh, Edinburgh, United Kingdom*, (4)*Nottingham Trent University, Nottingham, United Kingdom*, (5)*University of Nottingham, Nottingham, UNITED KINGDOM*, (6)*Salvesen Mindroom Research Centre, University of Edinburgh, Edinburgh, United Kingdom*, (7)*Centre for Clinical Brain Sciences, University of Edinburgh, Edinburgh, UNITED KINGDOM*

Background: Autistic and non-autistic people often communicate less effectively and establish lower rapport with each other than they do with someone of the same neurotype (Crompton et al., 2020). Previous findings suggest that people with more autism knowledge and contact often have more positive attitudes towards autistic people (Gillespie-Lynch et al., 2015). However, it is unclear whether these factors contribute to better real-world social interactions and experiences for autistic people. Further, it is unclear whether autistic people with a strong sense of autism identity establish better rapport with other autistic people.

Objectives: To investigate whether autism knowledge, contact, and identification are associated with real-world rapport among and between autistic and non-autistic adults in same- and mixed-neurotype dyads.

Methods: Forty-nine autistic adults and thirty-nine non-autistic adults (see Table 1) completed surveys to assess autism knowledge and contact. Autistic participants completed additional questions to assess their autistic identity. Participants were then allocated to one of three conditions: autistic dyads, non-autistic dyads, or mixed dyads (1 autistic and 1 non-autistic). Dyads were instructed to engage in an informal conversation for five minutes and complete a rapport measure (Crompton et al., 2020) afterwards about the interaction.

Results: Autistic participants reported significantly higher time spent ($t(82) = 3.91, p < .001$) and greater contact ($t(82) = 2.28, p = .025$) with autistic people than non-autistic participants. Among non-autistic participants, autism knowledge correlated significantly with time spent with autistic people ($r = .37, p < .001$) and the contexts they interact with them ($r = .55, p < .001$). Feeling part of an autistic community for autistic participants was associated with feeling positive about being autistic ($r = .46, p = .002$), which in turn correlated with self-understanding ($r = .34, p = .027$) and comfort disclosing their autism to others ($r = .46, p = .002$). Within autistic-autistic interactions, higher contact with other autistic people ($r = .39, p = .023$) and the contexts in which they interact with them ($r = .36, p = .038$) correlated with rapport; however, no aspects of autistic identity or autism knowledge related to rapport in these interactions. In mixed dyads, autistic participants' autism knowledge ($r = .62, p = .031$) and time spent with autistic people ($r = .61, p = .028$) were associated with their rapport with non-autistic partners but neither autism knowledge nor contact with autistic people were associated with non-autistic participants' rapport with autistic partners.

Conclusions: The current study examined how autism knowledge, familiarity, and identity related to rapport in same- and mixed-interactions. Autistic participants with higher contact with other autistic people expressed greater rapport with other autistic people, suggesting that familiarity with other autistic people may provide interpersonal benefits. However, contrary to expectations, higher autism knowledge and contact with autistic people were associated with greater rapport in mixed interactions for autistic participants but not for non-autistic participants. High autism knowledge and contact for autistic people may be proxies for more social experience and comfort within interactions, which could translate to better rapport with non-autistic people. Further work is needed to determine what predicts rapport with autistic participants among non-autistic people.

425.282 Are Restricted Interests of Autistic Adolescents Linked to Differences in Learning about Peer Preferences?

I. Mark^{1,2}, L. Mathis^{2,3}, M. Loughlin^{2,3}, E. Chapman^{2,3}, S. Cahalan^{2,3}, W. Liu^{2,3}, A. Clawson^{2,4} and G. Rosenblau^{2,3}, (1)Autism and Neurodevelopmental Disorders Institute, George Washington University, Washington, DC, (2)Department of Psychological and Brain Sciences, The George Washington University, Washington, DC, (3)Autism and Neurodevelopmental Disorders Institute, The George Washington University, Washington, DC, (4)Center for Autism Spectrum Disorders, Children's National Hospital, Washington, DC

Background: Learning about others is a crucial prerequisite for successful social interactions. While previous research has stressed that social cognitive differences and rigidity are separable dimensions of autism (Happé & Ronald, 2008), rigidity may predict social learning capabilities. For instance, restricted interests—a form of rigidity—could lead to less accurate and detailed representations of peer preferences. These social knowledge representations are used for learning in non-autistic groups (Rosenblau et al., 2021). An open question is whether higher rigidity in autistic individuals predicts social learning performance.

Objectives: This study uses a big data approach to investigate the relationship between parent-reported cognitive rigidity, restricted interests, and social learning strategies in autistic early adolescents compared to non-autistic controls. We expect rigidity to predict the use of detailed social knowledge during social learning in autistic individuals. We further expect that a data-driven clustering of early adolescents based on social learning and rigidity will predict autistic traits across participants and autism symptomatology in the autistic group.

Methods: The target sample size is 1000 participants with an autism diagnosis (aged 8-12 years) and 600 age-matched controls (<https://doi.org/10.17605/OSF.IO/8RZNY>). Participants complete three rounds of an online social learning task that involves rating the preferences of three peers on 60 items each. Peer profiles vary in diagnostic group (i.e., autistic / non-autistic) and the variability of preferences (i.e., overall distribution of self-preferences). Learning is quantified by reductions in prediction errors (PEs), defined as the difference between participants' trial-by-trial ratings of peer preferences and subsequent feedback. After the learning task, participants rate their own preferences for all task items. Additionally, parents assess their child's behavior, including rigidity and social cognitive abilities, on several demographic and clinical measures. Here, we report results of a preliminary sample of 296 early adolescents with autism (M age = 10.94 years old, 78.37% male, Social Responsiveness Scale (SRS) total score $M = 101.20$).

Results: Linear mixed effects models conducted in R (www.r-project.org R Core Team, 2014) revealed PE differences based on task profile, such that autistic adolescents' PEs were significantly higher for the autistic profile with the most variability in preferences, and lowest for the non-autistic profile. Participants' PEs did not decrease significantly over the task across profiles. The magnitude of PEs scaled with cognitive rigidity, as measured with the Behavioral Inflexibility Scale. This regressor remained marginally significant when controlling for overall ASD symptom load with SRS total score. When investigating the unique contributions of the Social Communication and Restricted/Repetitive Behavior subscales of the SRS on PEs, only the latter subscale, which measures cognitive rigidity, significantly predicted PEs.

Conclusions: Preliminary analyses suggest that early adolescents with autism are less accurate when making social inferences about autistic vs. non-autistic peers. As expected, cognitive rigidity scales with overall task performance, such that higher parent-reported rigidity predicts greater task-based PEs. We plan to examine social learning strategies in both autistic and non-autistic adolescents as a next step and will additionally consider the role of reported self-preferences.

425.283 Associations between Expressive and Receptive Facial and Vocal Affect Communication Abilities in Autistic and Typically Developing Youth

A. Lakhani and C. Demopoulos, Psychiatry & Behavioral Sciences, UCSF Center for ASD and NDDs, San Francisco, CA

Background: Individuals with autism spectrum disorder (ASD) may struggle with expressing emotions through facial or vocal expression (affect production; AP) and/or interpreting these expressions in others (affect recognition; AR). While deficits in social communication are a defining feature of ASD, the relationship between AP and AR difficulties remains unclear.

Objectives: We evaluated expressive and receptive affect communication abilities in youth with autism and typically developing controls (TDC) and investigated relationships between AP and AR abilities in ASD.

Methods: Participants included 160 youth, aged 8 to 16 years. ASD participants (N=113) were 39.8% female with a mean age of 12.3 (SD=2.7) and mean FSIQ of 98.16 (SD=22.0). Controls (N=47) were 51.1% female with a mean age of 12.4 (SD=2.5) and mean FSIQ of 115.85 (SD=10.8).

Participants completed measures to assess their ability to produce and recognize basic emotions (happy, sad, angry, afraid) through facial and vocal expression. Mann-Whitney U tests were applied to evaluate group differences in AP and AR. A two-way repeated measures ANOVA was used to test interaction effects of emotion and diagnostic group. Spearman's correlations were performed to assess relationships between facial and vocal AP and AR.

Results: Participants with autism scored lower on facial and vocal AR ($U = 1552, z = -3.74, p < .001, U = 1413, z = -4.23, p < .001$, respectively) and facial AP ($U = 888, z = -3.47, p < .001$). While no significant group differences were identified for vocal AP, a significant group by emotion interaction indicated that the ASD group was less effective at conveying happiness vocally ($F(3,339) = 3.956, p = .009$, partial $\eta^2 = .034$). As individuals with ASD are at increased risk for depression, a post hoc analysis of covariance was performed to determine if this difficulty conveying happiness through vocalization was driven by the presence of depression. After controlling for depression, the interaction effect remained significant ($F(3,333) = 4.815, p = .003$, partial $\eta^2 = .042$). No other significant interaction effects were identified. Significant correlations were identified between expressive and receptive tasks across facial and vocal modalities. Specifically, facial AP was significantly correlated with vocal AP ($\rho = .743, p < .001$) and facial AR was significantly correlated with vocal AR ($\rho = .547, p < .001$). Vocal AP was significantly associated with vocal AR ($\rho = .399, p < .001$); however, facial AP was not associated with facial AR ($\rho = .195, p = .083$).

Conclusions: Youth with autism had greater difficulty conveying and recognizing emotions via facial and vocal cues. Affect communication skills were strongly associated across facial and vocal modalities, suggesting that receptive and expressive affect communication impairments can manifest broadly and may operate distinctly. Although a subset of participants demonstrated impairments in both facial AP and AR, a linear relationship was not identified. In contrast, vocal AP was significantly associated with vocal AR, potentially due to an underlying deficit in auditory processing, which has been repeatedly demonstrated in autism studies. This may explain why a relationship between AP and AR was seen within only the vocal modality, as auditory feedback assists in evaluating and adjusting the sound of our own speech, whereas visual processing/feedback is not typically available during production of facial expressions.

425.284 Autism Spectrum Traits Predict Better Communicative Reasoning Ability in Late but Not Early Adolescence

C. Wang¹, Y. Su¹, L. Yi² and L. Zhu¹, (1)Peking University, Beijing, Beijing, China, (2)School of Psychological and Cognitive Sciences & Key Laboratory of Behavior and Mental Health, Peking University, Beijing, China

Background:

Challenges in social communication are core characteristics of autism spectrum disorder (ASD) in the clinical population and autism spectrum traits in the general population. Yet recent evidence suggests a more complex relationship between autism spectrum traits and social cognition. For example, nonclinical individuals with high autism spectrum traits are linked with similar or even better social psychological skills relative to those without.

Objectives:

Here, combining tools and methods from developmental psychology, computational pragmatics, game theory, and computational psychiatry, we investigated whether and how autism spectrum traits influence the ability to infer others' communicative intent based on communicative signals and contexts during the transition from childhood to adulthood in a nonclinical sample.

Methods:

A total of 541 subjects (ages 10-20) participated in a referential communication game previously established for examining the neural and cognitive processes of communicative reasoning ability in adults and children. We evaluated autism spectrum traits using the Autism Spectrum Quotient (AQ), a well-validated measure of autism symptoms in nonclinical samples.

Results:

Consistent with prior work, our data show that the ability to recover a speaker's intention develops continuously from childhood into adulthood. Interestingly, autism spectrum traits exhibit divergent effects on communicative performance in subjects at different developmental stages (interaction effect of AQ and age = $0.14, 0.04, P < 0.001$). Higher autism spectrum traits predict better communicative reasoning performance in subjects during their late adolescence (ages 16-20), but lower performance during early adolescence (ages 10-11). Results of computational modeling further show dissociable cognitive operations that are differentially associated with autism spectrum traits at different developmental stages. The association between autism spectrum traits and communicative performance in early adolescence is mediated by the extent to which a subject was engaged in the egocentric processing of communicative contexts (indirect effect = $-0.16, P < 0.01$). By contrast, the association seen in late adolescence is mediated by how well a subject could mentally simulate what a speaker would say given a communicative goal and context (indirect effect = $0.23, P < 0.01$). Finally, the individual differences in the key cognitive operation quantified by the computational modeling of communicative behavior can modulate how autism spectrum traits influence the self-reported intimate exchange of real-life friendship.

Conclusions:

Together, our findings provide quantitative evidence that autism spectrum traits in a nonclinical population differentially influence the ability of communicative reasoning across development. The dynamic effects point to a learnable social strategy for inferring others' intentions by mentally simulating rational goal-directed behavior in context, shedding light on potential ASD interventions.

425.285 Autistic People Differ from Non-Autistic People Subjectively, but Not Objectively in Their Reasoning

E. Bastan¹, A. Surtees² and S. R. Beck², (1)Psychology, Karadeniz Technical University, Trabzon, Trabzon, Turkey, (2)Psychology, University of Birmingham, Birmingham, West Midlands, United Kingdom

Background: Autism has been associated with difficulties in social interactions and rapid decision-making. The Dual Process Theory of Autism suggests that autistic people, in comparison to non-autistic people, tend to prefer and engage in a more deliberative and less intuitive reasoning style, indicating enhanced rationality in autism. However, this theory has not been systematically investigated across social and non-social domains.

Objectives: This study aimed to explore reasoning styles of autistic people, examining whether they prefer deliberative over intuitive thinking across different domains (social and non-social) or whether they apply consistent strategies in both.

Methods: A total of 24 autistic adults and 24 non-autistic adults, matched for age, gender, and non-verbal cognitive ability, participated in this study. They completed both subjective (self-reported) and objective measures of reasoning. A scenario-based task, covering social and non-social vignettes, was used to assess participants' reasoning strategies in their forced-choice judgments, to determine whether participants maintained a consistent strategy across domains or shifted between intuitive and deliberative reasoning.

Results: Autistic participants reported lower intuition on subjective reasoning measures compared to their non-autistic counterparts. However, on objective reasoning tasks, the reverse pattern emerged, with autistic people providing more intuitive responses. No significant group differences were observed in self-reported deliberation, objective reflectiveness, or forced-choice moral judgments across social and non-social domains.

Conclusions: The findings highlight complexities in reasoning, decision-making, and judgments among autistic people across various domains by suggesting possible discrepancy between autistic people's self-reported preferences and their actual performance.

425.286 Autistic Trait Similarity, Social Interaction Quality, and Empathic Accuracy in Close and Stranger Dyads

L. P. Reign and K. R. Warnell, Department of Psychology, Texas State University, San Marcos, TX

Background: The 'double empathy problem' posits that social interactive difficulties between autistic and non-autistic people are bidirectional, attributable to difficulties interacting across neurotypes (Milton, 2012). To date, studies testing this theory have frequently relied on strangers interacting with each other or participants watching videos of autistic or non-autistic speakers. Less is known about how the double empathy problem impacts social interaction in established social dyads versus strangers, particularly across the broad spectrum of autistic traits, and about whether there are differential impacts on subjective measures of interaction quality versus more objective measures of empathic accuracy (Livingston et al., in press).

Objectives: Using a naturalistic, dyadic paradigm, we quantified relations between partners' autistic trait similarity, subjective impressions of interaction quality, and objective measures of interactive empathic accuracy for both pre-existing close dyads and stranger dyads recruited from the general population.

Methods: Our sample was 50 close dyads and 52 stranger dyads aged 18 to 31 years ($N = 204$ participants). Close dyads (24 close friends and 26 romantic partners) had an average relationship length of 2.72 years ($SD = 3.07y$). Dyads completed an in-person semi-structured conversation in the lab. Afterwards, each participant privately viewed video of that conversation, reported on their own thoughts and feelings during the conversation, and guessed at their partner's thoughts and feelings. Empathic accuracy scores were calculated by comparing each participant's guesses about their partner's mental states to what their partner reported actually thinking or feeling (Ickes, 1993). All participants also completed measures of interaction quality (e.g., "Overall, how would you rate the conversation you had today?") and autistic traits (Autism Quotient [AQ]; Baron-Cohen et al., 2001). Close dyads completed measures of emotional and intellectual relationship satisfaction (Schaefer & Olson, 1981).

Results: Neither close nor stranger dyads showed significant concordance in partners' autistic traits ($r_s < .15$). Autistic trait similarity was not related to empathic accuracy for either close or stranger dyads and was also unrelated to overall relationship satisfaction for close dyads ($r_s < .10$).

However, larger within-dyad differences in autistic traits were related to lower interaction quality ratings for close dyads only ($r(36) = -.58, p < .001$; stranger dyads: $r(50) = .045, p = .75$). Follow-up analyses using an Actor-Partner Interdependence Model (APIM) found that the effect was driven by the dyad member with higher autistic traits score, such that their AQ score impacted both their own and their partner's interaction quality ratings (Figure 1). APIM analyses also indicated that empathic accuracy was not related to subjective interaction quality ratings for either dyad type.

Conclusions: Overall, autistic trait similarity improved subjective experiences of interaction quality, but only for pre-existing close dyads. Additionally, autistic trait similarity did not impact overall relationship satisfaction for those dyads, indicating the importance of considering time scale when interrogating social interactive success. The operationalization of the double empathy problem is also important, given that empathic accuracy did not relate to autistic trait similarity or subjective interaction quality. Future research should continue to investigate how the double empathy problem may impact a wide variety of social interactions for different types of relationships.

425.287 Autistic and Non-Autistic Children's Recounting of Basic and Self-Conscious Emotional Experiences

D. Davidson¹, B. Sawyer² and A. Mounir², (1)Psychology, Loyola University Chicago, Chicago, IL, (2)Loyola University Chicago, Chicago, IL

Background:

The ability to reflect on one's own emotional experiences is central to socioemotional development. Self-conscious emotions (e.g., guilt, embarrassment), in particular, facilitate social relationships and adherence to societal norms. Although a handful of studies have explored autistic children's recounting of basic and complex emotions (e.g., Losh & Capps, 2006), linguistic analyses of children's recounts across discrete basic and self-conscious emotions are lacking.

Objectives:

Although previous research has shown that autistic children may struggle with identifying self-conscious emotions, recognition tasks or hypothetical situations used to assess this may underestimate their understanding. Using detailed linguistic coding, the purpose of this study was to evaluate autistic and non-autistic children's recounting of personally-experienced basic and self-conscious emotions. Potential predictors of appropriate content included age, autism symptomatology, and receptive vocabulary ability.

Methods:

Twenty-three autistic and 38 non-autistic children participated in the study following IRB approval and parent/child consent. Table 1 shows participant characteristics (e.g., race, test scores). All autistic children had received a clinical diagnosis of autism by a licensed clinical psychologist prior to the start of the experiment, and were provided with services at their school for their autism diagnosis (e.g., assigned a paraprofessional). Children were asked to recount two experiences of each basic (i.e., fear, happy, sad), and self-conscious emotion (i.e., guilt, pride, embarrassment). In a quiet room at the child's school, children's responses were audio-recorded, and then later transcribed and coded by two raters. Each response was coded for appropriateness of the content (0-3), the role of others, length in number of clauses, and number of prompts needed to elicit a response.

Results:

Autistic children provided significantly less appropriate content in recounting self-conscious emotions compared to non-autistic children (see Table 1). However, no significant differences were found between children when recounting experiences of basic emotions. In terms of number of clauses, autistic children produced briefer descriptions of experiences pertaining to guilt and embarrassment, and were less likely to reference others for these emotions than non-autistic children (see Table 1). As shown in Table 2, autism symptomatology predicted appropriateness of content for guilt and pride. In contrast, receptive vocabulary level predicted appropriate content for sadness and embarrassment across children.

Conclusions:

Our findings revealed that autistic children were on par with their non-autistic peers in recounting personally experienced basic emotions, but showed less appropriate and less linguistically sophisticated content for self-conscious emotions. Autism symptomatology predicted appropriateness of children's recounts of guilt and pride, whereas receptive vocabulary level accounted for differences in children's ability to provide appropriate content for sadness and embarrassment. This suggests that both autism symptomatology and language play important roles in communicating about complex emotions in autistic children. In terms of implications, many emotion training programs for autistic children focus exclusively on teaching about basic emotions. Our results suggest that it would be beneficial if programs also focused on promoting children's understanding of discrete, self-conscious emotions.

425.288 Behavioral and Physiological Differences during an Emotion-Evoking Task in Children at Increased Likelihood for Autism Spectrum Disorder and Associations with Problematic Behaviour

L. A. Sacrey¹, L. Zwaigenbaum², J. A. Brian³, I. M. Smith⁴, T. Vaillancourt⁵ and S. Raza², (1)Autism Research Centre, University of Alberta, Edmonton, AB, Canada, (2)University of Alberta, Edmonton, AB, Canada, (3)Holland Bloorview Kids Rehab Hospital, Toronto, ON, Canada, (4)Dalhousie University / IWK Health, Halifax, NS, Canada, (5)University of Ottawa, Ottawa, ON, Canada

Background: Siblings of children with autism spectrum disorder (ASD) display higher rates of negative emotions and lower rates of positive emotions on parent-reported questionnaires. An under-explored area in younger siblings is behavioural and physiological measurement during emotion-eliciting tasks (e.g., bubbles). Because physiological indices of arousal can register differences in early-developing processes, they may be informative for mechanisms underlying emotional development and ASD symptom emergence.

Objectives: To examine behavioral and physiological responses during an emotion-evoking task in infants who are increased likelihood for ASD (younger siblings; IL) and low likelihood for ASD (no family history of ASD; LL). A secondary objective was to explore relationships between behavioural and physiological indices and internalizing and externalizing problem behaviours.

Methods:

Participants: IL (n=78) and LL (n=46) infants assessed at 6, 12, 18, and 36 months of age.

Activities designed to elicit positive and negative emotions (bubbles, toy play, toy removal, and negative task phases; Sacrey et al., 2021) to measure (1) percent time looking at the task object (gaze); (2) behavioral affect, coded for valence and intensity; and (3) heart rate, calculated as a change from baseline. Parents completed the Child Behaviour Checklist (CBCL) 1.5-5 years when their child was 3 years old.

The Autism Diagnostic Observation Schedule 2nd Edition, Autism Diagnostic Interview-Revised and clinical impression were used to inform diagnostic impression at 36 months of age to classify participants into three groups: LL (n=46), IL not classified with ASD (IL non-ASD; n=59), and IL classified with ASD (IL-ASD; n=19).

A series of linear mixed models with group (IL-ASD, IL-non-ASD, LL) and age (6, 12, 18) as the independent variables and scores on each phase of the EE-Task for heart rate, affect, and gaze as the dependent variables were run. Relationships between behavioural-physiological indices and internalizing and externalizing problem behaviours on the CBCL were also examined.

Results: The IL-ASD group displayed higher levels of negative affect during toy removal ($p=.03$) compared to IL-non ASD and hair brushing ($p=.009$) compared to the LL; the IL-ASD spent less time looking at bubbles at age 12 months ($p=.038$) compared to the other two groups. Further, the IL-ASD group showed a greater increase in heart rate from baseline during toy removal ($p=.007$) compared to the other two groups. For the associations with the CBCL, at 6 months, problem behaviours were associated with affect during face washing ($p < .05$). At 12 months, problem behaviours were associated with heart rate and affect during toy removal and negative tasks, as well as gaze during negative tasks ($p's < .05$). At 18 months, problem behaviours were associated with gaze during negative tasks ($p < .05$).

Conclusions: These results suggest that IL children diagnosed as ASD show differences in affect, gaze, and heart rate during an emotion-evoking task, which are associated with internalizing and externalizing problem behaviours at age 3. As such, behavioral and physiological reactivity during emotionally-evocative tasks may inform early intervention approaches for infants who show early signs of ASD, with potential implications for understanding mechanisms related to emerging ASD.

425.289 Child Emotional Regulation Mediates the Association between Parenting Stress and Behavior Problems in Autistic Toddlers

M. Kim and S. H. Kim, School of Psychology, Korea University, Seoul, Seoul, Korea, Republic of (South)

Background:

Parents of children with ASD often experience elevated parenting stress, which has been consistently associated with an increased behavior problems in young autistic children (Zaidman-Zait & Duku, 2014). Additionally, lower emotional regulation in autistic children strongly relates to increased behavioral problems (Berkovits & Eisenhower, 2017). Studies have also shown that parenting stress is associated with child emotional regulation in children with developmental delays (Chan & Neece, 2018). These suggest that a child's ability to regulate emotion can explain how parenting stress affects child behavioral outcomes. However, studies examining the interplay between these constructs altogether in young autistic children are rare. Understanding this mechanism can provide insight into the more targeted intervention for young autistic children.

Objectives:

To examine whether child emotional regulation mediates the association between parenting stress and behavior problems in autistic toddlers.

Methods:

The sample included 51 autistic toddlers (72.5% male) aged 18-35 months and their caregivers (88.2% mother). Parenting stress was measured using the Parent Stress Index-Short Form (PSI-SF), with Parental Distress, Parent-Child Dysfunctional Interaction, Difficult Child subdomain T-scores. The Emotional Regulation Index from the Behavior Rating Inventory of Executive Function (BRIEF) was used. Internalizing and externalizing behavioral problems were captured by the Child Behavioral Checklist (CBCL). Verbal and non-verbal developmental quotients (DQs) were assessed using the Mullen Scales of Early Learning (MSEL). Some children (n=30) were reassessed 12 months after their initial assessment (T2). Pearson correlations were used to examine associations among all variables. Stepwise hierarchical regressions were conducted prior to mediation analyses following Baron and Kenny's (1986) model to examine whether parenting stress influenced children's behavior problems while considering child emotional regulation, as well as child/caregiver age, gender, and non-verbal DQ. Mediation analyses using PROCESS macro were conducted to examine whether T1 child emotion regulation (M) mediates the impact of T1 parenting stress (X) on child concurrent and future behavior problems (Y), while controlling for factors mentioned above.

Results:

Higher parenting stress (PSI scores) was significantly correlated with poorer child emotional regulation and internalizing/externalizing problems at both T1/T2 ($r's .45-.71, p's < .01$). Child emotional regulation was also correlated with internalizing/externalizing problems ($r's .40-.65, p's < .01$). Regression analyses revealed that PSI scores except for Parental Distress significantly predicted T1/T2 internalizing/externalizing problems ($p's < .01$). However, when child emotion regulation was included in the model, which significantly predicted T1/T2 internalizing ($b=.368/b=.557, p's < .01$) and externalizing problems ($b=.59/b=.42, p's < .01$), the effects of PSI scores were not significant anymore. Similarly, the mediation analyses indicated that child emotional regulation fully mediated the indirect effects of the PSI Parental Distress on internalizing/externalizing problems at T1 ($b=.22, CI=[.06,.47]/b=.33, CI=[.11,.59], p's < .01$). Longitudinal analyses revealed a similar significant indirect effect on T2 internalizing problems ($b=.33, CI=[.02,.78] p < .05$).

Conclusions:

Consistent with earlier findings (Lin et al., 2020), this study showed that higher parenting stress significantly predicts behavior problems in autistic toddlers. Importantly, this is one of the first studies to show that child emotion regulation fully mediates this association. Therefore, targeting emotional regulation difficulties and supporting caregivers to manage stress should be a key intervention target for autistic toddlers.

425.290 Children with ASD Exhibit Heterogeneous Social Competence Based on Their Theory of Mind Developmental Stages: Insights from a Refined Analysis

Y. N. Wang¹, M. H. Liu², Y. T. Yu³ and K. L. Chen⁴, (1)Department of Occupational Therapy, College of Medicine, National Cheng Kung University, Tainan, Tainan, Taiwan, (2)Department of Rehabilitation, Ton-Yen General Hospital, Hsinchu, Taiwan, (3)School of Occupational Therapy, College of Medicine, National Taiwan University, Taipei, Taiwan, (4)Department of Occupational Therapy, College of Medicine, National Cheng Kung University, Tainan, Taiwan

Background: Children with autism spectrum disorder (ASD) often encounter difficulty in social competence (SC), largely attributed to their theory of mind (ToM) challenges. This is because ToM is to interpret mental states of self and others. However, few studies examined the SC across ToM developmental stages into three key dimensions: social skills elements (SSE), social reciprocity (SR), and social adjustment (SA) in children with ASD.

Objectives: To investigate differences in SC across three ToM developmental stages in children with ASD.

Methods: A total of 58 children with ASD aged 3 to 12 ($M=5:10$, $SD=1:8$) and their caregivers participated in this study. Children's SC was assessed across three dimensions (i.e., SSE, SR, and SA) using the Observational Social Competence Assessment (OSCA). Children's ToM was assessed using the Theory of Mind Inventory, Second Edition (ToMI-2), which categorized children into three groups: not developed/early, basic, and advanced ToM developmental stages. Analysis of covariance (ANCOVA) was employed to compare SC across the ToM groups, controlling for age and verbal comprehension.

Results: The three ToM groups showed an increasing trend in overall OSCA scores, with the advanced group scoring significantly higher than the early ToM group ($p=0.016$). A similar pattern was observed for SR ($p=0.042$) and SA ($p=0.039$), but not for SSE. These results indicate that while overall SC, SR and SA, increase with the ToM development, a notable distinction only becomes evident after reaching advanced ToM stage. Further item-level comparisons within the SR dimension revealed significant differences between the early and advanced groups in the quality of initiation ($p=0.030$) and response behaviors ($p=0.026$), and breadth of reciprocal behaviors ($p=0.032$). In the early group, the initiation and response behaviors were difficult to understand and struggled to maintain exchanges on any topic during interactions. In contrast, a greater proportion of children in the advanced group exhibited contextually appropriate initiation and response and extended interactions into daily topics. Additionally, the quality of initiation also distinguished the basic from the advanced ToM groups ($p=0.029$), indicating initiation requires more complex ToM to align with social situations. Regarding the depth of reciprocity behaviors, the advanced group showed greater depth in sharing emotions, events and comments than the basic ToM group ($p=0.029$).

In the SA dimension, comforting behaviors showed significant differences between the early and basic groups ($p=0.023$), and early and advanced groups ($p=0.003$). Although no significant differences were found in turn-taking, helping, and cooperating, similar patterns emerged, with the early group performing worse than the other two groups. This indicates abilities beyond basic ToM are crucial for comforting and may also play a role in other SA behaviors.

Conclusions: Children with higher ToM stages demonstrated significantly better SC, with advanced ToM being superior performance.

Specifically, ToM development was closely associated with the quality, breadth and depth of SR, and comforting in SA. However, due to the relatively small sample size and the reliance on caregiver-reported ToM assessment, future large-scale studies are recommended to investigate the influence of both ToM knowledge and real-life performance on SC in children with ASD.

425.291 Children with Autism Spectrum Disorder Exhibit Heterogeneous Social Competence Based on Their Verbal Comprehension Abilities

H. C. Hsu¹, Y. T. Yu², M. H. Liu³ and K. L. Chen⁴, (1)Occupational Therapy, National Cheng Kung University, Tainan, Tainan, Taiwan, (2)School of Occupational Therapy, College of Medicine, National Taiwan University, Taipei, Taiwan, (3)Department of Rehabilitation, Ton-Yen General Hospital, Hsinchu, Taiwan, (4)Department of Occupational Therapy, College of Medicine, National Cheng Kung University, Tainan, Taiwan

Background: Children with autism spectrum disorder (ASD) present highly heterogeneous neurodevelopmental profile, particularly in verbal comprehension and social competence. Social competence, which refers to the ability to engage with others, involves three dimensions: social skill elements (SSE), social reciprocity (SR), and social adjustment (SA). However, previous research has seldom conducted a detailed analysis of the relationships between verbal comprehension ability and these specific dimensions of social competence in children with ASD.

Objectives: This study aimed to examine the associations between verbal comprehension and social competence including with its three dimensions of SE, SR, SA in children with ASD, and to compare social competence across different levels of verbal comprehension within this population.

Methods: A total of 91 children with ASD participated in this study (mean age=69.29 months, $SD=16.77$, range=36-125 months). Children's social competence was assessed with the Observational Social Competence Assessment (OSCA) with its three dimensions of SSE, SR, and SA. Their verbal comprehension was assessed using verbal comprehension index (VCI) from either the Wechsler Intelligence Scale for Children – Fourth Edition (WISC- IV) or the Wechsler Preschool and Primary Scale of Intelligence – Fourth Edition (WPPSI- IV). The children with ASD were divided into three groups: lower ($VCI < 85$), average ($VCI = 85-115$), and higher groups ($VCI > 115$). Pearson correlation coefficients were used to examine the associations between the OSCA scores and the VCI. Analysis of covariance (ANCOVA) was used to compare the three VCI groups with the OSCA total and dimension scores across the three VCI groups while controlling for age.

Results: The VCI significantly correlated with the OSCA total score ($r=0.74$, $p<.05$) and each of its three dimensions: SSE, SR, and SA ($r=0.72$, 0.71 , and 0.63 respectively, $p<.05$). Significant differences were found among the three VCI groups in the OSCA total score ($F_{(2, 87)}=22.92$, $p<.05$) and in all three dimensions: SSE, SR, and SA ($F_{(2, 87)}=20.67$, 23.46 , and 4.25 respectively, $p<.05$). Specifically, the higher VCI group outperformed the lower VCI group in the OSCA total score and dimension scores (all $p<.0001$), and the average VCI group also showed significantly higher scores compared to the lower VCI group (all $p<.0001$). No significant difference was found between the higher and average VCI groups ($p=.30\sim.46$). A more detailed analysis of all items of the three dimensions showed significant differences across the VCI groups for most items ($F_{(2, 87)}=4.83\sim 21.04$, all $p<.05$), except for questioning behaviors ($F_{(2, 87)}=3.10$, $p=.05$) in the SR dimension and comforting ($F_{(2, 87)}=0.23$, $p=.80$) in the SA dimension.

Conclusions: This study demonstrates that children with ASD exhibit heterogeneous social competence based on their verbal comprehension abilities, and a clear association between their verbal comprehension and social competence. This insight could guide more nuanced intervention strategies that address aspects of social competence based on the verbal comprehension in children with ASD.

425.292 Collaboration Is Key: Unlocking the Neural Correlates of Autistic Friendships and Wellbeing

C. M. Nelson and **C. M. Hudac**, *Department of Psychology; Carolina Autism and Neurodevelopment (CAN) Research Center, University of South Carolina, Columbia, SC*

Background: Friendships are crucial to promoting adolescent wellbeing. Despite similar desires for forming friendships, autistic adolescents have fewer friends, less contact with friends, and lower quality friendships than neurotypical peers (Kasari et al., 2011). Atypical social attentional processes in autism may lead to poor interpersonal relationships, including friendships, and in turn impact wellbeing (Pavlova, 2012). Yet, poor social attention may not fully explain friendship experiences in autistic adolescents as many report having successful and beneficial friendships (Black et al., 2022). Therefore, a better understanding of the underlying neural mechanisms during friendship interactions and, in turn, their impact on autistic adolescent wellbeing is needed. Since collaboration is often strongest among friends and aids in developing cognitive and social skills (Sills et al., 2016), collaborative environments may be an important context in which we can better understand how neurobiological states influence autistic friendships and wellbeing.

Objectives: First, we aim to identify social attentional neural correlates unique to real-time autistic friendship interactions during goal-directed collaborative conversations. Second, we aim to investigate how social attentional neural correlates impact subsequent wellbeing and if these relationships differ between social contexts.

Methods: Preliminary data from five autistic adolescents and two neurotypical adolescents (9-17 years-old) across six dyadic sessions were included in these analyses (data collection ongoing). Participants completed a battery of interactive paradigms either with a friend or a stranger. During the goal-directed collaborative task (Figure 1), participants and their respective partners were shown an image (each person with a different photo) and then were asked to talk together to find the differences between the pairs. Electroencephalography (EEG), electrocardiogram (ECG), behavioral, and self-report data were collected from each dyadic partner during and after each session. We focus on frontal alpha asymmetry (FAA) as a neurobiological correlate of social attention that is associated with social communication abilities in autism (Neuhaus et al., 2023) and often conceptualized as reflecting approach/avoidance processes (Harmon-Jones & Gable, 2018). Additionally, we evaluate relationships between FAA, ECG, self-report, and behavioral data to better characterize associations between social attention, communication, and wellbeing.

Results: Autistic participants demonstrated slightly more approach-like (increased right FAA) neurobiological signatures ($M=1.50$, $SD=1.32$) than neurotypical adolescents ($M=1.12$, $SD=0.73$). Additionally, friend sessions were slightly less approach-like ($M=1.43$, $SD=2.20$) than stranger sessions ($M=1.51$, $SD=1.08$; Figure 2). Initial relationships between FAA and post-session wellbeing also indicated trending positive relationships between FAA and feeling satisfied ($r=0.49$, $p=0.074$) and content ($r=0.44$, $p=0.116$) for all participants. Finally, self-reported negative feelings following stranger sessions were negatively correlated with FAA ($r=-0.8$, $p=0.018$), such that as FAA became more approach-like, participants indicated less negative affect.

Conclusions: These findings highlight neurobiological correlates that are sensitive to contextual differences during goal directed collaborative conversations and initial impacts on wellbeing. Notably, this is one of the first studies that uses interactive tasks to build a more thorough conceptual model of friendship and wellbeing in autistic adolescents. Our overarching goal is to continue to identify individual strengths and mechanisms in autistic adolescents that aid in building and maintaining optimal friendships and subsequently improve wellbeing.

**425.293 Collective Imagination in Pretend Play: Comparison of Robot-Mediated Interactions with TD and ASD Toddlers**

H. Kozima, *Graduate School of Education, Tohoku University, Sendai, Japan*

Background: We can imagine non-existing things and events; humans have collectively produced and shared numerous stories and techniques, thus creating cultures. Here, we present a case study of how such co-imagination and co-creation emerged in kindergarten children, implicating the cognitive process underlying the development of communication and sociality. Friston's "predictive coding model" claims whatever we perceive in the world is strongly conditioned by an internally produced predictive image, which we project onto reality. The idea directly implies that schizophrenic hallucinations would emerge from abnormally strong and rigid predictions, but also that ASD's enhanced perceptual functioning (Mottron), which forcefully attracts one's attention to incoming piecewise information, would distract one from such top-down projection needed for interpreting the reality.

Objectives: We extend the idea to "collective imagination/expectation" as the fundamental mechanism of our social communication, where the participants project their predictive expectations onto the physical world (Figure 1). Those projected images may be incongruent with each other, but partially congruent to make sense of their actions. As each participant acts on the reality, others' responding actions would strengthen or weaken the prediction; thus, each can update their hypothetical predictions to fit into the concordance. This process is fundamental to our social communication. We here investigate how neurotypical and ASD children engage in or fail in "collective imagination/expectation."

Methods: We conducted a longitudinal observation of a group of neurotypical children (3-year-olds) at a kindergarten and a group of ASD children (3-to-4-year-olds) at a daycare center. In each setting, we introduced a simple robot to the children's playroom with their familiar toys, and we observed how they played with the robot (Figure 2). Throughout the observations, the robot was tele-controlled by researchers in a remote room to produce socially meaningful behavior. We video-recorded the children's interaction with the robot as well as their mutual interaction, which we then analyzed with an ELAN-like system quantitatively (by type and time of actions, etc.) and qualitatively (by role assignment, pretense and symbolic attitude, etc.).

Results: For the ASD children, we observed various dyadic interactions with the robot, but virtually no pretense or symbolic play. The ASD children often played with the robot alone, not having any company. They enjoyed interacting with the robot in a playful mood but did not project their imaginary expectations. On the other hand, neurotypical children showed a lot of group activities, such as playing house, with the robot. They often assigned some roles and symbolic meanings to the robot and objects. The qualitative analysis suggested that the children first had slightly different expectations (e.g., gender, roles, likes, and dislikes) of the robot and different interpretations of the objects, but they gradually converged into a shared range as they mutually exchanged actions and speech to the robot and objects.

Conclusions: From our observations of child-robot interactions, we identified several phenomenological evidence of "collective imagination/expectation" as the fundamental process of social communication. We are building a computational model of the mutual convergence of predictions and its disorders in ASD.

425.294 Comparing Empathic Responses in Different Components and in Different Emotion Situations in School-Aged Autistic Children to Non-Autistic Children

W. C. So¹, X. Li² and M. Lui³, (1)*Educational Psychology, The Chinese University of Hong Kong, Hong Kong, NA, Hong Kong (China)*, (2)*Chinese University of Hong Kong, Hong Kong, Hong Kong, China*, (3)*Psychology, University of Roehampton, London, NA, United Kingdom*

Background: Empathy, which is an ability to understand and share others' feelings (Singer, 2006), is composed of three component stages (Watson & Bird, 2020). In Stage1, after an individual noticing another person's feeling, he/she correctly interprets that person's emotional behaviour (Cognitive Empathy/CE). In Stage2, he/she feels for the person (Affective Empathy/AE). In Stage3, the individual responds to that person's emotion verbally and/or behaviourally (Prosocial Behaviour, PB). Prior studies have shown that autistic individuals lack empathy (e.g. Baron-Cohen & Wheelwright, 2004). However, there is no consensus on which stage(s) is/are related to such deficits (reviews in Song et al., 2019). Besides, many of the previous studies did not explore all three components simultaneously and used self-report measures (reviews in Fatima & Babu, 2023). Furthermore, autistic individuals respond differently to positive and negative emotions (e.g., Lamm et al., 2011). Thus, this study systematically investigated empathic responses in different component stages and in different emotion situations in autism. The findings will inform clinicians and researchers about the assessment and intervention for empathy in autism.

Objectives: The present study examined CE, AE, and PB in different emotional situations in autistic children and neurotypical children. We hypothesized that autistic children have poorer CE, AE, and PB than neurotypical children(H1) and such deficits are found in all kinds of emotional situations(H2).

Methods: 30 Chinese-speaking autistic children (25 males) aged 5-8 (mean=6.98) with verbal IQ above 85 (mean=97.23) and 24 age- and IQ-matched neurotypical children (18 males) were recruited via advertisement posted online. The autism diagnoses were confirmed by ADOS-2. Autistic children had lower Theory of Mind scores than controls. All children watched 8 videos describing emotional situations, two each on happiness, sadness, anger, and fear respectively, and answered five questions for each video (CE: "How does the main character feel?"; AE: "Why does he feel like this?"; AE: "How do you feel for his feeling?"; PB: "What should his friend do/say?"; PB: "What would you do/say if you were his friend?"). One mark was given for each correct answer.

Results: Figures 1 and 2 show the summary. The group effect was significant: autistic children had lower accuracy than neurotypical children across all empathy components and emotion situations, $F(1,52)=10.32$, $p<.002$, $\eta^2=.17$. The emotion effect was significant, $F(1,52)=13.58$, $p<.001$, $\eta^2=.34$: The accuracy was highest in happy situations across all questions, followed by sad, fearful, and angry situations. Participants were significantly more accurate in sad situations than in fearful and angry situations. There was no significant difference between fearful and angry situations. The question effect was significant, $F(1, 52)=207.74$, $p<.001$, $\eta^2=.80$: All children had higher accuracy in CE than in AE, with PB the lowest. When answering the PB questions, children tended to offer solutions to solve the problems for the main characters instead of showing empathy, especially when taking main character's perspectives.

Conclusions: Our hypotheses were supported. Autistic children have less empathic responses in all components than neurotypical children. Intervention should particularly focus on the empathic responses and appropriate prosocial behaviours in fearful and angry situations.

**425.296 De-Gendering in Mental Representations of Autistic Women and Men: Implications for Mechanistic and Infantilistic Forms of Dehumanization**

M. Elderkin¹, V. Nandhakumar² and A. Todd², (1)*UC Davis, Davis, CA*, (2)*University of California, Davis, Davis, CA*

Background: Autism as a pathology has been thoroughly researched; however, comparatively less work has explored its role as a social identity that can inform impressions of autistic adults. Limited research on impressions of autistic adults has primarily focused on male autistic targets. Accordingly, unanswered questions remain involving how autism might intersect with other social identities (e.g., gender) in shaping impressions. **Objectives:** We aimed to determine whether and how impressions of autistic men and women differ from those of neurotypical men and women. Specifically, we examined the ways that autistic men and women are de-gendered and dehumanized compared to their neurotypical counterparts. We also tested whether non-autistic and autistic participants differ in their impressions of each target group.

Methods: In the first two experiments, non-autistic participants were randomly assigned to evaluate one of four target groups: autistic women, autistic men, neurotypical women, or neurotypical men. In Experiment 1, participants first rated their assigned group on their likelihood of possessing masculine (e.g., competitive, dominant) and feminine traits (e.g., nurturing, sympathetic; Martin & Mason, 2022). Next, they completed measures assessing the mechanistic dehumanization (Bai & Zhao, 2024) and animalistic dehumanization (Kteily et al., 2015) of their assigned target group via pictographic scales displaying ascending silhouettes from highly machine-like (i.e., calculator) or animalistic (i.e., ape) to more human-like. In Experiment 2, participants rated their assigned target group on the same gendered traits. They also rated their assigned target group's likelihood of possessing childlike traits (e.g., gullible, naïve; Berry & McArthur, 1985) and completed a measure assessing the infantilization of their assigned target group via a similar pictographic scale displaying ascending silhouettes from highly childlike (i.e., crawling baby) to more adultlike. Finally, in Experiment 3, autistic and non-autistic participants rated all four target groups on the same three ascent scales and a feeling thermometer measure of general evaluations.

Results: Across experiments, autistic men and women were de-gendered (i.e., rated lower on gender-consistent traits), mechanistically dehumanized, and infantilized more than their neurotypical counterparts. Furthermore, the mechanistic dehumanization and infantilization of autistic targets were mediated by their de-gendering. Additionally, both autistic and non-autistic participants mechanistically dehumanized and infantilized autistic targets more than neurotypical targets, though these effects were weaker for autistic participants. Both participant groups displayed ingroup preferences on animalistic dehumanization and general evaluations.

Conclusions: Autistic men and women were viewed less favorably than neurotypical men and women, particularly by non-autistic participants. These negative impressions were especially prevalent in areas where specific stereotypes of autism exist, such as viewing autistic people as more childlike or machine-like. Furthermore, these stereotypic impressions, which suggest a stripping away of gendered traits from autistic people, were held (albeit more weakly) even by autistic participants.

425.298 Do Autistic Children Share with People in Pain: The Role of Empathy in Prosocial Behavior

T. Li¹, J. Decety², Z. Hua³, X. Peng^{4,5} and L. Yi^{6,7}, (1)Department of Psychology, School of Education Science, Qingdao University, Qingdao, Shandong, China, (2)Department of Psychiatry and Behavioral Neuroscience, University of Chicago, Chicago, IL, (3)School of Psychological and Cognitive Sciences & Beijing Key Laboratory of Behavior and Mental Health, Peking University, Beijing, China, (4)Peking-Tsinghua Center for Life Sciences, Peking University, Beijing, China, (5)Academy for Advanced Interdisciplinary Studies, Peking University, Beijing, China, (6)School of Psychological and Cognitive Sciences & Key Laboratory of Behavior and Mental Health, Peking University, Beijing, China, (7)PKU-IDG/McGovern Institute for Brain Research, Peking University, Beijing, China

Background:

Prosocial behavior plays an important role in human social interactions and has been regarded as a key social skill for children's development (Decety et al., 2021). Empirical studies are revealing reduced prosocial behavior in autism (Ryan-Enright et al., 2022). Empathy serves as a primary proximate mechanism that motivates prosocial behaviors (Jensen, 2016). However, autistic individuals have also been reported to show atypical patterns of empathy (e.g., Song et al., 2019; Li et al., 2024).

Objectives:

The current research investigated prosocial behavior in autistic children and how it is influenced by empathy in two interrelated studies. Study 1 examined whether empathy elicits prosocial behaviors indexed by sharing. We asked autistic and neurotypical (NT) children to share in an empathy-induced or a non-empathy-induced situation. We then examined the association between children's dispositional empathy measured by parent-reported questionnaires and empathy-induced sharing. Study 2 examined whether situational empathy would influence children's prosocial behavior. We adopted a pain-related empathy task to measure visual attention and emotional arousal during situational empathy using eye-tracking techniques. We then analyzed whether emotional arousal and visual attention to others' pain during situational empathy could predict children's empathy-induced prosocial behavior.

Methods:

In Study 1, seventy-nine 4- to 7-year-old autistic children and 81 age- and IQ-matched NT children participated in an adapted Dictator game (Table 1), sharing stickers with an anonymous child who was suffering in pain (i.e., empathy-induced condition) or busy at home (i.e., non-empathy-induced condition). Then, children's dispositional empathy was assessed using the Griffith Empathy Measure-Parent Ratings (GEM-PR; Dadds et al., 2008). Last, we explored the relationship between children's levels of dispositional empathy and empathy-induced sharing. In Study 2, thirty-nine 4- to 7-year-old autistic children and 37 age-matched NT children participated in a pain-related empathy task (Table 1). We measured children's visual attention and emotional arousal to others' pain during situational empathy using eye-tracking techniques. We then asked children whether they would share stickers with an anonymous child in the empathy-induced situation, as we did in Study 1. Finally, we examined whether emotional arousal and visual attention to others' pain during situational empathy could predict children's empathy-induced sharing.

Results:

Study 1 found that empathy elicited sharing behaviors in both autistic and NT children, while autistic children shared less than NT children (Figure 1a). Meanwhile, the level of dispositional empathy positively predicted empathy-induced sharing in both groups of children. Study 2 revealed emotional hypo-arousal as well as reduced visual attention to others' pain during situational empathy in autistic children (Figure 1b). More importantly, higher levels of emotional arousal to others' pain indexed by pupil dilation predicted more empathy-induced sharing in both groups of children.

Conclusions:

Our findings highlight the important role of empathy in eliciting prosocial behavior in autistic children, address a research gap in this area, and offer implications for clinical services aiming at enhancing social skills in autism.

**425.299 Early Joint Attention Behaviors in Autism Spectrum Disorder: Are There Sex Differences?**

J. Montenegro¹ and E. Duerden², (1)Faculty of Education, University of Western Ontario, London, ON, Canada, (2)University of Western Ontario, London, ON, Canada

Background: Autism spectrum disorder (ASD) is estimated to affect males more than females; however, more recent studies have suggested that the prevalence rate in females has been historically underestimated, leading to many females being under-identified or misdiagnosed, especially in early childhood. It has been suggested that females might present a distinct ASD phenotype compared to males. Early signs of ASD can be detected in the first and second years of life. Impairments in Joint Attention (JA) are one of the earliest indicators of ASD diagnoses and are often included in developmental screening and diagnostic tools. JA is characterized by the ability to follow the gaze of others and share common interests with other individuals or objects. In developmental screening tools, JA behaviours have been equally assessed in male and female children. However, little is known about whether JA patterns differ in early childhood in females from males.

Objectives: In this study, we aimed to examine JA behaviours and sex differences in relation to ASD diagnosis in young children with an increased familial risk of developing ASD.

Methods: In this study, behavioural data from 869 children (61.2% males) with an increased familial risk for developing ASD were collected as part of the ACE Study and IBIS Network from the National Database for Autism Research (NDAR). In this sample, 173 children received an ASD diagnosis (59.5% males). Behavioural data from the Autism Diagnostic Observation Schedule (ADOS) was collected in the second year of life and was used to examine early JA behaviours. The mean age of the ADOS was 24.8 months. Data from two items related to JA behaviours, responding to joint attention (RJA) and initiating joint attention (IJA), from the ADOS were used for further analysis. Binomial logistic regression analyses were conducted to assess the relationship between RJA and IJA behaviours and biological sex within Diagnostic (Dx) groups (i.e., ASD vs. no-ASD). The outcome variable was biological sex (male/female); the predictor variables included were RJA and IJA behaviours, controlling for age. **Results:** Using a regression method, it was found that, in children who received an ASD diagnosis, RJA behaviours ($B=-0.570$, $aOR=0.566$, $p=0.015$) classified male and female children. In contrast, IJA behaviours were not statistically significant ($B=-0.14$, $aOR=0.869$, $p=0.577$). In the model, RJA behaviours could differentiate males and females in the group that developed ASD, correctly classifying 60.1% of the cases. For the group who did not develop ASD, the model did not accurately predict biological sex.

Conclusions: Findings suggest that RJA behaviours may look different in females with a familial risk for developing ASD who received an ASD diagnosis compared to males at two years of age. Specifically, children who presented lower scores on RJA measures, which means less impaired RJA behaviours, and received an ASD diagnosis were more likely to be females. A better understanding of JA behaviours in females could aid in developing more sensitive tools to detect the female ASD phenotype at an early age.

425.300 Emotion Dysregulation Related Impairment Is Elevated across Social Contexts in Autistic Preschoolers

J. B. Northrup¹, A. Saunders¹, E. Anderson², L. Wakschlag³ and C. A. Mazefsky¹, (1)Department of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, PA, (2)Institute for Innovations in Developmental Sciences, Northwestern University, Chicago, IL, (3)Department of Medical Social Sciences, Northwestern University, Chicago, IL

Background: Although not part of the core criteria of autism, accumulating evidence indicates that emotion dysregulation is common in autistic individuals across the lifespan (Cibralic, Kohlhoff, Wallace, McMahon, & Eapen, 2019; Conner et al., 2021). Challenges like meltdowns, outbursts, and tantrums can impact child and family life across contexts by damaging peer and family relationships, reducing community engagement, and impacting school participation and performance. To date, no research has examined how emotion dysregulation impacts various aspects of child and family life in autistic children as compared to their non-autistic peers.

Objectives: The present study aimed to characterize impairment associated with emotion dysregulation across various social contexts (home life, out-and-about, with siblings, with peers, with nonparental adults, and in school/day care) in children with and without an autism diagnosis.

Methods: Participants were parents of 3- and 4-year-old (mean age: 4.12 (0.55)) children with ($N=30$) and without ($N=37$) autism. Parents were interviewed using an adapted version of the Early Childhood Irritability-Related Impairment Interview (E-CRI), which assesses impairment (0 = no impairment; 3 = severe impairment) associated with irritable, angry moods and tantrums across six different contexts: home life, out-and-about in the community, with siblings, with peers, with nonparental adults, and in school/day care. A linear mixed model was used to analyze the effects of diagnostic group, context, and the interaction between group and context on impairment severity scores, controlling for child age, gender, IQ scores, and adaptive communication ability.

Results: The model revealed a significant main effect of diagnostic group, $F(1,57.22) = 16.06$, $p<.001$ and a significant main effect of context, $F(5,261.6) = 22.4281$, $p<.001$. Autistic children had more severe impairment than non-autistic children. Post-hoc pairwise comparisons on impairment across contexts revealed that impairment in home life was higher than impairment across all other contexts (see Figure 1). While the overall interaction between diagnostic group and context was not significant, $F(5, 261.6) = 1.51$, $p = 0.18$, an exploratory post-hoc analysis revealed an interaction between diagnostic group and impairment out-and-about versus impairment at home. Specifically, the autism group had no difference in impairment at home versus out-and-about, while the non-autism group had significantly reduced impairment out-and-about compared to at home.

Conclusions: While prior research has established elevated emotion dysregulation in autistic children, this is the first study, to our knowledge, to examine how emotion dysregulation impacts child and family life across social contexts. Autistic children had more impairment across all contexts than their non-autistic peers. In general, emotion dysregulation impacted home life more than any other context, though autistic children had as much impairment out-and-about in the community (e.g., in grocery stores, church, extracurriculars, restaurants, etc.) as they did at home. Despite the clear impact of emotion dysregulation on autistic children and their families across social contexts, emotion dysregulation is rarely the target of early intervention. This study calls attention to the urgent need and broad potential impact of targeting emotion dysregulation early in life.

425.301 Emotion Regulation in Children with Autism Spectrum Disorder and Attention Deficit Hyperactivity Disorder: A Scoping Review

S. W. Huang¹, C. L. Koh^{2,3} and K. L. Chen^{2,3,4}, (1)Department of Occupational Therapy, College of Medicine, National Cheng Kung University, Tainan, Taiwan, (2)Department of Physical Medicine and Rehabilitation, National Cheng Kung University Hospital, College of Medicine, National Cheng Kung University, Tainan, Taiwan, (3)Department of Occupational Therapy, College of Medicine, National Cheng Kung University, Tainan, Taiwan, (4)Institute of Allied Health Sciences, College of Medicine, National Cheng Kung University, Tainan, Taiwan

Background: According to James J. Gross, emotion regulation (ER) refers to the process by which individuals manage their emotions for their emotional experience and expressions. Recent research has found that children with poor ER skills tend to struggle with social interactions and peer relationships. Autism spectrum disorder (ASD) and attention deficit hyperactivity disorder (ADHD) are common neurodevelopmental disorders in children, each with distinct symptoms. However, studies suggest that children with either ASD or ADHD experience significant difficulties with ER.

Objectives: Therefore, this study used a systematic and iterative approach to identify and synthesize an existing and emerging body of literature to explore the differences in ER between children with ASD and ADHD.

Methods: A scoping review was conducted using keywords relevant to ASD, ADHD, and ER across multiple databases, including PubMed, Cochrane Library, Embase, CINAHL, and Google Scholar. A total of 469 studies from 2000 to 2024 were identified. Among them, 14 studies focusing on 4- to 12-year-old children met the inclusion criteria in this review.

Results: This review revealed that children aged 4 to 12 with ASD and ADHD both face greater challenges in effectively regulating and expressing their emotions compared to typically developing (TD). Children with ADHD tend to display heightened emotional responses and react more intensely to emotionally arousing situations. During negative situations, they tend to focus on the obstruction, thus maintaining a high arousal level without solving the problems. Their ER is less effective, even though they understand the social rules, leading to greater levels of positive and negative emotions, which often in turn contribute to behavioral issues. Similarly, children with ASD show increased emotionality, but tend to rely on maladaptive ER strategies (e.g., suppression, avoidance) and use adaptive strategies (e.g., cognitive reappraisal, seeking social support) less frequently. This reliance on less effective strategies hindered their ability to describe and identify emotions and decreased insight into more complex emotional processes, and thus made them unable to regulate emotions, resulting in reduced emotional expression compared to TD children.

Conclusions: ER difficulties pose a significant challenge for both children with ASD and ADHD. The main difference between these two groups lies in the outcome of ER efforts: children with ADHD tend to display a wider range of emotion including both positive and negative emotions, whereas children with ASD show more restricted emotional expressions. Although several studies have explored the ER strategies commonly used by ASD children, the different types of strategies applied for regulating negative and positive emotions remain unclear. Also, there is limited research on ER strategies among children with ADHD. Future research should focus on understanding the ER strategy patterns in both children with ASD and ADHD, which could enable more tailored approaches to addressing ER difficulties in both groups from a more nuanced perspective.

425.302 Emotional Expressions Trajectories in Autistic and Non-Autistic Children: Insights from Adapted Observational Contexts
C. Lacelle^{1,2}, A. Bastien¹, K. Sotelo^{1,2}, I. Soulières^{2,3} and C. Jacques^{1,2}, (1)Université du Québec en Outaouais, Gatineau, QC, Canada, (2)Centre de Recherche, Évaluation et Intervention en Autisme (CRÉIA), Montreal, QC, Canada, (3)Department of Psychology, Université du Québec à Montréal, Montreal, QC, Canada

Background:

Studies suggest that autistic children, whether at preschool or school age, tend to express fewer positive emotional expressions in contrast to more neutral and negative ones compared to non-autistic (Trevisan et al., 2018). Certain emotional expressions are also challenging to recognize.

However, when exposed to the preschool version of the Montreal Stimulating Play Situation (MSPS) autistic children showed similar amount of positive, negative, and neutral emotional expressions as non-autistic, despite some unrecognizable/ unknown emotional expressions (Jacques et al., 2022). Utilizing a context tailored to school-age autistic children could provide deeper insights into the developmental trajectory of their emotional expressions.

Objectives:

1) Document the developmental trajectory of emotional expressions in autistic and non-autistic children, using the preschool and the new school version; 2) Compare emotional expressions at school-age between the two groups; 3) Examine how cognitive profiles may influence emotional expressions.

Methods:

Twenty-five autistic and 25 non-autistic children participated in the MSPS, with an average age of 47.7 and 43.6 months in the preschool version and 130.5 and 132.2 months in the school version ($p = 0.078$). Two naïve raters coded positive, neutral, negative and unknown emotional expression on Observer XT ©. Frequency, duration and proportion of children displaying emotional expression were analyzed. Wilcoxon Signed-Rank and McNemar tests were used for intragroup comparisons over time, while Mann-Whitney U tests were used for intergroup comparisons at school-age. Mixed longitudinal regressions were performed to explore the interaction of emotional expressions with time and group, and with IQ (WISC-V FSIQ) and NVIQ (Raven's 2), with only the results presented if significant in both duration and frequency. Holm-Bonferroni corrections led to an adjusted alpha level of 0.05.

Results:

From preschool to school age, autistic children showed an increase in both frequency and duration of neutral and unknown emotional expressions. For negative emotional expressions, duration decreased for autistic children, while frequency increased in both groups, with less pronounced changes for autistic children. Non-autistic children showed a decrease in positive emotional expressions over time in terms of duration, frequency and proportion.

At school-age, autistic children displayed positive and unknown emotional expressions more frequently and for longer along with a higher frequency of neutral emotional expressions than non-autistic children. Positive emotional expressions were expressed by 80% of autistic and 64% of non-autistic children, while negative emotional expressions were less common (28% and 32%, respectively), with no significant differences between groups.

Over time, higher FSIQ scores are linked to increased neutral emotional expressions in non-autistic children. Higher scores in both IQ and NVIQ measures are related to reduced negative emotional expressions in autistic children, while only FSIQ scores to decreased frequency and duration of negative emotional expressions in non-autistic children. Both measures are associated with attenuated increases in unknown emotional expressions in the two groups.

Conclusions:

Using a context that prompts positive emotional expressions offers valuable insights into the emotional expression trajectories of autistic children. Notably, it highlights the persistence of unknown emotional expressions over time and enables the exploration of how cognitive profiles influence emotional patterns.

425.303 Emotional Recognition in Autistic Individuals: A Nuanced Approach

R. Villeneuve¹, C. Letendre², C. Jacques³ and I. Soulieres⁴, (1)Psychology, Université du Québec à Montréal, Montreal, QC, Canada, (2)Université du Québec à Montréal, Montreal, QC, Canada, (3)Université du Québec en Outaouais, Gatineau, QC, Canada, (4)Department of Psychology, Université du Québec à Montréal, Montreal, QC, Canada

Background:

Emotional recognition (ER) is an adaptive skill essential for individuals to function socially (Izard et al., 2001). Most studies indicate that autistic individuals have greater difficulty than neurotypical individuals in recognizing emotions, particularly negative and complex emotions (Yeung, 2022; Tang et al., 2019). This difficulty has been linked to a decline in the quality of social interactions in autistic individuals (Lozier et al., 2014). However, as most studies have employed static emotional stimuli (Harms et al., 2010), the extant scientific literature does not indicate whether exposure to a more ecological context, involving dynamic emotional stimuli, would reveal different ER characteristics in autistic individuals.

Objectives:

The aim of this study was to investigate whether there are differences in ER between an autistic and a non-autistic group when exposed to a dynamic task in terms of 1) emotional valence (positive vs negative) and 2) response precision.

Methods:

The Geneva Emotion Recognition Test — Short Version (GERT-S), consisting of 42 video clips, was administered to an autistic group ($n = 30$; Age(Sd) = 35(7); 16M/14F) and a non-autistic group ($n = 55$; Age(Sd) = 30(11); 10M/45F). Participants were asked to indicate which of 14 emotions was expressed by the actor in each video clip (1 to 3 seconds; with visual and auditory cues: face, movement, upper body and prosody). Response accuracy was computed in two ways: 1) exact emotion (i.e., correct response = the target emotion) or 2) similar emotion (i.e., correct response = the target emotion or most similar emotion, e.g. joy and pride; anger and irritation). Group X Valence ANOVAs were conducted on response accuracy.

Results:

The autistic group had significantly lower ER accuracy than the non-autistic group in the exact emotion analysis (means 57 vs 64%; $F(1, 83) = 5.36, p = 0.02$). In contrast, the between-group difference was not significant in the similar emotion analysis ($F(1, 83) = 3.20, p = 0.08$). Positive emotions were better recognised than negative emotions by both groups in the exact emotion analysis ($F(1, 83) = 7.82, p = 0.01$), whereas there was no difference in the similar emotion analysis ($F(1, 83) = 2.37, p = 0.13$).

Conclusions:

The results suggest that autistic individuals have slightly lower ER abilities than their neurotypical counterparts when they must identify the exact emotion conveyed by an actor. However, the similar performance of both groups when considering similar emotions to the target emotion suggests that autistic individuals can recognize broad emotion categories as well as non-autistic individuals. This highlights the importance of exploring different flexible assessment conditions that are better suited the clinical population of autistic individuals. The study is particularly notable for its use of dynamic stimuli, a relatively ecological context, which allows the emotional abilities of autistic individuals to be more accurately reflected.

425.304 Epeekaboo: A Novel Eye-Tracking Paradigm to Track the Development of Contingency Learning and Anticipation

Z. Yu¹, M. McEllin¹, N. Kong¹, Y. C. Kuo¹, Z. Zheng¹ and C. C. Clements², (1)University of Notre Dame, South Bend, IN, (2)Labs of Cognitive Neuroscience, Boston Children's Hospital Labs of Cognitive Neuroscience, Brookline, MA

Background: The social motivation hypothesis of autism asserts that autistic people find social stimuli less rewarding on average (Chevallier et al., 2012; Clements et al., 2018). However, the term “rewarding” encompasses a broad set of processes that are poorly defined, especially in early childhood research. The developmental model of reward processing argues that in the early years, reward processing can be broken down into constituent components of contingency learning, effort, anticipation, response, and others (Clements et al., 2023). Longitudinal study of each component across early childhood will provide a foundation for how the components of reward processing develop typically – and atypically – across a variety of conditions including autism. Thus, we developed a novel experimental paradigm that blends the peekaboo game with the Doors Guessing task in a computerized experiment “ePeekaboo.” ePeekaboo was designed to measure contingency learning and anticipation through anticipatory saccades; future complementary EEG data will integrate response to reward. This project presents the first results of anticipatory saccades to social and nonsocial stimuli.

Objectives: To test whether a novel paradigm elicits measures of anticipation to social and nonsocial stimuli

Methods: ePeekaboo was completed by 30 children ages 3-6 years (Table 1). In ePeekaboo, a social (caregiver) or nonsocial (abstract art) video appears on the screen in the left or right doorway, predicted by one of two auditory cues (Fig 1). We measured anticipation during the 2500ms between the cue and video with four outcomes: A) which doorway (target or non-target) the child looked to first; B) time until first fixation on target doorway; C) number of fixations to target versus nontarget doorway; D) duration of all fixations to target versus nontarget doorway. Fixations were extracted using the dispersion-threshold algorithm for fixation identification (I-DT) from data recorded by a 120Hz Tobii Pro Fusion eye tracker. We applied an angular threshold of 0.5° and a minimum duration threshold of 100ms. For each outcome measure, we compared anticipation during social and nonsocial blocks using Wilcoxon sign-rank tests or paired t-tests when data were normally distributed. Significance was assessed using a Bonferroni-adjusted threshold of $p < 0.0125$.

Results: Participants appeared quicker to fixate on the target doorway during social trials than nonsocial trials ($M(SD)$ social = 527.7(206.0)ms, $M(SD)$ nonsocial = 596.0(472.3)ms), but the difference was not statistically significant ($W = 160.0, p = 0.50$). Similarly, participants fixated on the target doorway first in more social trials than nonsocial trials ($M(SD)$ social = 5.8(3.1), $M(SD)$ nonsocial = 5.3(3.7)), but the result was not significant ($t(29) = 0.54, p = 0.59$). No trends emerged in the number or duration of fixations to the target side (all p 's > 0.01).

Conclusions: Two outcome measures using the novel paradigm ePeekaboo appear promising for assessing anticipation in preschool-age children: time to fixation on target doorway, and number of trials with first fixation to target doorway. Future directions include individual trial analyses to assess contingency learning over trials, behavioral coding of positive affect during response, and integration of Event-Related Potential data to assess neural anticipation and response to reward.

425.305 Estimating Social Responsiveness of Adults with ASD in Group Conversations

I. Hoshina¹, C. Kobayashi², T. Sakato³, M. Tsujii^{2,3}, F. Nihei⁴, C. Takayama⁴, R. Ishii⁴, K. Stefanov^{2,3} and Y. Nakano², (1)Seikei University, Musashino-shi, Tokyo, (2)Seikei University, Musashino-shi, Tokyo, Japan, (3)Chukyo University, Nagoya-shi, Aichi, Japan, (4)NTT Human Informatics Laboratories, NTT Corporation, Yokosuka-shi, Kanagawa, Japan, (5)Monash University, Clayton, VIC, Australia

Background: Psychological tests, such as Social Responsiveness Scale (SRS-2), are widely used to screen autism spectrum disorder (ASD). However, conducting psychological tests requires professional skill and knowledge. Aiming to support the screening process, this study proposes machine learning techniques that estimate SRS-2 scores from verbal and nonverbal behaviors captured in video recordings.

Objectives: This study, first, analyzes the correlation between SRS-2 scores and verbal and nonverbal behaviors, such as prosodic features and facial expressions, in video-recorded group conversations. Based on these findings, regression models are proposed to estimate SRS-2 scores using the extracted verbal and nonverbal information.

Methods: Three-person group conversations were recorded, each group comprising one individual with ASD and two neurotypical individuals. A total of 38 participants (11 ASD and 27 neurotypical individuals) participated in the recording sessions, and 22 conversations, each of which was 5-15 minutes long, were collected. SRS-2 self-report scores were collected from all participants. In addition, family-reported SRS-2 scores were collected for ASD individuals. Audio, video, and utterance transcriptions were obtained from the recordings. From these audio, video, and text sources, prosodic features, facial features, and utterance embedding from the RoBERTa language model were extracted as input features for machine learning. To identify useful features for estimating SRS-2 scores, Pearson correlation coefficients were calculated between SRS-2 score and all audio and facial features, and features with statistically significant correlations were identified. Based on the results, regression models, including linear regression and XGBoost, were created to estimate both the overall SRS-2 score and the social communication sub-scale score. **Results:** Correlation analysis found that facial features, such as downward head movements and certain facial expressions (e.g., AU07 and AU04), were significantly correlated with SRS-2 scores. For audio features, speech intensity and some MFCC values were correlated with SRS-2 scores. Several regression models were created by combining different modalities (audio, facial, and language features). The best performing model for overall SRS-2 score estimation was an XGBoost model using language and audio features, with a root mean square error (RMSE) of 21.48. For social communication sub-scale score, the best model was an XGBoost model using the language, facial, and selected audio features that significantly correlated with SRS-2 score, achieving an RMSE of 8.68. It was also found that model performance was better in estimating family-reported SRS-2 scores than self-reported ones for ASD individuals.

Conclusions: This study proposed regression models to estimate SRS-2 scores from multimodal data, including audio, facial, and language features extracted from audio and video recordings. The XGBoost model using language and audio features outperformed others. It was found that feature-selection was useful to improve model performance, and family-reported SRS-2 scores were more reliable than self-report scores for ASD individuals.

425.306 Examining Associations between Social Experiences and Loneliness Among Autistic Youth

N. Libster¹, R. Adams², S. Zheng³, S. Bishop⁴ and J. L. Taylor⁵, (1)Vanderbilt University Medical Center, Nashville, TN, (2)Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (3)Psychiatry and Behavioral Sciences, The University of Texas at Austin, San Francisco, CA, (4)Psychiatry and Behavioral Sciences, University of California, San Francisco, San Francisco, CA, (5)Department of General Pediatrics, Vanderbilt University Medical Center, Nashville, TN

Background: Given the elevated rates of loneliness among autistic youth (Grace et al., 2022), it is important to understand which social experiences are associated with loneliness in autistic populations. Prior research examining predictors of loneliness among autistic youth have focused on the amount of time they spent interacting with others and alone (Parenteau et al., 2024). However, it may not just be the amount of time in social interactions and alone that is critical to understanding loneliness, but how the individual feels about their social interaction and solitary experiences (Adams et al., 2024). Experiences in peer groups are also associated with loneliness among autistic youth (Storch et al., 2012) and are thus equally important to consider when understanding loneliness in this group.

Objectives: Examine associations between loneliness, social interaction/solitary experiences (i.e., time spent alone and interacting, feelings about time spent alone and interacting) and peer experiences (i.e., victimization, being ignored, and being included) among autistic youth.

Methods: Autistic youth (N=241) between 15-26 years old (M=18.7) participated in the current study. Via online survey, youth reported their levels of loneliness using the Loneliness in Context Questionnaire for Adults (Weeks & Asher, 2014). Youth indicated the degrees to which they were ignored and included by their peers using the Ostracism Experiences Scale for Adolescence (OESA; Gilman et al., 2012), and the degree to which they were victimized by their peers using the Revised Schwartz Peer Victimization Scale (RSPVS; Schwartz et al., 2002). Furthermore, at 9PM each day for 7 consecutive days, participants were prompted via a smartphone app to report events that occurred within five specific time frames throughout that day (waking to 9AM, 9AM to 12PM, etc.). Youth reported how long they participated in each event and whether they were interacting with others or alone. Summary variables were derived to approximate the average amount of time that participants spent interacting and alone per day. In addition, for the longest lasting activity in each time frame, participants were presented with a list of 3 positive feelings (e.g., happy) and 7 negative feelings (e.g., stressed). Youth rated how strongly they experienced each feeling on a 3-point scale. Summary variables were derived from the ratings to approximate the average weekly positive and negative feelings scores when interacting and when alone. Multiple regressions were conducted to test the associations between each social experience measure and loneliness.

Results: Model estimates are shown in Table 1. Higher levels of being ignored were associated with higher levels of loneliness. Meanwhile, more negative feelings when alone were associated with increased loneliness, and more positive feelings when alone were associated with reduced loneliness. More negative feelings when interacting were also associated with increased loneliness. Neither time spent alone nor time spent interacting with others were significantly associated with loneliness.

Conclusions: Rather than focusing on the amount of time autistic youth spend alone and interacting, it is equally important for future interventions to facilitate positive peer experiences and consider ways to meet youth's needs for interaction and solitude.

425.307 A Computer Vision-Driven Measure of Facial Expression Atypicality in Autism

M. McNealis¹, B. Tunc², E. Sariyanidi³, L. D. Yankowitz⁴, J. Pandey⁵, R. T. Schultz⁵ and J. D. Herrington¹, (1)Children's Hospital of Philadelphia-Center for Autism Research, Philadelphia, PA, (2)Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, (3)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (4)Laboratories of Cognitive Neuroscience, Boston Children's Hospital/Harvard Medical School, Boston, MA, (5)The Center for Autism Research/CHOP, Philadelphia, PA

Background: For decades, researchers and clinicians have struggled to quantify the atypical profile of facial expressions often associated with autism. Computer vision provides us with new ways to accomplish this goal, with unprecedented precision and granularity. This study examines the coordination of facial movements constituting a smile, in a large transdiagnostic sample engaging in naturalistic social interaction.

Objectives: 1) To identify a signature of facial expression atypicality in autism. 2) To replicate prior findings of diminished smiling behavior in autism and establish the specificity of this finding to autism versus anxiety symptoms.

Methods: 192 participants (93 female; Mean age/SD/range=15.02/1.77/6.22) completed a five-minute “get-to-know-you” conversation with a confederate based on the Contextual Assessment of Social Skills, while both were video-recorded (1280x720 pixels, 60 frames/second). 42 participants carried an Autism diagnosis, 116 carried one or more non-autism psychiatric diagnosis (PSY group; 33 depression, 106 anxiety, 54 ADHD, 29 other), and 34 were neurotypical without psychiatric diagnoses (NT group; see Table 1). Confederates completed the Conversation Rating Scale (CRS), which includes items rating the prototypicality and genuineness of participants’ facial expressions. Videos were analyzed using the program OpenFace, which decomposes expressions into facial action units (AUs), including those corresponding to a smile (AUs 6 and 12) – the predominant facial expression during this type of social interaction. Atypical smiling behavior was operationalized as a diminished correlation (Pearson r) between the two smiling AUs – a metric from our prior work reflecting of the extent to which the primary facial constituents of a smile are coordinated. Analyses followed categorical (group difference) and continuous approaches (multiple regression with the Social Communication Questionnaire [SCQ] and the parent-report Multidimensional Anxiety Scale for Children [MASC-2]).

Results: As predicted, the Autism group showed a diminished correlation between smiling AUs relative to the NT group ($t(74)=3.38, p=0.001$). The PSY group was not significantly different from Autism or NT. However, the Autism group showed diminished correlation relative to the largest diagnostic category within PSY (anxiety disorders; $t(146)=2.38, p=0.019$). Multiple regression analysis (SCQ and MASC-2 predicting AU6/AU12 correlation) followed the same pattern of specificity to autism and not anxiety; autism symptoms (SCQ) were significantly related to the AU correlation ($\beta=-0.007, p<0.001$; see Fig 1.), but anxiety symptoms (MASC-2) were not ($\beta=0.001, p=0.241$). As predicted, the SCQ correlated negatively with overall smile magnitude ($r=-0.31, p<0.01$). AU correlation significantly predicted CRS items related to facial expression naturalness ($r=-0.22, p=0.003$) and emotional expressiveness ($r=0.25, p<0.001$), establishing the real-world validity of the smile AU correlation metric.

Conclusions: The present findings identify a robust, automated behavioral marker of smiling atypicality in autism. By including a transdiagnostic sample and continuous measures of both autism and anxiety, the study established specificity of this effect to autistic characteristics versus anxiety, though future research is needed to fully establish specificity relative to other traits. Future research should focus on ways of characterizing facial movements (besides AU correlations) that may prove more sensitive to expression differences in autism, as well as data collected in other interaction contexts with varying conversational partners.

**425.308** Examining the Social Content of Spontaneous Thought in Autism Spectrum Disorder

A. Green¹, L. Byrge² and D. P. Kennedy³, (1)Psychological and Brain Sciences, Indiana University - Bloomington, Bloomington, IN, (2)University of North Florida, Jacksonville, FL, (3)Psychological and Brain Sciences, Indiana University, Bloomington, IN

Background: Up to half of our waking lives are spent engaged in spontaneous thoughts, and the content of these thoughts are causally linked to a variety of mental health outcomes (e.g., anxiety, depression, well-being). Content-wise, 70% of our spontaneous thoughts involve thinking about the self and other people. This spontaneous social thought aids in both the processing of social stimuli and preparing for future social interactions, both of which have been linked to increased social success. Whether spontaneous social thought is related to social outcomes in autism spectrum disorder (ASD) – which is characterized by difficulties in social communication and interaction – remains an underexplored question.

Objectives: The aim of this research is to 1) examine whether spontaneous social thought is related to continuous traits of social aloofness, as captured by the Broad Autism Phenotype Questionnaire (BAP-Q) Aloof Subscale, and 2) examine whether there are group differences in the proportion of social vs. non-social spontaneous in autistic compared to non-autistic adults.

Methods: Participants [neurotypical controls (NT) = 117; ASD = 11] sat in front of a blank screen for 30 minutes and were instructed to let their thoughts drift. Every 20-80 seconds, a prompt would ask them to freeze their thoughts, followed by forced-choice question probes that asked if their thought was about 1) themselves, 2) other people, 3) both, or 4) neither (non-social). Participants then completed the Broad Autism Phenotype Questionnaire (BAP-Q) as a measure of social aloofness. Toward Aim 1, we examined whether the proportion of spontaneous social thought (responses indicating that the participant was thinking about other people or both themselves and other people) was correlated to the BAP-Q Aloof subscale. Toward Aim 2, we examined whether there were any differences in the proportion of responses to the four question probes between individuals with a diagnosis of ASD and our NT control sample.

Results: In our sample of NT controls, self-reported continuous traits of social aloofness were not significantly related to the proportion of social thought ($r=-0.12, p=0.21$). In our preliminary sample of autistic individuals, the ASD group reported numerically lower proportions of thought about themselves [ASD: 36.5% (SD=16.0); NT: 42.8% (19.8); $p=0.31$] and numerically higher proportions of non-social thought [ASD: 25.5% (23.5); NT: 17.4% (15.9); $p=0.13$], but these differences were not significant (Figure 1).

Conclusions: Though still preliminary, our results do not convincingly support the idea of different amounts of social thinking in ASD, or in relation to aloofness in the general population. However, our ongoing data collection will provide more convincing evidence for these claims. This work begins to fill a gap in our understanding of inner experience in ASD. Further investigation into similarities and differences into both the amount and nature of inner thought in ASD are warranted.

425.309 Executive Function Challenges: Associations with Social Communication in Autistic Teens

C. Candy¹, J. R. Bertollo², H. Behar³, A. Lopez⁴, A. Verbalis⁵, C. E. Pugliese⁶ and L. Kenworthy⁶, (1)Center for Autism, Children's National Medical Center, Washington, DC, (2)Department of Psychology, Virginia Tech, Blacksburg, VA, (3)Children's National Medical Center, Washington, DC, (4)Children's National Hospital, Washington, DC, (5)Center for Autism Spectrum Disorders, Children's National Health System, Washington, DC, (6)Center for Autism Spectrum Disorders, Children's National Hospital, Washington, DC

Background:

Challenges in social communication (SC) are common in autistic youth and predict outcomes such as loneliness, psychopathology, and quality of life. Executive function (EF) challenges are also prevalent in autism and are linked to SC abilities in children. Limited research exists on how EF predicts SC challenges in autistic teenagers. Exploring this relationship could inform interventions that help autistic youth build meaningful relationships at an age when social pressures begin to shift.

Objectives:

This study investigates how parent- and self-reported EF challenges, as measured by the Behavior Rating Inventory of Executive Function (BRIEF-2), predict parent-reported SC, as measured by the Social Communication and Interaction (SCI) index of the Social Responsiveness Scale-2nd Edition (SRS-2), in autistic teenagers. Of the BRIEF-2 indices, we hypothesized that BRI and ERI, but not CRI, would predict SCI.

Methods:

This study included 184 autistic individuals (35% female assigned at birth) ages 14-18 years old ($M=16.1$, $SD=1.19$), with a mean Full-Scale IQ (FSIQ) of 103 (Range=66-141). As part of two larger treatment trials, parents completed the BRIEF-2 and SRS-2. Teens completed the BRIEF-2 self-report. Pearson correlations were used to assess relationships between self- and parent-reported BRIEF-2 and parent-reported SRS-2 scores. Bidirectional stepwise regression models then examined how BRIEF-2 Parent indices differentially predicted SRS-2 SCI beyond age, sex, and FSIQ, using the AIC method of variable selection. After testing associations at the index level, the relationship between prominent BRIEF-2 Parent subdomain scores and SCI scores was assessed to gain a more precise understanding of the specific aspects of EF driving SC challenges. Analyses were then repeated using BRIEF-2 Self and parent-reported SRS-2 SCI to evaluate the consistency of these associations.

Results:

All BRIEF-2 Parent indices (BRI, CRI, ERI) were positively correlated with SCI. Multiple regression was first used to assess the relationship between covariates (age, sex, FSIQ) and SRS-2 SCI; none reached statistical significance ($F=1.20$, $R^2=0.019$, $p=0.31$). Stepwise regression models including covariates followed by variables of interest (parent-reported BRIEF indices) explained 45% of the variance ($F=49.74$, $R^2=0.45$, $p<.001$), revealing that parent-reported ERI ($\beta=0.55$, $p<.001$) and CRI ($\beta=0.17$, $p<.05$), but not BRI, were significant predictors of SCI, with ERI showing the largest effect. Evaluating ERI subdomains, stepwise regressions showed that parent-reported Emotional Control ($\beta=0.14$, $p<.04$) and Shift (flexibility; $\beta=0.56$, $p<.001$) subdomains explained statistically significant variance in SCI ($F=55.63$, $R^2=0.48$, $p<.001$); flexibility was the strongest factor in explaining SCI. Using self-reported EF, ERI scores, but not BRI or CRI, predicted parent-reported SRS-2 SCI scores ($\beta=0.27$, $p<.001$), with flexibility as the only statistically significant subdomain in explaining SCI ($\beta=0.29$, $p<.001$).

Conclusions:

Flexibility is a consistent predictor of SC challenges in autism; findings held true across both self- and parent-reports, increasing the robustness of these results. These findings complement research showing that EF interventions improve social skills in early childhood. Therefore, flexibility may also be a key target for social communication interventions in teens to improve key outcomes like psychopathology and loneliness, while helping autistic teens develop skills for social relationships aligned with their personal goals.

425.310 Exploring Loneliness through Cognitive Profiles: Understanding Executive Function and Mentalizing across Autistic and Non-Autistic Youth

E. L. Reckner, E. Redcay, H. A. Yarger and A. Vallorani, Department of Psychology, University of Maryland, College Park, MD

Background: Difficulties with executive function (EF) and mentalizing are hallmark cognitive features in autism spectrum disorder (ASD). Challenges in these cognitive domains are shown to be related to poor social outcomes. Across EF and mentalizing research in autistic youth, discrepant findings suggest that the heterogeneity of autism symptomatology is a major limiting factor in fully understanding cognition in autism. It is crucial to understand the complex relationship between cognitive traits and loneliness to best support autistic youth's well-being.

Objectives: Characterize the profiles of EF and mentalizing cognitive features in autistic and non-autistic youth. Explore the relationships between these profiles and social loneliness outcomes.

Methods: *Sample:* 163 eligible participants (Autistic $n=57$; Non-Autistic $n=106$) between the ages of 11 and 14 enrolled in this study (Table 1). Study recruitment is ongoing. *Measures:* IQ was estimated using the Kaufman Brief Intelligence Test, Second Edition (KBIT-2). Two executive function domains were measured using the NIH Toolbox Cognitive Battery: Dimensional Change Card Sort (DCCS) Test (flexibility), and Flanker Inhibitory Control Test (inhibition). Mentalizing was captured across two distinct tasks: The first task (STOMP) is a laboratory-developed task in which participants watched an emotionally charged film clip and described what occurred, capturing spontaneous mentalizing. The second mentalizing task, the face task, captured accuracy in labeling complex emotional states from dynamic faces (face-based mentalizing). Loneliness was captured using a modified Children's Loneliness and Social Dissatisfaction Scale. Using tidyLPA to conduct an LPA in R, we generated the estimated number of profiles and model specifications to identify the best solution based on the model fit.

Results: The autistic group reports higher levels of loneliness compared to the non-autistic group (autistic $\bar{x} = 51.31$; non-autistic $\bar{x} = 38.11$; $p < 0.001$). Groups differ significantly on Flanker ($p < 0.001$), percent accuracy on the Face Task ($p < 0.001$), and frequency of mentalizing words ($p < 0.001$), in which the autistic group scored lower than the non-autistic group. As demonstrated in our group's prior work, none of the selected measures of EF and mentalizing domains predict loneliness when we account for group differences. Preliminary LPA results indicate that 5 distinct EF and mentalizing profiles best fit the data (Figure 1). These profiles significantly predicted loneliness ($\beta = -1.80$, $p = 0.03$) controlling for the diagnostic group.

Conclusions: Supporting prior claims, our results indicate that autistic youth experience more feelings of loneliness than their non-autistic peers. Based on our group's previous work suggesting that a profiles approach is best to explore the heterogeneous nature of cognitive skills in autism, these results provide novel evidence that distinct profiles of mentalizing and executive function exist in autistic samples. In interpreting our results, participants fitting Profile #4, with low spontaneous mentalizing, moderate face-based mentalizing, and high executive functioning scores, reported the lowest loneliness rates. Participants fitting Profile #5, who had low executive function and low spontaneous and face mentalizing, reported the greatest rates of loneliness. Future directions include a more robust sample upon completion of study data collection and additional diagnostic exploration of these profiles.

425.311 Exploring Parental Monitoring of Digital Media in Autistic Adolescents and Young Adults: Insights from Factor Analyses
M. E. Contreras-Perez¹, X. Tao¹, L. Micalizzi², K. Bradley³, C. A. Cragin³, A. Spirito³, K. M. Jackson³ and S. J. Sheinkopf⁴, (1)Psychiatry, Rutgers University, Piscataway, NJ, (2)Brown University, Providence, RI, (3)Rutgers University, New Brunswick, NJ, (4)Thompson Center for Autism & Neurodevelopment, University of Missouri, Columbia, MO

Background: Parental monitoring is linked to lower engagement in risky behaviors in youth (Dittus et al., 2023). Restrictive monitoring may be associated with problematic internet use in adolescents, while active and deference monitoring show more positive family outcomes (Hernandez et al., 2023). Youth diagnosed with Autism Spectrum Disorders (ASD) use digital media differently than their peers, potentially increasing their risk for adverse outcomes, including cyberbullying and online miscommunication (Gwynette et al., 2018; Phillips & Anderson, 2020). Measurement development is needed to study caregiver monitoring and online experiences in autistic youth effectively.

Objectives: This study explores the factor structure of the Digital Parenting Mediation Attitude Scale (DPMAS; Navarro et al., 2023) adapted for use on adolescents and young adults diagnosed with ASD, and explores age-related differences in parental monitoring of digital media use.

Methods: Data were drawn from an ongoing longitudinal investigation of alcohol and other substance use in adolescents and young adults with ASD ($N = 238$, aged 12-24, 54.2% male, $M = 19.06$ years, $SD = 3.68$). The original DPMAS was adapted to a 35-item self-report Likert scale by removing nine items related to modeling and adding "not applicable" as a response option. Exploratory and Confirmatory Factor Analyses (EFAs and CFAs) were conducted. Iterative modifications included removing items with low factor loadings, allowing items with high residual correlations to covary, and combining highly related factors (Sarmiento & Vera-Costa, 2019; Wider et al., 2023). Factor scores were then analyzed by age group (adolescents ages 12-17 vs. young adults ages 18-24).

Results: Five factors were extracted in the EFA, explaining 75.23% of the variance. Using a split sample approach, CFA resulted in four factors with acceptable model fit indices ($CFI = 0.898$, $TLI = 0.887$, $RMSEA = 0.061$, $SRMR = 0.067$; see Figure 1). Standardized factor loadings ranged from 0.44 to 0.98. Factor scores analysis by age group revealed differences in digital media use patterns (Table 1). Adolescents reported significantly higher "Limits and Monitoring" ($p = .013$), and "Discussions of Online Behavior and Content," although this difference was not statistically significant ($p = .565$). Young adults reported significantly higher "Parent-Youth Interaction in Social Media and Games" ($p = .048$) and "Parent Involvement in Digital Platforms and Activities" ($p = .028$).

Conclusions: Exploratory and confirmatory analyses resulted in 4 factors that describe different aspects of caregiver limit setting, monitoring, and involvement with digital and social media experiences in autistic youth. Age-related differences were identified between adolescents and young adults diagnosed with ASD, indicating that adolescents reported that their parents set more limits and more actively monitor online activity than parents of young adults. These age-related differences in control and guidance mirror the developmental pattern of parental monitoring observed in the general population. Interestingly, young adults with ASD reported higher parent-youth interaction in social media and online games, indicating persistent engagement of parents in media use into young adulthood. This preparatory work lays the foundation for future research and intervention to improve the well-being of youth diagnosed with ASD in the digital age.

425.312 Exploring Social Goal Achievement for Youth with ASD and ADHD: Insights from PEERS for Adolescents

E. C. Turner¹, C. T. Moody², K. L. Fisher³ and E. A. Laugeson⁴, (1)UCLA Department of Psychiatry, PEERS lab: UCLA PEERS Clinic, Los Angeles, CA, (2)UCLA Semel Institute for Neuroscience and Human Behavior, University of California Los Angeles, Los Angeles, CA, (3)UCLA Semel Institute for Neuroscience and Human Behavior, UCLA PEERS Clinic, Los Angeles, CA, (4)UCLA Semel Institute for Neuroscience and Human Behavior, UCLA PEERS® Clinic, Los Angeles, CA

Background: Both autistic adolescents and adolescents with attention-deficit hyperactivity disorder (ADHD) may experience social challenges leading to peer difficulties (Mikami et. al, 2017). Literature suggests that youth with co-occurring diagnoses of autism and ADHD may have greater treatment needs as compared to youth with a singular diagnosis (Zablotsky et al., 2020; Sprenger et al., 2013). The PEERS® for Adolescents social skills program (Laugeson et al., 2014) has a strong evidence base in promoting positive social outcomes for autistic teens (Zheng et al., 2021). Data has also demonstrated that PEERS® is effective in improving relational skills through standardized questionnaires for adolescents with ADHD with or without autism (Geannopoulos et al., 2024). However, in the wake of the neurodiversity movement, it is essential to center neurodivergent voices and ensure that social skills programming helps youth meet their own unique social goals (Pellicano & den Houting, 2022).

Objectives: Recent research indicates that across a neurodiverse sample of PEERS® participants, teens report significant improvements in satisfaction with their individualized social goals (Fisher et al., 2024). However, less is known regarding the types and achievement of these individualized social goals by diagnosis.

Methods: Participants included 72 adolescents ($M_{age}=14.01$, $SD=1.85$; 59.7% male) who enrolled in PEERS® for Adolescents. Adolescents had diagnoses of ADHD without autism ($n=18$), autism without ADHD ($n=26$), or co-occurring ADHD and autism ($n=28$). Adolescents identified 1-3 social goals, with goals later coded into six different types (i.e., conversational skills, making friends, deepening friendships, conflict resolution, social confidence, and other) with 80% inter-rater reliability. Adolescents ranked their satisfaction with each goal on a 7-point Likert scale from “very dissatisfied” to “very satisfied” the first week of PEERS® (T1), after 8-weeks (T2), and at 16-weeks upon completing the program (T3). Using the goal satisfaction outcome, a repeated measures ANOVA was conducted to test for the presence of an interaction between time and diagnostic group (ADHD, autism, autism+ADHD).

Results: Crosstabulation analysis indicated no differences in the types of social goals endorsed across the three diagnostic groups, $\chi^2(10) = 5.53$, $p = .853$. A repeated measures ANOVA revealed a significant time by diagnostic group interaction, $F(3.3,258)=2.66$, $p=.043$. The nature of this interaction suggested that although all diagnostic groups significantly improved in their ratings of social goal satisfaction, $p's<.001$, the co-occurring autism+ADHD group showed the greatest rate of improvement over the course of PEERS® for Adolescents.

Conclusions: Results provide continued support for the social validity of PEERS® for Adolescents, as participants with varying neurodivergent presentations endorsed progress toward self-identified social goals. Interestingly, despite distinct symptom profiles and associated social challenges (Mikami et al., 2019), adolescents with ADHD, autism, and co-occurring presentations were similarly likely to endorse different goal types. The finding that the co-occurring autism and ADHD group reported greater improvements in goal satisfaction differs from previous research that suggested similar outcomes across these diagnostic groups using standardized measures (Geannopoulos et. al, 2024). This may suggest the presences of qualitative differences in PEERS®program response that are not being fully captured by standardized questionnaires, warranting further investigation.

425.313 Exploring the Associations between Autistic Traits, Alexithymia, Social Competence, and Parent-Child Attachment Among Autistic Children

R. Batra¹, T. Q. Boucher², C. L. McIntyre², I. Bharadwaj², M. Gurm², A. Minniss² and G. Iarocci², (1)Psychology, Simon Fraser University, Burnaby, BC, (2)Psychology, Simon Fraser University, Burnaby, BC, Canada

Background: Attachment theory emphasizes the critical role of parent-child attachment in non-autistic children's socio-emotional development, though the relationship between parent-child attachment and socio-emotional development is under-studied in autistic children (Groh et al., 2016). Attachment insecurity may be more common among autistic people (Kahane & El Tahir, 2015), and autistic traits are predictive of avoidant attachment (Gallitto & Leth-Steensen., 2015). Attachment insecurity has been linked to higher levels of alexithymia (difficulty interpreting and expressing emotions; (Besharat & Shahidi, 2014) while secure attachment has been associated with better socio-emotional skills, lower alexithymia, and reduced social difficulties (Jin et al., 2022; Takhashi et al., 2013). However, a few studies have reported conflicting or null results (Oskis et al., 2013). Given the higher potential for attachment insecurity in autistic populations, more research is needed to understand its potential impact on socio-emotional functioning.

Objectives: The purpose of this study was to determine the relationship between attachment insecurity, autistic traits, alexithymia, and social competence among autistic children.

Methods: Participants were 56 autistic children (Mean age=10.07, SD=2.06; 33 boys, 23 girls), aged 6-13 years, and their parents participated in this study by completing online questionnaires. Caregivers completed the Autism Spectrum Quotient (AQ; Baron-Cohen et al., 2001) measuring autistic traits, the Children's Alexithymia Measure (CAM; Way et al., 2010) assessing alexithymia traits, the Multidimensional Social Competence Scale (MSCS; Yager & Iarocci, 2013) measuring children's social competence, and the Adolescent Attachment Anxiety & Avoidance Inventory (AAAAI; Moretti & Obsuth, 2009) assessing attachment insecurity. Bivariate correlations and linear regressions were conducted to examine the relationships between AQ, CAM, MSCS, and AAAAI scores.

Results: Correlational analyses demonstrated that alexithymia traits were positively correlated with attachment avoidance ($r(54)=.28, p=.03$) but not attachment anxiety ($r(54)=.14, p=.36$). Linear regressions showed that attachment avoidance accounted for 28% of the variance in alexithymia traits ($F(1,54)=4.61, p<.05$). Autistic traits did not account for any variance in either attachment anxiety or attachment avoidance. Additionally, both attachment anxiety and attachment avoidance did not account for any variance in social competence.

Conclusions: Only attachment avoidance was related to alexithymia traits, suggesting that autistic children with higher attachment avoidance struggle more with emotional awareness and expression. Attachment avoidance has shown strong linkage to emotional suppression and inhibition (Mikulincer & Shaver, 2019). However, attachment style was not related to autistic children's social competence. Contrary to research with autistic adults (Gallitto & Leth-Steensen., 2015), we did not observe a link between autistic traits and insecure attachment. This may be because attachment is more malleable in middle childhood as compared to adulthood (Kobak & Madsen, 2008), and caregivers' increased involvement at this stage may mitigate the impact of autistic traits on attachment. Our findings suggest that the connection between attachment and socio-emotional development may be weaker in autistic children than what is found in non-autistic children (Groh et al., 2016). A limitation of our study is the lack of a non-autistic comparison group to determine if attachment avoidance is also related to alexithymia traits or if this association is unique to autistic children.

425.314 Exploring the Continuum of Autistic-like Traits: Insights from Demographic, Genetic, and Neuroimaging Correlates in the Adolescent Brain Cognitive Development Study

L. Huang¹, L. Fei², T. Ren³ and F. Li⁴, (1)Xinhua Hospital Affiliated to Shanghai Jiao Tong University School of Medicine, Shanghai, Shanghai, (2)Xinhua Hospital Affiliated to Shanghai Jiao Tong University School of Medicine, Shanghai, Shanghai, China, (3)Developmental and Behavioral Pediatric Department & Child Primary Care Department, Brain and Behavioral Research Unit of Shanghai Institute for Pediatric Research and MOE Shanghai Key Laboratory for Children's Environmental Health, Xinhua Hospital, Shanghai, Shanghai, China, (4)Developmental and Behavioral Pediatric Department & Child Primary Care Department, Brain and Behavioral Research Unit of Shanghai Institute for Pediatric Research and MOE Shanghai Key Laboratory for Children's Environmental Health, Shanghai, Shanghai, China

Background: An increasing number of studies have utilized autistic-like traits in the general population as an outcome measure to gain insight into autism spectrum disorder (ASD), aligning with the dimensional understanding of the condition. However, autistic-like traits have not been well characterized in large child cohorts, particularly regarding its similarities and differences to ASD in terms of demographics, genetics, neuroimaging, and comorbidities.

Objectives: This study aims to explore the demographic, genetic, neuroimaging, and mental health comorbidities associated with autistic-like traits, comparing those with the highest levels of these traits with individuals diagnosed with ASD.

Methods: This study included 9,788 non-ASD children and 182 autistic children aged 9-11 years from the Adolescent Brain Cognitive Development Study. Autistic-like traits were assessed using the short social responsiveness scale (SSRS). Generalized linear mixed-effect models were applied to evaluate the associations of SSRS with a spectrum of demographic, genetic, neuroimaging, and clinical characteristics. We estimated the heritability of SSRS using twin and sibling data.

Results: Our finding revealed that children with higher SSRS exhibited a higher male-to-female ratio. SSRS had a high heritability of 0.52 (95% CI, 0.45 to 0.63), and higher SSRS scores were correlated with increased polygenic risk for ASD ($P < 0.001$). Neuroimaging analyses identified both overlapping and unique neurobiological underpinnings, with sex-specific variations in structural and functional connectivity similar to those observed in ASD. Higher SSRS scores were linked to lower fluid intelligence, more behavioral problems, more sleep problems, and more psychotic-like symptoms.

Conclusions: These findings underscore the continuity and divergence between ASD and autistic-like traits, advocating for a more inclusive understanding of autism within the general population. Our findings emphasize the need for nuanced diagnostic and therapeutic approaches that accommodate the wide spectrum of autistic expressions.

425.315 Exploring the Interplay between Depression and Mentalizing in Autistic Young Adults

A. Kataria¹, M. C. Hunsche² and C. M. Kerns², (1)Psychology, University of British Columbia, Vancouver, BC, Canada, (2)University of British Columbia, Vancouver, BC, Canada

Background:

Difficulties mentalizing (i.e. interpreting others' thoughts and emotions), including more overmentalizing (i.e., over-attributing mental states), undermentalizing (i.e., missing social cues), and nonmentalizing (i.e., relying on non-mental explanations) (Müller et al., 2016) appear more common in autistic relative to non-autistic individuals. Depression has also been linked with mentalizing differences, particularly under-interpretation of others' mental states (Zwick & Wolkenstein, 2017); however, results are inconsistent (Nestor et al., 2023). Nonetheless, limited research has examined how mentalizing abilities relate to the frequent co-occurrence of autism and depression in adults. The use of both implicit (i.e., automatic, flexible cognitive processes) and explicit (i.e. deliberate, reasoned judgments) mentalizing measures has been particularly lacking, though together, they may offer complementary perspectives into both spontaneous and reflective aspects of an individual's social cognition.

Objectives:

To investigate how depressive symptoms relate to overall mentalizing accuracy and specific social-cognitive errors (under-, over-, and non-mentalizing) in autistic young adults. We hypothesized that depressive symptoms would be associated with reduced accuracy overall and greater undermentalizing specifically, as in non-autistic samples (Wolkenstein et al., 2011).

Methods:

Fifty-eight autistic young adults (see Table 1 for characteristics) were recruited from Canada and the US (50% participated in person, 50% online via Zoom). Eligibility criteria included English proficiency, no history of psychotic disorder, and an autism diagnosis (confirmed via clinical documentation and meeting clinical cut-offs per the Autism Diagnostic Observation Schedule-2 [in-person sample] or Ritvo Autism & Asperger Diagnostic Scale [online sample]). Participants completed self-report measures of depression (Patient Health Questionnaire-9; Kroenke, Spitzer, & Williams, 2001), autistic traits (Social Responsiveness Scale-2), and social anxiety (Liebowitz Social Anxiety Scale; Liebowitz, 1987), a video-based measure implicit task (Movie for Assessment of Social Cognition; MASC; Dziobek et al., 2006) and a vignette-based explicit task (Strange Stories Task; Happe, 1994). Five hierarchical linear regressions tested relationships between depressive symptoms and overall MASC and Strange Stories accuracy, and as well as specific MASC errors (undermentalizing, overmentalizing, nonmentalizing errors), covarying for IQ, autistic traits and social anxiety.

Results:

Greater depressive symptoms were associated with more accurate performance on the MASC ($\beta = .302, p = .050, R^2 \text{ change} = .053$) and Strange Stories task ($\beta = .161, p = .008, R^2 = .084$; see Table 2). Analyses of subtype errors showed no significant associations, though higher IQ was significantly associated with fewer errors of all types, and higher autistic traits with more undermentalizing.

Conclusions:

Contrary to our hypothesis, more accurate mentalizing was linked to higher depressive symptoms among autistic young adults. Greater awareness of social cues may increase vulnerability to depression by heightening sensitivity to one's social differences and negative cues (as in non-autistic adults; Bechtoldt & Schneider, 2016; Hunsche & Kerns, under review). Alternatively, successful mentalizing may come at the cost of well-being, as these efforts could stem from feelings of insecurity or camouflaging (Cage et al., 2019; Hull et al., 2021). Our sample's characteristics (eg., above-average IQ, 50% gender-diverse) limit generalizability, highlighting the need for more diverse samples in future research.

425.316 Facial Expressivity in Autistic and Non-Autistic Adults during Mild and Intense Emotional Experiences

S. J. Foster¹, A. E. Pinkham² and N. J. Sasson², (1)Psychology, University of Texas at Dallas, Richardson, TX, (2)University of Texas at Dallas, Richardson, TX

Background: Autistic adults often differ in facial expressivity (Faso et al., 2015; Foster et al., 2024) in ways that can be perceived negatively and misinterpreted by non-autistic people (Sasson et al., 2017; Sheppard et al., 2016). Automated emotion recognition software indicates that autistic and non-autistic adults differ in expressivity across contexts, with non-autistic adults displaying more positive affect, and negative affect in autistic adults relating to less favorable first impressions (Foster et al., 2024). However, no studies have yet examined whether these differences are driven by differences in the experience of emotion rather than the expression of it.

Objectives: To determine whether emotional expressivity differs in autistic and non-autistic adults when experiencing mild and intense emotional events.

Methods: Twenty autistic and twenty non-autistic adults, comparable on age ($M_A = 25.55$, $M_{NA} = 25.85$, $p = .180$), gender ($p = .321$), ethnicity ($p = .143$), and IQ using the WASI-II ($M_A = 114.00$, $M_{NA} = 113.30$, $p = .435$) were video recorded after being coached to re-live mild and intense experiences of happiness, sadness, and anger using an established methodology (Faso et al., 2015). Participants rated how much emotion they experienced during each recounting. Later, the positive, neutral, and negative affect of participants was classified from videos with iMotions software used in previous studies quantifying expressivity in autism (Foster et al., 2024; Trevisan et al., 2016).

Results: A mixed model ANOVA with group as the between-group variable and emotion and intensity as the within-group variables on self-reported scores of experienced emotion found a main effect of emotion ($p < .001$) and intensity ($p < .001$), indicating that participants reported more experienced emotion for sadness than anger, and for strong compared to mild events. However, the main effect of diagnosis was not significant ($p = 0.69$), indicating that autistic and non-autistic participants did not differ in how much emotion they experienced. When videos of these experiences were analyzed with iMotions, there was a significant interaction between intensity, emotion, and diagnosis ($p = .013$). More positive affect was detected in non-autistic faces ($M = 33.89$, $SD = 5.56$) compared to autistic ones ($M = 16.69$, $SD = 5.56$; $p = .035$), and more neutral affect was detected in autistic faces ($M = 74.67$, $SD = 5.34$) compared to non-autistic ones ($M = 54.12$, $SD = 5.34$; $p = .010$) when recounting mild emotional experiences (figures 1-2).

Conclusions: Despite autistic and non-autistic participants not differing in the amount of emotion experienced, iMotions classified more positive affect in non-autistic expressions and more neutral affect in autistic participants in the mild condition, suggesting that autistic and non-autistic people may be more similar in their expression of intense emotion. However, differences emerged in more subtle emotional expressions. Autistic people may not express mild emotion in their faces as prominently as non-autistic people do or do so in ways that are less identifiable to automated software and non-autistic people. Greater positive affect in non-autistic faces relative to autistic faces may relate to positivity biases favoring non-autistic people. We are now collecting non-autistic rater data to determine if raters also have more difficulty identifying mild emotional states of autistic participants. These data will be included at the time of the conference.

425.317 Friendships in a Diverse Group of Autistic Adolescents and Adults: A Mixed-Methods Approach

D. R. Jones¹, V. Alleluia Shenge¹, A. Rao², D. Harris¹, M. Botha³, H. A. Yarger⁴, P. Munshell¹, O. Oladiran¹, K. Dow-Burger², N. J. Sasson¹ and E. Redcay¹, (1)Department of Psychology, University of Maryland, College Park, MD, (2)University of Maryland, College Park, MD, (3)Department of Psychology, Durham University, Stirling, United Kingdom, (4)University of Texas at Dallas, Richardson, TX

Background: Friendships are crucial during adolescence, providing support and social development (Moore et al, 1991). Autistic people may experience differences in communication styles, sensory sensitivities, and social presentation, which can influence peer interactions (Daugherty et al., 2019). Additionally, external factors such as peer attitudes, access to social support, and inclusive environments play a significant role in shaping friendship opportunities (Ridgway et al., 2023). These barriers to friendship may predispose autistic people to an increased risk of loneliness and social isolation (Deckers et al., 2017). Therefore, a better understanding of the interplay of individual, peer, and environmental factors related to autistic friendship is essential.

Objectives: This work sought to better describe the characteristics of friendships in a diverse set of autistic adolescents and adults, as well as potential barriers to these relationships.

Methods:

Study 1: 15 autistic teens from diverse racial and ethnic backgrounds ($M_{age} = 15.2$ years, $SD = 1.7$; 44% Black, 22% White, 17% Asian, 13% more than one race, 17% Hispanic or Latino) participated in interviews and focus groups related to their social experiences. Responses were recorded and transcribed verbatim, with an inductive approach to thematic analysis (Braun and Clarke 2006, 2022) used to identify salient themes in the data.

Study 2: 16 Black and 16 White autistic adults ($M_{age} = 26.3$ years, $SD = 6.9$) participated in an interview about their social experiences. Interviews were recorded, transcribed, and analyzed following a similar procedure to study 1. A quantitative content analysis was also conducted to compare experiences of belonging in Black and White autistic people.

Results:

Study 1: Several themes related to friendship and social interaction were identified. Participants described 1) the characteristics of friendships, including a preference for similar peers, 2) the benefits and challenges associated with friendships, and 3) the barriers they face within broader peer interactions. Overall adolescents reported challenges with peers and high rates of loneliness. They also described the importance of having good friends and being around similar peers to help protect against these negative experiences.

Study 2: The social experiences of autistic adults shared many similarities with those of adolescents, especially when describing preferred characteristics in friends. Participants often experienced sensory barriers in social settings, and felt a pressure to mask their autistic traits to fit in better, contributing to social withdrawal. The content analysis suggested that Black autistic adults were more likely to report a lack of community support ($p = .001$), and more likely to form cross-group friendships ($p = .023$) compared to White autistic adults.

Conclusions: These findings suggest that autistic youth and adults may face similar barriers to friendship, and value similar characteristics when forming friendships. The results also highlight the importance of incorporating diverse samples, as certain social experiences may differ as a function of race. By understanding the factors contributing to friendship experiences in diverse groups of autistic people, we can encourage the development of supports that help foster genuine, lasting connections, ultimately improving social connection and well-being in autistic youth as they grow.

425.319 Gender and Autistic Camouflaging: CAT-Q Scores in Transgender, Nonbinary, and Cisgender Autistic Adults

A. E. Winge-Breen^{1,2}, M. I. Pascoe³, W. Ai⁴, Z. Lin⁵, A. I. van der Miesen⁶, K. Cooper⁷ and M. C. Lai⁸, (1)Psychology, University of Toronto, Centre for Addiction and Mental Health, Toronto, ON, Canada, (2)Campbell Family Mental Health Research Institute, Centre for Addiction and Mental Health (CAMH), Toronto, ON, Canada, (3)Queen's University, Kingston, ON, Canada, (4)Department of Psychology, University of Toronto, Toronto, ON, Canada, (5)Psychology, University of Toronto, Toronto, ON, Canada, (6)Department of Child and Adolescent Psychiatry, Center of Expertise on Gender Dysphoria, Amsterdam University Medical Centers, Location Vrije Universiteit, Amsterdam, Netherlands, (7)Department of Clinical, Educational and Health Psychology, University College London, London, London, United Kingdom, (8)Campbell Family Mental Health Research Institute, Centre for Addiction and Mental Health, Toronto, ON, Canada

Background:

Gender diversity and autistic identity commonly coexist. Substantial disparities are encountered by autistic, gender-diverse and transgender individuals in assessment and healthcare. Research has identified disparities in autism diagnosis in subpopulations not represented by the stereotypical autism profile (primarily based on cisgender boys) and is beginning to explore specific autistic experiences in underserved populations. "Camouflaging", or "masking" autistic traits, is one such experience which can contribute to under-identification. The Camouflaging Autistic Traits Questionnaire (CAT-Q) has been used to study subjectively perceived camouflaging differences between predominantly cisgender autistic men and women, and in limited research, has included gender-diverse autistic people on a broad level. Yet, research has not addressed how CAT-Q scores vary among specific gender-diverse and transgender groups.

Objectives:

This study investigates how CAT-Q scores differ among autistic binary transgender men and women, nonbinary individuals, and cisgender men and women as an exploratory step in understanding the applicability of the CAT-Q and potential camouflaging differences in these groups.

Methods:

A total of 900 autistic adults, including transgender and gender-diverse participants (58 transgender men, 51 transgender women, 309 nonbinary individuals, 261 cisgender men, 221 cisgender women), were recruited through Prolific. Participants who reported a professional or self-diagnosis of autism were included in this study. Camouflaging experiences were measured using the CAT-Q. An Analysis of Variance (ANOVA) examined differences in CAT-Q total score among autistic transgender men, transgender women, nonbinary individuals, cisgender men, and cisgender women. A Multivariate Analysis of Variance (MANOVA) examined how the three CAT-Q subscores (compensation, masking and assimilation) differed between these groups.

Results:

Significant differences in CAT-Q total score across groups ($p < 0.001$) were found. Post-hoc comparisons revealed that cisgender autistic men scored significantly lower than cisgender autistic women and nonbinary autistic individuals ($p < 0.001$), and that transgender autistic women scored lower than cisgender autistic women ($p = 0.030$). The MANOVA also showed significant differences in CAT-Q subscores by groups (Wilks' Lambda = 0.915, $F(12, 2362.9) = 6.70$, $p < 0.001$). Post-hoc ANOVAs for each subscore showed that cisgender autistic men scored significantly lower than cisgender autistic women on compensation ($p < 0.001$) and masking ($p = 0.016$). Transgender autistic women scored significantly lower than cisgender autistic women on compensation ($p = 0.030$) and masking ($p = 0.002$). In assimilation, cisgender autistic men scored lower than cisgender autistic women ($p < 0.001$), while nonbinary autistic individuals scored higher than cisgender autistic men ($p < 0.001$).

Conclusions:

CAT-Q scores differed on average between cisgender, binary transgender, and nonbinary autistic adults. While this may indicate camouflaging differences between cisgender, gender-diverse and transgender autistic groups, it may also reflect the yet undetermined measurement invariance of the CAT-Q as a measure across transgender and gender-diverse populations. The unbalanced representation of transgender groups, where binary transgender individuals were proportionally the least represented in the sample, should be taken into account. Future research should focus on validating the CAT-Q in gender-diverse groups, and exploring factors that contribute to differences in CAT-Q scores and camouflaging.

**425.320 Having Older TD Siblings Is Associated with Better Social Functioning in Autistic Children; What about Having Older Autistic Siblings?**

Y. Rum¹, A. Dolev², D. A. Zachor³, E. Avni⁴, **M. Ilan**⁵, G. Meiri⁶ and J. Koller², (1)Seymour Fox School of Education, Autism Research Centre - University of Cambridge, Jerusalem, United Kingdom, (2)Seymour Fox School of Education, The Hebrew University of Jerusalem, Jerusalem, Israel, (3)ALUT The Israeli Society for autistic children, Tel-Aviv, Israel, (4)The Autism Center/ALUT, Pediatrics, ALUT-Israeli organization for Children with ASD, Zerifin, Israel, (5)Psychology Department, Ben-Gurion University of the Negev, Beer Sheva, Israel, (6)26 YA'ARA ST., Beer-Sheva, Israel

Background:

Previous research showed that having older, typically developing (TD) siblings is associated with better social functioning in autistic children. Modeling by the older sibling and the fact that siblings provide a social companion to practice social skills were suggested as explanations. This raises the question of what occurs when autistic children have older autistic siblings. In this case, modeling by the sibling might lead to more autistic symptoms, and at the same time, greater companionship might be expected between two autistic siblings under the double empathy problem framework.

Objectives: To investigate whether findings of a positive effect of older TD siblings on the social functioning of autistic children replicate and whether having older autistic siblings is associated with a similar or an opposite pattern.

Methods: The National Autism Database of Israel was used to retrieve collected data for secondary analyses (1,596 autistic children who completed the Autism Diagnostic Observation Scale [ADOS]). After removals according to exclusion criteria (>18 years of age, non-Hebrew speakers, missing data, no diagnosis, not living with biological parents, older non-TD siblings), a cohort of 794 children was scanned to identify autistic children with no siblings (No-Sib; $n=135$), older TD siblings (Older-TD-Sib; $n=261$), and older autistic siblings (Older-Autistic-Sib; $n=27$). Each Older-Autistic-Sib child was matched to 1. Older-TD-Sib, and 2. No-Sib, by sex, age, and cognitive scores, resulting in 25 triads of three matched participants (i.e., 25 participants in each group, see Table 1). The groups were compared on a measure of social functioning (ADOS social effect [SA] sub-domain; A lower score (0-10) indicates less severe social-communication symptoms [better social functioning]).

Results: The effect of group (No-Sib/Older-TD-Sib/Older-Autistic-Sib) on autistic children's social functioning (ADOS-SA) was compared using a repeated measures ANOVA, which indicated a significant difference between at least two groups ($F_{(2, 24)}=3.88, p=.027, \eta^2=.073$). Results from three paired t-tests revealed that autistic children with older TD siblings had better social functioning than autistic children with no siblings ($t_{(24)}=-3.84, p<.001, d=.761$), and no significant difference between the social functioning of autistic children with older autistic siblings compared with autistic children with no siblings ($t_{(24)}=-1.57, p=.129, d=.343$), or with older TD siblings ($t_{(24)}=-1.01, p=.321, d=.294$).

Conclusions: We replicated the finding of a positive effect of having older TD siblings on the social functioning of autistic children. There was no evidence of a significant effect of having an older autistic sibling on either better or worse social functioning of autistic children. However, while autistic children with TD siblings outperformed those with no siblings, they did not outperform those with older autistic siblings. The group of autistic children with autistic siblings demonstrated an "intermediate pattern" between the other two groups. This implies that there could be a positive effect of having an older autistic sibling, albeit smaller, and more statistical power is needed to detect it. This could be explained by complex relationships between sibling modeling and sibling companionship or the impact of parenting measures, such as experience or knowledge. These speculative explanations should be directly examined in future research.

425.321 How Autistic Children Recognize Mask-Wearing and Sunglasses-Wearing Faces: Implications for Face Processing

Z. An¹, W. Ni², X. Peng^{3,4}, T. Li⁵, R. Shi⁶ and L. Yi⁷, (1)Yuanpei College, Peking University, Beijing, China, (2)School of Psychological and Cognitive Sciences & Key Laboratory of Behavior and Mental Health, Peking University, Beijing, China, (3)Academy for Advanced Interdisciplinary Studies, Peking University, Beijing, China, (4)Peking-Tsinghua Center for Life Sciences, Peking University, Beijing, China, (5)Department of Psychology, School of Education Science, Qingdao University, Qingdao, Shandong, China, (6)Qingdao Autism Research Institute, Qingdao, Shandong, China, (7)PKU-IDG/McGovern Institute for Brain Research, Peking University, Beijing, China

Background: Face recognition deficit is a key characteristic of autism. Two kinds of hypotheses have been proposed to explain this phenomenon. One kind of explanation emphasizes the different generalized face processing strategies in autism due to holistic processing deficits (Rose et al, 2006) or local processing bias (Deruelle et al., 2006). Another explanation is the eye avoidance hypothesis (Tanaka & Sung, 2016), which suggests that less attention to the eye region in autism leads to deficits in face recognition. After the COVID-19 pandemic, wearing a mask has become more common. It can also disrupt the holistic processing of faces and make people focus more on the eyes. This may lead to different challenges for face recognition in autism and neurotypical (NT) individuals.

Objectives: This study explored the effects of facial occlusion on recognition abilities and gaze patterns in autistic and NT children using eye-tracking technology, aiming to provide new evidence for the two kinds of hypotheses for face recognition deficits in autism.

Methods: Thirty-one autistic children (age: 5.91 ± 0.80 years) and 29 NT children (age: 5.43 ± 0.81 years) participated in this study. Participants conducted a face recognition task with three blocks using original faces, mask-wearing faces, and sunglasses-wearing faces as stimuli. Each block contained ten trials. During each trial, the target face was displayed for 5 seconds in the familiarization phase. After a random interval of 1-2 seconds, the distractor and target face were presented at the same time with randomized position assignments. Participants chose which face was the target with no time limit. We used a Tobii Pro Fusion eye tracker to record participants' eye movements during the familiarization phase. Statistical analysis was performed using Mann-Whitney U tests, Wilcoxon signed rank tests, linear mixed models (LMM), and generalized linear mixed models (GLMM).

Results: The analysis of behavioral data showed that wearing a mask ($p = .007$) or sunglasses ($p = .034$) significantly reduced only NT children's recognition accuracy. We found no significant group difference in the accuracy of recognizing three types of faces. The analysis of gaze patterns revealed that the eye region's gaze proportion of mask-wearing faces ($p = .017$) and the mouth region's gaze proportion of sunglasses-wearing faces ($p < .001$) were significantly higher than the corresponding region of original faces for all participants. Autistic children's gaze proportion of eye region was significantly lower than NT children ($p = .002$). GLMM analysis showed that autistic children's gaze proportion of the eye region positively predicted their recognition accuracy of mask-wearing faces ($p = .007$), and NT children's gaze proportion of the mouth region positively predicted their recognition accuracy of sunglasses-wearing faces ($p = .039$).

Conclusions: This study found that the disruption of holistic processing caused by facial occlusion did not impair face recognition in autistic children, suggesting different holistic-local processing strategies between autistic and NT children. While autistic children demonstrated eye avoidance, it did not lead to recognition deficits.

425.322 How Do Laypeople Define Social Competence?

J. S. Stobbart¹, A. Hodges², I. Chow¹, L. Nolet-Mulholland³ and G. Iarocci³, (1)Simon Fraser University, Burnaby, BC, Canada, (2)University of Alberta, Edmonton, AB, Canada, (3)Psychology, Simon Fraser University, Burnaby, BC, Canada

Background: Social competence (SC) is an important aspect of functioning that contributes to social well-being. It is also an area of challenge for many autistic individuals. This complex and dynamic construct has been difficult to define, presenting a challenge for researchers aiming to understand its role in autism and in the social stigma that is commonly experienced by autistic people. Previous work has shown value in consulting lay persons' perspectives on SC to gain insight into whether researchers' conceptualization of SC is comprehensive.

Objectives: The present study aimed to examine whether the layperson's definition of SC is reflected in researchers' definition, as defined by the seven domains of the Multidimensional Social Competence Scale (MSCS): *social motivation, social inferencing, demonstrating empathetic concern, social knowledge, verbal conversation skills, nonverbal sending (communication) skills, and emotion regulation*. To this end, we explored the layperson's understanding of SC through a thematic analysis.

Methods: Undergraduate students (69.9% female; $M_{age} = 18.77$, $SD = 2.04$) provided written responses to report their perception of a socially competent person. These responses were examined using thematic analysis.

Results: Three overarching themes, with respective subthemes, in the layperson's definition of social competence emerged: (1) knowledge of social norms (aware of social norms and adapting behaviour according to social norms), (2) social skills (communication, building relationships, regulating, reading people and environments, and leadership) and (3) personal attributes (empathetic, calming and comfortable presence, general positive traits, non-judgemental and open, not anxious, and extroverted).

Conclusions: The themes in layperson definitions of SC share several similarities with researchers' definitions of the concept, as outlined by the MSCS. However, laypeople often include additional qualities that extend beyond the MSCS's seven established domains, such as leadership skills, a calming presence, openness and strong problem-solving abilities. These additional aspects can create gaps between how researchers measure SC and how the general public perceives it. This discrepancy highlights challenges in accurately assessing SC, especially when studying autism. The results of our research indicate that non-autistic individuals may use certain criteria when judging SC, which could influence the social perception of autistic individuals. This insight is valuable for refining both the assessment of SC and our understanding of social stigma toward autism.

425.323 Hyper-Sensitivity or Ignorance? Evidence from Automatic Encoding of Social Information

J. Zheng¹, E. Tang¹, Y. Chen², Y. Gao¹, Z. Chen¹, M. Shen¹, Y. Wang³, T. Wang¹ and H. Chen¹, (1)Department of Psychology and Behaviour Science, Zhejiang University, Hangzhou, Zhejiang, China, (2)University of Rochester, Rochester, NY, (3)Department of Psychology, Grand Valley State University, Allendale, MI

Background: Children with autistic spectrum conditions (ASC) are frequently reported with atypical social cognition, but whether such impairments derive from hypo- or hyper-reactivity is still under debate. Previous studies typically probed task-relevant social and non-social information, which could not effectively distinguish between these two hypotheses. Here we propose that testing the task-irrelevant information can better distinguish between the automaticity and sensitivity in the processing of social information.

Objectives: The current study intended to investigate automatic encoding of social information in children with ASC, and to better verify the underlying mechanism of their atypical social cognition.

Experiment 1-Methods: Analysis included data from 20 children with ASC and 20 IQ- and age-matched typical developing (TD) children. Participants were instructed to memorize the color of mushrooms (non-social condition) or colored faces (social condition), while ignoring their orientation (irrelevant non-social feature) or identity (irrelevant social feature), and quickly decide whether the colors changed on the probe display. In half of the trials, the irrelevant feature changed between the memory display and probe display. If irrelevant feature is automatically encoded into working memory, its change would make participants response more slowly according to the previous studies (i.e., the irrelevant distracting effect). By comparing the irrelevant distracting effect between different groups, we could index their processing of task-irrelevant social and non-social features.

Experiment 1-Results: For non-social stimuli, both TD and ASC group responded significantly slower when irrelevant feature changed (TD: $t(19)=3.909$, $p<0.001$, Cohen's $d=0.874$, 95% CI [0.348, 1.384]; ASC: $t(19)=4.313$, $p<0.001$, Cohen's $d=0.965$, 95% CI [0.422, 1.49]), and the distracting effects were comparable between groups ($F(1,38)=1.681$, $p=0.203$, partial $\eta^2=0.031$), while for social stimuli, such effects were observed only in TD group (TD: $t(19)=3.237$, $p=.004$, Cohen's $d=0.724$, 95% CI [0.222, 1.211]; ASC: $t(19)=-0.68$, $p=.505$, Cohen's $d=-0.152$, 95% CI [-0.591, 0.291]; interaction: $F(1,38)=5.387$, $p=.026$, partial $\eta^2=0.124$). This pattern was further confirmed by three-way interaction ($F(1,38)=8.831$, $p=.009$, partial $\eta^2=0.189$).

Experiment 2-Methods: Experiment 2 was designed to test whether children with ASC would automatically encode social feature into working memory and quickly suppress it, so we decreased the display time to 250ms so that they do not have enough time to suppress the social information. Considering the ability of children, we decreased the memory item to one at the same time. Additionally, only social condition was retained because the result of Experiment 1 showed that both groups can encode non-social information into working memory automatically.

Experiment 2-Results: Both TD and ASC group responded significantly slower when irrelevant feature changed (TD: $t(19)=2.35$, $p=.029$, Cohen's $d=0.527$, 95% CI [0.052, 0.990]; ASC: $t(19)=2.03$, $p=.057$, Cohen's $d=0.454$, 95% CI [-0.012, 0.910]), and the distracting effects were comparable between groups ($F(1,38)=0.047$, $p=.83$, partial $\eta^2=0.001$).

Conclusions: The results showed that children with ASC automatically encode task-irrelevant social information at early processing stage, while they could further exclude it at late stage, indicating that atypical processing of social information in children with ASC cannot be simply explained by hypo-sensitivity hypothesis, but rather supporting the hyper-sensitivity with instant suppression.

425.324 Identifying Social Profiles in Autism: Cluster Analysis Using the Multidimensional Social Competence Scale (MSCS)

J. S. Stobbart¹, N. E. Scheerer², N. G. Van Esch² and G. Iarocci³, (1)Simon Fraser University, Burnaby, BC, Canada, (2)Psychology, Wilfrid Laurier University, Waterloo, ON, Canada, (3)Psychology, Simon Fraser University, Burnaby, BC, Canada

Background: Social competence can vary widely, particularly among autistic individuals. This complex social construct is thought to be comprised of seven domains, as defined by the Multidimensional Social Competence Scale (MSCS): *social motivation, social inferencing, demonstrating empathetic concern, social knowledge, verbal conversation skills, nonverbal sending (communication) skills, and emotion regulation*. While previous research reveals general challenges in social competence among autistic individuals, not all autistic people have the same social challenges. Similarly, there are social competency strengths in certain individuals that have not been recognized such as empathic concern.

Objectives: This study sought to identify subtypes of social competence among autistic individuals using the MSCS, as well as whether executive functioning and IQ vary across these subtypes.

Methods: Participants completed the MSCS online or in-person. Data from children and adolescents was obtained through the parent-version of the MSCS, where parents provided responses regarding their child or adolescent.

Results: We conducted exploratory k-means cluster analyses across three samples (autistic children ($n = 268$, $M_{age} = 8.61$, $SD = 1.32$, range: 5.98 – 10.98), adolescents ($n = 148$, $M_{age} = 12.80$, $SD = 1.70$, range: 11.00 – 17.28), and adults ($n = 433$, $M_{age} = 29.91$, $SD = 9.96$, range: 18.00 – 67.00). Across all three samples, a four-cluster solution had the best explanatory power. These solutions gave rise to the following subtypes: (1) socially adaptive (i.e., high scores across all social competence domains), (2) global social difficulty (i.e., low scores across all domains), (3) verbal-emotional strengths (i.e., high scores in verbal communication and emotion regulation), and (4) empathetic and motivated-nonverbal communicators (i.e., high scores in social motivation, empathetic concern, and non-verbal communication skills). Preliminary data were examined to identify differences in executive functioning (child $n = 95$, adolescent $n = 48$, adult $n = 73$) and IQ (child $n = 201$, adolescent $n = 104$, adult $n = 26$) across the four subtypes. Results revealed no significant differences among children, adolescents, nor adults in IQ across the subtypes. However, children in subtypes 1 and 3 exhibited significantly greater executive functioning, in comparison to subtypes 2 and 4 (p -values $< .001$). This suggests that the characteristics of subtype 3, such as strong emotion regulation, may help offset the challenges with executive functioning that are often coupled with low social competence. Meanwhile, high scores in social motivation, demonstrating empathetic concern, and nonverbal communications skills, as exhibited in subtype 4, do not appear to preserve executive function in the same way. Additionally, adolescents in subtype 2 had significantly poorer executive functioning than subtypes 1, 3, and 4 (p -values $< .004$) while differences in executive functioning across the subtypes were not significant among adults, suggesting these challenges may be intertwined with development.

Conclusions: These findings have important clinical implications for autistic individuals. By identifying one's social competence subtype, intervention strategies can be tailored to better suit their specific strengths and challenges. Implications of these subtypes on current knowledge of autism will be discussed.

425.325 Identifying Subgroup Differences in Camouflaging and Impression Management across Behavioral, Motivational, Cognitive, and Mental Health Domains

C. H. J. Lee¹, W. Ai², B. K. Jacob³ and M. C. Lai⁴, (1)Ministry of Health and Welfare Tsao-Tun Psychiatric Center, Tsao-Tun, Nan-Tou County, Taiwan, (2)Department of Psychology, University of Toronto, Toronto, ON, Canada, (3)Department of Psychology, University of Toronto Mississauga, Mississauga, ON, Canada, (4)Campbell Family Mental Health Research Institute, Centre for Addiction and Mental Health, Toronto, ON, Canada

Background: Camouflaging and impression management (IM) are observed across social and neurodiverse groups. Researchers have documented varied patterns of motivations, cognitive skills, and mental health issues associated with camouflaging in autistic and non-autistic people. It remains unclear whether there are distinct neurodiverse groups who employ and experience IM/camouflaging differently.

Objectives: 1) To identify subgroups in the general population based on IM/camouflaging tendencies; and 2) To characterize subgroup differences across behavioral, motivational, cognitive, mental health and neurodivergent trait domains.

Methods: A total of 972 adults (461 cisgender men, 491 cisgender women, 20 gender-diverse, Mean-age=44.2years, 72.7% Caucasian, 7.51% neurodivergent) completed an online survey assessing IM (i.e., camouflaging, self-presentation, self-concealment, compensation), mental health (i.e., anxiety, depression, self-regulatory fatigue, subjective authenticity), social pressure (i.e., internalized stigma, social anxiety), and neurodivergent traits (i.e., autism and ADHD dimensional traits). Exploratory Factor Analysis (EFA) on the subscale-scores from all IM measures identified latent dimensions, which were then applied as features in a Latent Profile Analysis (LPA) to identify IM subgroups (Figure 1A). Univariate analyses described IM and mental health patterns across subgroups. Multinomial logistic regression examined the associations of demographics, cognitive capacities, social pressure, and neurodivergent traits with subgroup membership.

Results: EFA and item review suggested three latent dimensions within IM: active strategies, defensive strategies, and IM ability. LPA identified three IM subgroups that we termed "Compelled", "Optimal", and "Striving" based on their profile characteristics (Figure 1B). The subgroups differed in IM patterns, neurodivergent traits, and mental health outcomes (Table 1A). The "Compelled" subgroup, characterized by high IM engagement, high social needs, and low cognitive capacity, showed the poorest mental health (73% male, Mean-age=36.3). The "Optimal" subgroup, with better cognitive capacity, balanced IM strategies, and lower social needs, exhibited the best mental health (56% female, Mean-age=53.0). The "Striving" subgroup displayed moderate IM, social needs, and mental health (57% female, Mean-age=40.7). Higher autism traits were associated with lower chances of being in the "Optimal" ($OR = 0.913$, $p < 0.001$) and "Striving" subgroups ($OR = 0.932$, $p < 0.001$) than in the "Compelled" subgroup (Table 2B). Similarly, higher ADHD traits were associated with lower chances of belonging to the "Optimal" group compared to the "Compelled" subgroup ($OR = 0.904$, $p = 0.001$). Higher internalized stigma and social comparison tendencies were linked to a higher likelihood of being in the "Compelled" subgroup, while better emotional regulation and social competence were linked to a lower likelihood.

Conclusions: This study identified three IM/camouflaging subgroups in the general population. The "Compelled" subgroup had the poorest mental health, while the "Optimal" subgroup showed the inverse. Neurodivergence was linked to the "Compelled" group. Meanwhile, better emotional regulation and social competence were linked to the "Optimal" subgroup, suggesting that these capacities may highlight individuals with more effective IM/camouflaging. These findings offer novel insights into potential distinctions in how neurodiverse subgroups of individuals experience and employ IM/camouflaging.

425.326 Social Cognition and Visual Attention in Complex Social Interaction Scenes

M. Oliva¹, Y. Huang², H. Nobel Norrman³ and J. Neufeld⁴, (1)Center for Neurodevelopmental Disorders at Karolinska Institutet (KIND), Karolinska Institutet, Stockholm, Sweden, (2)Karolinska Institutet, Stockholm, Stockholm, Sweden, (3)Center for Neurodevelopmental Disorders at Karolinska Institutet (KIND), Department of Women's and Children's Health, Karolinska Institutet, Stockholm, Stockholm, Sweden, (4)Center for Neurodevelopmental Disorders at Karolinska Institutet (KIND), Department of Women's and Children's Health, Karolinska Institutet, Stockholm, Sweden

Background:

Effective social interaction depends on our ability to interpret others' thoughts, emotions, and intentions, using verbal and non-verbal cues like facial expressions, eye gaze, and body language. This real-time integration of social cues, known as social cognition or theory of mind (e.g., Tager-Flusberg, 2007), allows us to understand others' mental states. Individuals on the autism spectrum, however, may struggle to process multiple social cues simultaneously. While someone may correctly interpret simple social interactions, difficulties can arise as the number of cues or their complexity increases, revealing potential social cognition challenges. Even within the typical population, variations in theory of mind can lead to differences in how social cues are processed and understood.

Objectives:

This project aims to investigate how autistic traits influence social cognition by examining differences in visual attention to complex social scenes.

Methods:

Participants watched short videos of interactions between four friends and answered questions about the characters' thoughts and feelings (*Movie for the Assessment of Social Cognition*, Bölte, S., Fleck, S., & Dziobek, I., 2014). Eyetracking was performed as participants watched the social movies. Autistic traits were measured through self-report questionnaires.

Results:

Pilot results (N = 15) indicated that the number of autistic traits influenced the participants' performance in the MASC task, where a higher number of traits predicted lower social cognition abilities ($p = 0.018$). Additionally, slower responses regarding the characters' mental states were associated with lower social understanding ($p < 0.001$), suggesting a need for longer deliberation times. Data collection is ongoing, and the final analysis will include eyetracking data to investigate whether differences in social cognition relate to how participants allocate visual attention to social cues.

Conclusions:

Our preliminary findings suggest significant variation in social cognition even within the typical population. The final analysis will include visual attention differences and their implications for understanding how autistic traits influence social cognition.

**442.318 Social and Non-Social Autistic Traits Synergise to Impair Facial Emotion Recognition in Men but Not Women: Why You Should Include Sex/Gender in Your Model**

M. Belmonte¹ and J. H. Ong², (1)The Com DEALL Trust, Bangalore, INDIA, (2)School of Psychology and Clinical Language Sciences, University of Reading, Reading, United Kingdom

Background: Aspects of individual differences in perception, cognition and action throughout the general population can be described in terms of dimensional autistic traits, whose strongly polygenic and multifactorial bases give rise to a continuum of individual variation. Two major domains of autistic traits are superior attention to detail and difficulties in neurotypical social interaction. These non-social and social domains of measured autistic traits interact with each other and with sex to determine how and to what extent social information is gathered from eyes and from other facial regions (<https://doi.org/10.3389/fpsyg.2013.00286>): in men but not women, attention to detail synergises with social difficulty to impair recognition of eyes-only faces, yet also synergises with social prowess to facilitate eyes-only face recognition. Facial masking during the recent COVID-19 pandemic offered an ecologically valid opportunity to test the extent of this effect.

Objectives: Might this interaction of sex with social and non-social dimensional autistic trait domains during face recognition extend also to facial emotion recognition? That is, does autistic-like attention to detail facilitate eyes-only facial emotion recognition in men with intact social function but impair it in men with autistic-like social impairment? And if so, does this impairment encompass only more subtle facial emotions, or all facial emotions, and can it be overcome with practice? We addressed these hypotheses using data from the natural laboratory provided by pandemic facial masking.

Methods: We re-analysed a data set (<https://osf.io/xn3g4/>) of emotion recognition from masked faces, in 302 adults (234 women, 68 men) sampled during the first wave of the COVID-19 pandemic and 250 (208 women, 42 men) sampled during the second wave about ten months later. 10% of each sample self-reported with an autism spectrum condition. 32 were common to both samples. Facial emotion stimuli, masked to the eyes only, were taken from the EU Emotion Stimuli (<https://doi.org/10.3758/s13428-015-0601-4>) in the case of simple emotions, and from the 'Reading the Mind in the Eyes' Test (<https://doi.org/10.1111/1469-7610.00715>) in the case of complex emotions. Augmenting the data set's original analysis (<https://doi.org/10.1177/17470218221135585>), the sample was split by sex and by the separate Autism Spectrum Quotient factors social interaction (AQSoInt) and attention to detail (AQDeT), yielding an overall model in which facial emotion recognition was predicted by sex, AQSoInt, AQDeT, time point in the pandemic, emotion complexity, and the subject's self-rated familiarity with interacting with masked social partners.

Results: A significant AQSoInt x AQDeT x Sex x Emotion complexity x Time interaction for facial emotion recognition replicated our earlier sex-specific findings on facial identity recognition as a function of interacting social and non-social autistic traits, but only for recognition of complex emotions, and only at the beginning of the pandemic when subjects were not yet practised at processing masked faces.

Conclusions: In face perception as in so many other dimensional and categorical aspects of autistic variation, sex and gender matter and should be included in models. Pooling samples across sexes or genders can mask effects that may be specific to a single sex or gender, or even opposite across sex or gender.

426 - Combined Topics III

May 2nd, 2025, 12:30 PM - 1:30 PM - Hall 4A

426.327 fNIRS-Based Markers of Cognitive Improvements Following a Nintendo Exergaming Intervention in Autistic Children – a Pilot Randomized Control Trial*J. M. Tsai¹, J. Corey¹, S. Kathiravan¹, L. Alexander² and A. N. Bhat³, (1)Physical Therapy, University of Delaware, Newark, DE, (2)540 S College Ave, University of Delaware, Newark, DE, (3)Department of Physical Therapy, University of Delaware, Newark, DE***Background:**

Children with Autism Spectrum Disorder (ASD) often display co-occurring challenges with executive functioning (EF) and motor skill performance, which can influence their core social communication challenges and overall functioning. Exergaming is the use of videogaming platforms for motor/exercise training. It is an innovative method to promote whole-body movement / exercise for autistic children. However, few studies have examined behavioral and brain activation-related outcomes following exergaming interventions in autistic children.

Objectives:

To compare behavioral and cortical activation patterns in autistic individuals between the Nintendo exergaming intervention group (NE) and control group (CO) during an fNIRS Flanker task with 2 conditions (congruent and incongruent). To examine the relationship between task performance (i.e., reaction time/RT), other domain measures at baseline, and cortical activation patterns (baseline and intervention-related changes).

Methods:

30 individuals between 5-19 years (M=12.6, SD=3.5, 2 Females) were matched on baseline measures of Social Responsiveness Scale (SRS), Repetitive Behavior Scale-Revised (RBSR), and Vineland Adaptive Behavioral Scale (VABS) and were randomized into NE and CO group. The NE group completed an 8-week Nintendo exergaming intervention while the CO group received treatment as usual. We measured the pre- and post-test EF performance and cortical activation outcomes during the Flanker task of EF using functional near-infrared spectroscopy (ETG-4000, Hitachi Medical System, Inc.). BRIEF parent-report questionnaires were used to measure EF performance in various domains pre- and post-test. fNIRS-based cortical activation data were processed using custom MATLAB codes. 52 channels were divided into 5 ROIs for the left and right hemispheres. A repeated-measures ANOVA was conducted (2 Groups X 2 Conditions X 2 Hemispheres X 5 Regions and 2 Timepoints) with a covariate of VABS adaptive functioning and Age. Significance set at $*p < 0.05$, with FDR corrections.

Results:

NE group showed improved RT post intervention, both in congruent and incongruent conditions, compared to the pretest. NE group decreased in overall bilateral hemispheric cortical activation, post-intervention, compared to the pretest. Older NE participants (>13 years) showed training-related reduction in cortical activation in overall MFG, IFG, STS, and IPL post intervention compared to the pretest, whereas younger participants reduced activation in PCG and IPL only. In addition, at baseline, faster **incongruent RT** correlated with **Lower** R/L MFG, Left IPL, Left PCG activation; better **EF performance via BRIEF** correlated with **higher** Right IPL, PCG but, **lower** Left STS, PCG activation. Intervention-related improvements in EF in Flanker task are associated with greater Right STS and Left PCG activation (posttest vs. pretest); Improved EF on BRIEF is associated with **greater** activation in R/L IFG and **reduced** activation in Right MFG, PCG (posttest vs. pretest).

Conclusions:

Default mode network regions including prefrontal, frontal, inferior parietal and superior temporal regions, seem to capture changes in activation that are associated with Flanker task performance. 8-week Nintendo switch exergaming intervention improved EF performance of autistic individuals, and their EF performance correlated with fNIRS cortical activation. We recommend Nintendo exergaming as a home/community-based intervention to facilitate enjoyable physical activity that has added benefits of improved executive functioning and cortical activation patterns.

426.328 How Do Motor Impairments Help Explain the Variability in Children with ASD?*A. N. Bhat, Department of Physical Therapy, University of Delaware, Newark, DE***Background:**

There is a growing body of literature supporting the presence of motor impairments in children with ASD (Bhat et al., 2022, 2023). Yet, motor issues are missing from the ASD definition. It could be argued that motor issues should be included as an ASD specifier to better recognize, assess and treat motor problems from early on in life.

Objectives:

This study examined the value of an added motor measure, Developmental Coordination Disorder-Questionnaire (DCD-Q) to classify a large autistic sample into high vs. low delay group compared to only using diagnostic measures (Social Communication Questionnaire (SCQ) and the repetitive behavior severity screener called the Repetitive Behaviors Scale – Revised (RBS-R)).

Methods:

The SPARK study dataset (N ASD=13,887) was analyzed using K-Means Clustering to determine different subgroups that emerge by adding the DCD-Q, SCQ, and RBS-R measures, as well as parent-reported current levels of cognitive, functional, and language impairments (i.e., current ASD specifiers).

Results:

While 87% of children matched between the subgroups (high vs. low delay) obtained from the 2 analyses (core vs core+motor measures), 13% of the sample did not match indicating more unique subgroups based on motor delay inclusion. Accuracy of detecting high vs. low delay subgroups was better when the core+motor measures were used vs. core measures alone. Parent-reported functional delays validated the shifts in subgroup assignments using the new motor trends following the 2nd clustering analysis. These findings will be further explained in the poster.

Conclusions:

These results highlight the unique role played by motor measures in better explaining the sub-phenotypic variability of school-age children with ASD. These findings have important implications for utilizing tailored motor assessment and intervention approaches to meet the varying motor needs of autistic children. Specifically, motor measure better characterized children's impairment severity (high vs. low delay) that matched parent reports of functional delays.

426.329 Service Receipt in Children with Autism As a Function of Various Demographic and Child-Related Factors: A SPARK Dataset Analysis.*A. N. Bhat, Department of Physical Therapy, University of Delaware, Newark, DE***Background:**

~85% of children with Autism Spectrum Disorder (ASD) from the SPARK study receive standard interventions such as speech-language (SLT) and occupational (OT) therapies (Bhat, 2020,2021). In contrast, only 32 to 13% of children with ASD received movement therapies such as physical and recreational therapies (PT and RT), respectively (Bhat, 2020). Little is known about how service receipt (SLT, OT, PT, RT, ABA, and Social Skills Interventions) changes as a function of various demographic and child-related/impairment-based factors.

Objectives:

This study examined the differences in service receipt (SLT, OT, PT, RT, ABA, and Social Skills Interventions) in children with ASD as a function of various demographic and child-related factors.

Methods:

13,528 parents of children with ASD ages 5-17 years from a nationwide SPARK study conducted by the Simons foundation completed online surveys to provide a report of their child's social communication / motor difficulties and repetitive behavior rates using the Social Communication Questionnaire (SCQ), Developmental Coordination Disorder-Questionnaire (DCD-Q), and Repetitive Behavior Scales-Revised (RBS-R). Parent-reported language, cognitive, and functional delays were also obtained (no, some, or significant delay). Parents also stated the services received (Yes, No to Speech language therapy=SLT, occupational therapy = OT, physical therapy = PT, Behavioral Therapies = ABA, Social Skill Interventions = SSI, Recreational Therapies = RT, etc.).

Results:

While therapies increased commensurate with domain-specific impairments, (e.g., SLT increased in children with language delays) there continued to be large disparities in PT (37-55%) and RT services (15-19%) compared to OT/SLT (85-92%) indicating clear unmet needs for specific motor services. Additionally, demographic factors such as income and age were significant predictors of multiple service receipts.

Conclusions:

These findings once again highlight the disparities in services received by autistic children and the various demographic and child-related factors that influence service receipt. Factors affecting service receipt will inform service providers and policy makers about recommendations for improving service receipt for autistic individuals.

Poster Session**427 - Autism Community Issues and Experiences II**

May 2nd, 2025, 6:00 PM - 7:00 PM - Hall 4A

427.001 How Growing up with an Autistic Sibling Influences Decisions about Marriage, Parenthood, and Careers*O. F. Ward^{1,2}, R. L. Harmon¹ and T. S. Tomeny¹, (1)Psychology, The University of Alabama, Tuscaloosa, AL, (2)Department of Psychology, The University of Alabama at Birmingham, Birmingham, AL*

Background: Sibling relationships are often the longest-lasting connection in an individual's life (Cicirelli, 2013). The experience of having an autistic sibling has a unique impact on an individual's life, often shaping various aspects of one's life, including familial and social relationships (Moss et al., 2019) and psychological adjustment (Quatrosi et al., 2023). However, less is known about how having an autistic sibling may shape lifelong decisions related to marriage, parenthood, or career choices. Research suggests that adults who have a sibling with a neurodevelopmental disability, including autism, are more likely to remain unmarried or delay marriage compared to age-matched peers (e.g., Hodapp et al., 2017; Howlin et al., 2015). Individuals with a sibling with a disability describe thoughts and fears around parenthood due to concerns their child may have a similar disability to their sibling (Free et al., 2022). Individuals with an autistic sibling also report that their sibling was an influential factor in their career choice (Martins, 2007). Whereas evidence suggests that having an autistic sibling shapes one's personal decisions related to marriage, parenthood, and careers, this area of study remains under investigated. Qualitative exploration may increase understanding of factors non-autistic siblings consider when making lifelong decisions.

Objectives: To explore how growing up with an autistic sibling is perceived to shape lifelong decisions in three key domains: marriage, parenthood, and career choices.

Methods: Data collection for this mixed-methods study is ongoing. The current sample includes 32 adults ($M_{age} = 36.06$, $SD = 10.90$) who were predominantly female (59.4%), white (59.4%), and non-Hispanic (75.0%) with an autistic sibling ($M_{age} = 33.81$, $SD = 14.72$). Non-autistic siblings completed an online survey with closed- and open-ended questions about whether having an autistic sibling influenced their decisions related to marriage, parenthood, and career choices, and if so, to describe why. Whereas preliminary themes are offered here, qualitative data will be further analyzed utilizing thematic analysis to identify patterns in non-autistic siblings' thoughts when making lifelong decisions.

Results: Preliminary analyses revealed that having an autistic sibling did influence decisions related to marriage, parenthood, and career choices for 50% of the sample on at least one of these domains. Specifically, 15.6% of participants reported an influence on decisions related to marriage, 34.4% on parenthood, and 15.6% on career choices. Qualitative responses suggest a complex interplay between lifelong decisions and their experience growing up with an autistic sibling (See Table 1). Responses highlight how growing up with an autistic sibling is perceived to both positively and negatively influence non-autistic adult's lifelong decisions about marriage, parenthood, and careers.

Conclusions: Exploration into life decisions of non-autistic siblings provides a more nuanced understanding of the influence of growing up with an autistic sibling. Non-autistic siblings have been found to have higher levels of stress and depression and lower life satisfaction compared to siblings of individuals with other disabilities (Hodapp & Urbano, 2007; Tomeny et al., 2017). Understanding concerns and considerations of adults with autistic siblings will allow for more targeted support for non-autistic siblings.

427.002 How's Dad?: An Investigation of Support, Stress, and Relationship Satisfaction of Fathers of Autistic Children

J. Brennan and T. E. Davis, Department of Psychology, The University of Alabama, Tuscaloosa, AL

Background: A support network is most effective when support is accessible, tailored to the parent's needs, and reciprocated within the relationship. However, fathers of autistic children report decreased social support, increased parenting stress, and decreased relationship satisfaction. Support reciprocation (the mutual exchange of aid within a relationship) is necessary to develop a support network and each reciprocal exchange of support strengthens the relationship. Difficulties reciprocating support have been identified as a contributor to decreased support, as infrequent reciprocation is associated with increased distress and relationship dissatisfaction. Fathers of autistic children are particularly likely to struggle with support reciprocation due to frequent and high levels of stress and demands associated with caring for their child. Support reciprocation is necessary to consider for this population as it highlights the bandwidth fathers have to contribute to and engage with members of their support network. It can also potentially clarify why fathers may struggle to maintain a support network and frequently report relationship dissatisfaction. However, how, when, and to whom fathers of autistic children reciprocate support is underexamined and poorly understood.

Objectives: The aim of this study is to 1) explore how support reciprocation interacts with support, parenting stress, and relationship satisfaction and 2) identify when support is likely to be reciprocated by fathers of autistic children.

Methods: 39 fathers (aged 25–64 years old; 41% white) of autistic children (aged 5–12 years) completed the Support in Intimate Relationships Scale-Revised, the Modified Inventory of Socially Supportive Behaviors, the Autism Parenting Stress Index, the Burns Relationship Satisfaction Test, and the Autism Impact Measure – Impact Scale via an online survey. Pearson's bivariate correlation coefficient was used to determine the relationships between variables of interest. A series of separate moderation models were examined using the SPSS PROCESS macro.

Results: Support reciprocation positively correlated with parenting stress, $r(37) = .89, p < .001$, child autism symptomology, $r(37) = .64, p < .001$, and instrumental support, $r(37) = .57, p < .001$. Child autism symptomology moderated the relationship between reciprocated support and relationship satisfaction and a conditional effect of reciprocated support at high levels of autism symptomology was found. Parenting stress moderated the relationship between reciprocated support and relationship satisfaction and conditional effects of reciprocated support at mean and high levels of stress were found. Parenting stress and child autism symptomology, respectively, moderated the relationships between instrumental support and support reciprocation.

Conclusions: This study revealed that for fathers of autistic children with high autism symptomology, their relationship satisfaction significantly increased the more they reciprocated support. Their relationship satisfaction also significantly increased across stress levels as their support reciprocation increased. Surprisingly, both 1) fathers with high stress and 2) fathers of autistic children with high autism symptomology reported the greatest support reciprocation across levels of instrumental support. Examining support reciprocation is necessary to better understand how fathers interact with and seek support. A more nuanced understanding of when fathers struggle to reciprocate support can help clinicians identify when and how to intervene to help improve a father's support network, relationship satisfaction, and well-being.

**427.003** Impact of the COVID-19 Pandemic on the Roles and Mental Health of Caregivers of Children with ASD: Experiences of Puerto Rican Mothers.C. Borja¹, K. Lebron-Rojas² and F. Ruiz-Alfaro³; (1)Psychology, University of Puerto Rico, Río Piedras Campus, San Juan, PR, (2)University of Puerto Rico, Río Piedras Campus, San Juan, PR, (3)Psychology, University of Puerto Rico, Río Piedras Campus, San Juan, PR

Background: During the COVID-19 public health crisis, families and caregivers of children with autism spectrum disorder (ASD) faced particular challenges (Bellomo et al., 2020). Adapting to teletherapy and virtual education intensified the difficulties of children with ASD (Dahiya et al., 2021). Studies have addressed these challenges with Spanish-speaking populations in the United States (Baires et al., 2023) and the impact on the children, but further analysis must explore the complex ways in which these effects have impacted caregivers and families of children with ASD living in Puerto Rico, a United States unincorporated territory.

Objectives: This qualitative study explored the experiences of a small group of primary caregivers of children with ASD in Puerto Rico during the COVID-19 pandemic. It focused on how their roles changed, the technological challenges they faced while seeking care for their child, and the emerging social, behavioral, emotional, and economic difficulties.

Methods: Primary caregivers were recruited through social media and flyers that were advertised in ASD centers. Caregivers were selected after an initial eligibility screening was conducted. Nine (9) mothers, who were the primary caregivers of children with ASD living in urban areas of Puerto Rico, were recruited. The children's ASD diagnoses were made through formal evaluations with standardized instruments and clinical observations. Data were collected through virtual semi-structured interviews to elicit how caregivers' roles changed during the pandemic. These interviews were transcribed and coded to identify recurring themes. Informed consent was obtained before the interview. Demographic data is in Table 1.

Results: A thematic qualitative analysis of the interviews revealed key themes in caregivers' experiences regarding diagnosis acceptance, support networks, and parenting challenges. Caregivers reported that COVID-19 disrupted social routines and limited in-person services, which, according to them, had a significant impact on their children's behavioral problems and delayed diagnoses and interventions. The caregivers adapted therapy at home without adequate resources, feeling like "co-therapists." Increased family stress, economic tensions, and job insecurity during the pandemic further strained them. Caregivers also reported feeling overwhelmed by added responsibilities, their children's skill decline due to isolation, and challenges with teletherapy.

A key quote reflecting caregiver overload is: *"I had to be everything: the teacher, the therapist, the psychologist. At first, it was very difficult because he wouldn't cooperate; he had never taken classes at home."*

Conclusions: In Puerto Rican families, the strong involvement of mothers in therapeutic and educational roles reflects cultural values of closeness and protection (Martinez-Torres, 2023). This caregiving approach contrasts with other countries where responsibilities may be more distributed among external caregivers, institutions, or shared between parents. We conclude that the lack of in-person services placed significant burdens on the mothers in our sample, which led to mental health impacts for both them and their children. These findings align with current research (Bellomo et al., 2020; Franz et al., 2022) but also highlight cultural factors specific to the social context of Puerto Rico.

427.004 Internalizing Mental Health Challenges in Transition-Age Autistic Youth*M. J. Crown, S. Krishnan and G. I. Orsmond, Department of Occupational Therapy, Boston University, Boston, MA*

Background: Autistic people experience internalizing challenges, such as anxiety and depression, at higher rates than the general population. Research on parent and youth agreement in the identification of internalizing challenges in autism has been mixed, warranting further examination. Further, little is known about how parent- and youth-reported symptoms correspond with clinical diagnoses of anxiety and depression and how they may change over the transition to adulthood.

Objectives: The objectives of this longitudinal study were to examine: (1) whether internalizing challenges differed between parent- and youth-report for transition-age autistic youth, (2) whether internalizing challenges persisted over the transition years, and (3) whether anxiety and depressive symptoms corresponded to a parent-reported anxiety or depression diagnosis.

Methods: Autistic youth (14-20 yrs) and a parent completed measures of internalizing mental health challenges at an initial time point (T1; $N=55$ parents; $N=56$ youth) and approximately 18 months later (T2; $N=43$ parents; $N=36$ youth). At T1, all youth (73.3% male) were in high school, expected to graduate with a regular high school diploma, and had a parent-reported professional autism diagnosis (Table 1). Parents also reported any co-occurring youth mental health diagnoses. Parents completed the Adult Behavior Checklist (ABCL; for youth ≥ 17 years old) or Child Behavior Checklist (CBCL; for youth < 17 years old). Autistic youth completed the Depression Anxiety Stress Scales-21 Items (DASS) and the Adult Self Report (ASR; ≥ 17 years old) or Youth Self Report (YSR; < 17 years old). To analyze internalizing challenges over time, we used normative T-scores for Internalizing and its subscales: Anxious/Depressed, Withdrawn, and Somatic Complaints of the Achenbach measures (ABCL/CBCL/ASR/YSR). To compare anxiety and depressive symptoms across diagnostic status, we used scaled scores for Depression and Anxiety subscales of the DASS.

Results: Parent and youth ratings on Achenbach measures were moderately correlated at T1 ($r = .35 - .63$; p 's $< .05$) and T2 ($r = .46 - .70$; p 's $< .05$). Two-way repeated measures ANOVAs (Rater X Time) indicated a main effect of rater for Internalizing and Withdrawn T-scores (F 's > 4.67 , p 's $< .05$), with post-hoc Bonferroni pairwise comparisons indicating greater internalizing challenges for parent-report compared to youth-report (Figure 1). No main effect of time or interaction effect was found. Independent samples t-test revealed that youth with a parent-reported anxiety diagnosis (48%) did not have significantly higher T1 DASS anxiety scores compared to those without a diagnosis. Youth with a parent-reported depression diagnosis (27%) had higher DASS depression scores at T1 ($t(50) = -2.578$; $p < .05$) than those without a diagnosis.

Conclusions: Autistic transition-age youth experienced internalizing challenges that persisted over the transition to adulthood. Discrepancies across reporters likely reflect differences in perspective when identifying internalizing challenges – e.g., parents might over-report symptoms or autistic youth might misinterpret their symptoms. Regardless, misalignment between anxiety symptoms and clinical diagnoses suggests potential barriers to accurate measurement and identification of anxiety in this population. A collaborative approach across autistic youth, parents, and providers might yield more accurate identification of internalizing challenges and potential target areas for intervention during the transition to adulthood.

**427.005** Investigating How School-Based Career Guidance Is Provided to Autistic Young People

S. Dexter¹, A. Remington², L. Crane³ and B. Irvine⁴, (1)Centre for Research in Autism and Education, University College London (UCL), London, United Kingdom, (2)UCL Centre for Research in Autism and Education, London, UNITED KINGDOM, (3)University of Birmingham, Birmingham, Birmingham, United Kingdom, (4)Centre for Research in Autism and Education, Centre for Research in Autism and Education (CRAE), UCL Institute of Education, University College L, London, United Kingdom

Background: Careers guidance, also known as careers education, has long been positioned as a tool to improve young people's transition from education to employment. Yet limited research has investigated how careers guidance is provided to autistic young people.

Objectives: The current programme of research aimed to investigate how careers guidance is being provided to autistic young people attending specialist settings (including those with intellectual disabilities) through eliciting the views of school staff and parents/carers.

Methods: The views of staff from specialist settings and parents/carers were gathered using a mixed method design consisting of online surveys and semi-structured interviews. This research adopted a participatory design. Specifically, five autistic young people, aged 17-23 with the lived experience of accessing careers guidance activities (such as work experience and 1:1 careers advice) were involved as collaborators in the research. Their role included supporting the development of survey and interview materials, and reviewing and commenting on initial findings, which informed the data analysis process.

Results: Staff working with autistic young people ($n=103$) completed an online survey, in which they self-reported the careers guidance activities they were providing for their autistic students. Twenty of these staff members then took part in detailed semi-structured interviews about their experience of delivering these careers guidance activities to autistic young people. Quantitative survey results showed that schools are providing a broad range of careers guidance activities, including embedding learning about careers within the curriculum, work experience and 1:1 careers advice for their autistic young people. Interview data was analysed using thematic analysis and showed that staff working with autistic young people were taking a hugely personalised approach to many careers guidance activities they provide, such as 1:1 careers advice and work experience. However, they also discuss how this could be very time consuming and limited by external factors, such as employers' attitudes towards autism.

Parents/carers of autistic young people ($n = 82$) completed an online survey about their experience. Following this, 19 parents/carers took part in follow-up interviews. Preliminary thematic analysis from the qualitative elements of the online survey and interviews showed that while many parents appreciate the careers guidance activities provided to their child and want them to be involved in them; they feel disheartened about the lack of opportunities available to their child when they leave school. Parents/carers also described feeling responsible for knowing what options were available to their child when they leave school, and that that process could be very challenging to navigate, even with school support.

Conclusions: This research is the first evaluation of careers guidance activities provided to autistic young people educated in specialist settings (including those with intellectual disabilities). Our initial findings demonstrate that school staff are working hard to provide personalised careers guidance support for autistic young people. However, despite what schools are doing, parents/carers do not feel there are suitable opportunities available for their autistic young person when they leave school. The final aspect of this research will investigate autistic young people's experience with careers guidance.

427.006 Investigating Neurodevelopmental and Mental Health Features in Parents of Autistic Children in the AIMS Longitudinal European Autism Project (LEAP)

M. L. Law¹, B. Oakley², T. Charman³, J. K. Buitelaar⁴, D. Murphy⁵, E. Loth⁶ and E. U. AIMS LEAP⁷, (1)Forensic and Neurodevelopmental Sciences, King's College London, London, United Kingdom, (2)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (3)Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, UNITED KINGDOM, (4)Department of Cognitive Neuroscience, Donders Institute for Brain, Cognition and Behaviour, Radboud University Nijmegen Medical Center, Nijmegen, NETHERLANDS, (5)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, UNITED KINGDOM, (6)Department of Forensic and Neurodevelopmental Sciences, Flat 2, 116, South Hill Park, London, London, United Kingdom, (7)EU-AIMS Consortium, London, United Kingdom

Background: Previous studies indicate high co-occurrence between neurodevelopmental and psychiatric conditions in autistic people (Simonoff et al., 2008) and their relatives (Bolton et al., 1994, 1998). Parents with autistic traits (also called the broader autism phenotype (BAP)) have been reported to have elevated mental health problems (e.g., stress, depression) (Ingersoll and Hambrick, 2011). The dimensional evaluation of neurodevelopmental and mental health traits in parents is important to establish a holistic view of familial patterns and support needs. These might also contribute to developmental trajectories in autistic probands via genetic or psychosocial mechanisms and can inform service provision by increasing access to personalised support for families. This study examines the characteristics of parents of autistic probands in the Longitudinal European Autism Project (LEAP), a heterogeneous, well-defined sample assessed across six research centres in the UK and Europe.

Objectives: The current study aims to a) describe the frequencies of neurodevelopmental (autism and ADHD) and mental health features (depression and anxiety) in parents of autistic probands, b) explore the occurrence of neurodevelopmental and mental health features in families where one or both parents have these traits, c) investigate the relationship between neurodevelopmental and mental health features in mothers and fathers.

Methods: Parents (289 biological mothers and 188 biological fathers) of autistic probands who took part in LEAP completed self-report questionnaires about autistic traits (Social Responsiveness Scale, Second Edition; SRS-2), ADHD (hyperactivity/impulsivity and inattention; DSM-5 rating scale of ADHD), and mental health features (Beck Anxiety Inventory (BAI) and Beck Depression Inventory–Second Edition (BDI-II)). We assessed the proportion of parents scoring above clinical cut-offs as defined by the original measures. The Pearson correlation coefficient was used to assess strength of associations between neurodevelopmental and mental health features in mothers and fathers.

Results: Firstly, the proportion of parents who scored above cut-off for clinically relevant traits were as follows: SRS-2, 15.21% fathers and 10.38% mothers; ADHD, 3.85% fathers and 3.51% mothers; Anxiety (BAI), 21.93% fathers and 35.07% mothers; and Depression (BDI-II), 15.05% fathers and 22.49% mothers. Across three subgroups (based on scores for autism and ADHD features), more mothers than fathers reported mental health features (Table 1). Secondly, of 159 families with data from both parents, 25 (15.70%) families had both parents, and 52 (32.70%) families had one parent with at least one neurodevelopmental or mental health feature. Thirdly, in mothers and fathers, we found moderate-to-strong positive correlations of autistic traits with ADHD, anxiety and depression (Table 2).

Conclusions: In the LEAP cohort, a large percentage of families had either one or both parents that met threshold for at least one neurodevelopmental or mental health condition; 12.00% of mothers and 16.10% of fathers were neurodivergent. Mental health problems were moderate-to-highly correlated with neurodevelopmental traits in the entire sample, with higher occurrences of mental health problems in mothers compared to fathers. These findings highlight the need to consider parental mental health when examining mechanisms underlying the development of clinical features in autistic probands, and the need to adopt a neurodiversity-affirmative family perspective to offer targeted support.

**427.007** Latino Parents' Perceptions of Bilingualism in Autistic Children: Psychometric Validation of the Bravo Scale

J. L. Saenz¹, A. C. Ramirez², J. R. Maldonado Coronado³ and C. Montiel-Nava², (1)Psychology, University of Texas Rio Grande Valley, Edinburg, TX, (2)Department of Psychological Science, University of Texas Rio Grande Valley, Edinburg, TX, (3)Universidad de Celaya, Celaya, GJ, Mexico

Background:

Approximately one in four children with autism spectrum disorder (ASD) grows up in a bilingual household (Trelles & Castro, 2019), with 71% of non-English-speaking parents in the U.S. being Spanish-speaking Latinos (Pompa et al., 2017). As both bilingualism and ASD prevalence rise (Lund et al., 2017), it becomes essential to investigate how bilingualism influences language development in autistic children. Despite growing evidence that bilingualism does not delay language development in autistic children (Beauchamp et al., 2020; Gilhuber et al., 2023; Prévost & Tuller, 2022; Siyambalapitiya et al., 2022), misconceptions persist. Current research on parental perceptions of bilingualism within autistic families has been primarily qualitative (Howard et al., 2021), partly due to the lack of validated instruments tailored to this population. Understanding how Latino parents' cultural backgrounds and belief systems shape their views on autism, bilingualism, and language development is vital for creating reliable assessment tools.

Objectives:

This study aims to conduct an exploratory factor analysis to assess the construct validity and reliability of the Bilingualism Reflections: Assessment of Values and Opinions (BRAVO) scale, which measures parental perceptions of bilingualism in Latino families of autistic children.

Methods:

Data were collected via an anonymous REDCap survey, including demographic information, the Child Language Exposure Questionnaire, the Social Communication Questionnaire, and the BRAVO scale. The sample consisted of 102 parents of children aged 6 to 12 years, with 78.4% (n=80) identifying as Hispanic, 64.7% (n=66) born in the U.S., and 54.9% (n=56) having an autistic child. An Exploratory Factor Analysis (EFA) was conducted using Principal Axis Factoring with Varimax rotation after confirming factorability of the correlation matrix (Fabrigar et al., 1999).

Results:

Parallel analysis indicated the retention of three latent factors. After rotation, Factor 1: *General Perceptions of Bilingualism*, explained 54.78% of the variance; Factor 2: *Cultural and Emotional Benefits of Bilingualism*, explained 10.05%; and Factor 3: *Value of Bilingualism in the U.S.*, explained 7.07%. Together, the three factors accounted for 71.86% of the variance. Factor correlations were as follows: Factor 1 and 2 ($r = .42$), Factor 1 and 3 ($r = .67$), and Factor 2 and 3 ($r = .27$), supporting a three-factor model for the BRAVO scale in this sample.

Conclusions:

This study is the first to quantitatively assess parental perceptions of bilingualism in Latino parents of autistic children, contributing to the literature on autism and bilingualism. It offers a validated, psychometrically sound instrument (BRAVO) to measure bilingualism perceptions in both autistic and non-autistic children. By involving the Latino autistic community, this research addresses a gap in representation, advancing both the field of autism and bilingualism research by giving a voice to an often-underrepresented population, which is a significant improvement in current research methods in the field.

427.008 “Stop Yelling at Me”: The Identification of a Constructivist Grounded Theory Framework for Neurodiversity-Affirming Approaches.

J. Gibson¹, K. Brooks¹, M. Bull¹, T. Chodorowski¹, E. Seymour¹, L. Baird^{1,2} and C. Thompson¹, (1)Curtin School of Allied Health, Curtin University, Perth, Western Australia, Australia, (2)Rockybay, Perth, Western Australia, Australia

Background: Neurodiversity was first coined by sociologist, Judy Singer in 1998 to reframe neurological diagnoses in a more positive light, emphasising a person's strengths rather than their weaknesses. Neurodiversity can be described as variations in brain function that should be considered a natural and normal part of biodiversity and should be valued, respected and accommodated. Despite a growing prevalence of neurodivergent diagnoses, neurodivergent adults continue to report negative healthcare experiences. Consequently, neurodiversity-affirming approach provides an alternative option to traditional approaches based in the medical model and aims to embrace an individual's unique characteristics and reframe differences as strengths. Early evidence suggests that neurodiversity-affirming approaches have a positive effect on the well-being of neurodivergent individuals. In the workplace and education contexts, there is a growing body of evidence that suggests that education and awareness of neurodivergence is having a positive effect on productivity, communication and sensory regulation for both neurodivergent and neurotypical populations. However, there is limited information on neurodiversity-affirming approaches in healthcare.

Objectives: This study aimed to conceptualise neurodiversity-affirming approaches within healthcare services from the perspectives of neurodivergent adults in Australia.

Methods: A Constructivist Grounded Theory (CGT) approach was used to explore how neurodivergent adults experience healthcare services in Australia. Theoretical sampling was employed to identify participants for this study. A total of 19 neurodivergent adults (female n=14; male n=4; non-binary n=1) identified as autistic (n=8), having attention-deficit/hyperactivity disorder (ADHD; n=5), and/or both (n=6). Participants engaged in semi-structured interviews online via Microsoft Teams. Data were analysed using grounded theory analysis.

Results: The findings of this study developed a CGT framework to guide the delivery of neurodiversity-affirming care to neurodivergent adults. This framework encompasses three themes. The first theme was *finding and partnering with a healthcare professional (HCP) or healthcare service*: finding and partnering with an HCP or healthcare service is important. Improved results occur through informal approaches such as word of mouth. Theme one also outlined aspects such as appointment booking approaches and costs. Theme two, *the partnership environment*, described the importance of receptionists and administration staff on experiences. The importance of the physical environment was important to navigate a healthcare service. Theme three, was *the neurodivergent person-HCP partnership*, described the importance of communication, interaction and knowledge of neurodivergence. The neurodivergent persons journey through healthcare was underpinned by the threads of transparency and clarity, communication, and education and awareness. The framework developed depicts how the themes, subthemes and central threads intertwine and shape the experiences of neurodivergent adults when accessing healthcare services.

Conclusions: The findings suggest that HCPs and healthcare services adopting neurodiversity-affirming approaches such as the CGT framework by would be beneficial. The experience of neurodivergent adults can be improved by transparency and clarity, communication, and education and awareness. The adoption of neurodiversity-affirming approaches would significantly benefit neurodivergent adults, helping to improve engagement and reduce the stress and anxiety associated with accessing and using healthcare services, and ultimately, provide better health outcomes.

427.009 Learning about Autism Diagnosis Among Korean Autistic Adults

D. Lee¹, W. H. Yoon², H. Yoo³ and S. Y. Kim¹, (1)Korea University, Seongbuk-gu, Seoul, Korea, Republic of (South), (2)Korean Research Center for Guardianship and Trusts, Seoul, Korea, Republic of (South), (3)Psychiatry, Seoul National Univ Bundang Hospital, Seongnam, Korea, Republic of (South)

Background: Being informed about an autism diagnosis refers to the process by which an individual becomes aware of their diagnosis, including when, how, and by whom the information is conveyed. Understanding these factors is essential to help individuals positively accept their autism diagnosis and foster self-understanding and empowerment. However, there is a lack of research on how autistic individuals are informed about their diagnosis, particularly in South Korea, where heightened stigma toward autistic people has been observed (Kim et al., 2021).

Objectives: This study aimed to investigate the experiences and perspectives of Korean autistic adults in being informed about their autism diagnosis.

Methods: Survey questions were developed iteratively by interviewing eight autistic adults with a formal autism diagnosis. The survey, consisting of both open- and closed-response questions, was administered to four participants who received a formal autism diagnosis as adults and five participants whose diagnosis was made in childhood and later disclosed to them by parents (Table 1). We present a summary of descriptive statistics about participants' experiences of being informed about autism and their perspectives on how autism should be disclosed and explained.

Results: Participants reported a range of emotions associated with being informed about their diagnosis. Those who received a formal diagnosis as adults (mean age at diagnosis 30.3 years) generally experienced positive emotions, including joy and relief. Participants whose diagnosis was disclosed by parents during childhood (mean age of notification 11.8 years) reported more negative emotions, with confusion and anxiety being the most prevalent. When disclosing the diagnosis, doctors and parents both explained autistic characteristics and associated challenges ($n=8$, 8), and no participants received a strengths-based or neurodiversity-focused explanation ($n=0$, 0%). Factors that helped participants accept their diagnosis included receiving clarity from the diagnosis ($n=3$; 33.3%) and emphasizing that an autism diagnosis is not the individual's fault ($n=2$; 22.2%). Social stigma toward autistic individuals ($n=5$; 55.5%), difficulty accepting the diagnosis ($n=5$; 55.5%), and negative parental attitudes toward autism ($n=3$; 33.3%) were identified as challenges at the time of being informed about the diagnosis. Participants also shared perspectives on how autism should be explained (Table 2). Many felt it would be helpful to explain autism by highlighting that it is okay to have different characteristics ($n=7$, 77.8%) and from a neurodiversity perspective ($n=7$, 55.6%). When discussing the timing of disclosure, participants believed it was beneficial to provide information gradually, allowing for questions and additional support if needed ($n=5$; 55.5%). Following up after being informed about the diagnosis, participants valued opportunities to ask questions, connect with autistic support groups, and receive psychological support (all $n=7$, 77.8%).

Conclusions: Participants emphasized the need for strengths-based explanations and valued follow-up support, such as opportunities to ask questions and access to psychological services. Societal stigma was closely associated with the experiences of being informed about autism diagnosis. We aim to collect more data and develop comprehensive training materials for stakeholders to equip them with tools to communicate diagnosis in a way that fosters acceptance and empowerment for autistic individuals.

427.010 Linguistic Acculturation Moderates the Relationship between Autism Diagnosis and Vaccine Hesitancy in U.S.-Based Latine Families

D. L. Limon-Mialkowski¹, C. A. Patino-Celedon², C. Coca², B. Buranosky³, M. South⁴, R. A. Lundwall⁵ and R. P. Goin-Kochel¹, (1)Brigham Young University, Clinical Psychology, Provo, UT, (2)Brigham Young University, Provo, UT, (3)Baylor College of Medicine, Houston, TX, (4)Psychology & Neuroscience, Emory Autism Center, Decatur, GA, (5)Psychology & Neuroscience, Brigham Young University, Provo, UT

Background: Parents of children with autism have higher rates of vaccine hesitancy (VH) towards early childhood vaccines (i.e., concerns that may lead to vaccine delay/refusal) than parents in the general population. This finding holds true among Spanish-speaking Latine caregivers, as we previously observed nearly three times higher rates of VH in the autism group compared to the non-autism group. VH is concerning for public health because it increases risks for vaccine-preventable illnesses, decreases herd immunity from infectious diseases, and drives up healthcare costs. Some studies suggest that different levels of acculturation within Latine families may actually mitigate anti-vaccine attitudes. However, results are inconsistent and differ based on the type of vaccine in question. Further understanding the influence of acculturation on vaccination attitudes is necessary to improve healthcare accessibility and tailor vaccine education strategies for Latine caregivers.

Objectives: To explore how linguistic acculturation impacts the relationship between diagnostic status (autism vs. non-autism) and VH. Given that caregiver values and trust in medical care likely shift with increased cultural adaptation, we expected acculturation levels to consistently moderate diagnosis on VH.

Methods: US-based Latine caregivers ($N = 201$) participated in a Spanish-language survey about early childhood vaccines and autism perspectives; 74 (37%) had children with autism, 127 (63%) had children without autism. The *Parent Attitudes about Childhood Vaccines* (PACV) was used to identify a binary outcome of VH (i.e., yes or no). The *Short Acculturation Scale for Hispanics* (SASH) was used to create a latent variable for acculturation using the caregiver's linguistic preferences. A probit analysis with a two-way interaction effect was conducted using Mplus to examine the combined effect of an autism diagnosis and acculturation level on VH.

Results: A probit analysis was conducted as a preliminary step to interpret the Johnson Neyman (J-N) region of significance plot. Probit results yielded a significant relationship between autism diagnosis and VH ($p = 0.001$). The J-N technique illustrated the moderation effect that a parent's US acculturation level has on autism diagnosis and VH (see Figure 1). The plot showed that the impact of an autism diagnosis on VH varied according to the parent's acculturation—where the effect of an autism diagnosis on VH became more pronounced as acculturation levels decreased. However, increases in the SASH variable (i.e., acculturation) eventually reached a point where acculturation no longer moderated the relationship between diagnosis and VH.

Conclusions: Our findings suggest that lower acculturation levels significantly moderated the relationship between an autism diagnosis and VH. However, greater assimilation with the US dominant culture (integration of the English language) did not have a significant impact on the association between VH and diagnosis. Linguistic preservation, as well as lack of Spanish-language resources, may prevent acceptance of health messages about vaccines in Spanish-speaking Latine families managing autism. Notably, our latent acculturation variable solely included linguistic predictors of acculturation. A more nuanced look at acculturation (e.g., cultural backgrounds of caregivers' social networks) may be helpful in identifying additional factors that contribute to VH among Latine caregivers.

427.011 Making a Mentorship Program Where Autistic College Students Mentor Autistic High School Students Increasingly Participatory

A. Yan¹, V. Peak², L. L. Barrow³, C. Stevens², W. Alberts², B. Ayzenberg³, B. Sawantdesa², B. Myers², N. Wang², D. D. Onwumere¹, J. N. S. Akrofi¹, S. O'Brien⁴, R. Caragliano⁶, L. M. Ellzey², L. Rotondo⁶, A. R. Arista¹, K. Gillespie-Lynch⁸, W. Martin⁹ and K. P. Patten¹⁰, (1)New York University, NY, NY, (2)NYU, NY, NY, (3)CUNY, NY, NY, (4)OT, New York University, NY, NY, Ghana, (5)2800 Victory Blvd 4s-103, College of Staten Island, CUNY, Staten Island, NY, (6)College of Staten Island & The Graduate Center CUNY, Staten Island, NY, (7)Center for Children and Technology, Education Development Center, New York, NY, (8)Department of Psychology, CUNY Graduate Center, Staten Island, NY, (9)Education Development Center, New York, NY, (10)Occupational Therapy, New York University, New York, NY

Background: Autistic people are underemployed regardless of educational attainment.¹ Self-determination, the ability to act as a causal agent in life, supports autistic people's social, educational, and employment success.² While programs for autistic students often focus on self-determination skills, including self-advocacy, they often position them as needing help from non-autistic people rather than leaders. Participatory approaches increase the validity and impact of autism research but require careful planning to avoid inequalities.³⁻⁵

Objectives:

1. Describe the ongoing process of making *Making Mentors* increasingly participatory.
2. Share initial feedback from mentors and mentees.

Methods:

Making Mentors is a program where autistic college students mentor autistic high school students. In Year 1, 11 autistic mentors (one a consultant) from 2 colleges mentored 10 mentees from 2 high schools. Mentors and mentees complete surveys/interviews around the beginning and end of each year. Mentorship started slowly and was often online due to bureaucracy.

Over a month in Summer 1, mentors, mentees, and staff worked 5 hours weekly to revise materials for Year 2. They completed surveys about summer work. In Year 2, *Making Mentors* expanded to 4 high schools, approximately doubling the number of mentors and mentees.

Results:

Surveys after Year 1 revealed that mentees enjoyed "trying something new," learning about "who I was," "neurodivergent artists," and "college," making "a few friends and acquaintances," and completing "a project I wanted to create for years, with people with similar interests."

However, mentees wished "we touched on college life more," noted scheduling conflicts with academic support, critiqued mentors' commitments and program structure. One noted, "I didn't like how it kind of rushed me to grow up."

Mentors enjoyed weekly meetings, coaching, "neurodivergent staff," receptiveness to "critique," "connecting with my community," "having a support system of people who won't judge me," and "making a difference" with "younger autistic folks to...give them a better sense of belonging in society/make them less scared of the future" by providing "what I didn't have in high school-- proof that you can be your autistic self and enjoy college."

However, mentors noted "lack of direction," difficulties connecting online, and time constraints, highlighting the need for more "structure from the administrators," accessibility, and professional development including greater focus on LGBTQIA+, Zoom etiquette, and strategies for addressing "mentee's autism-related questions."

Mentors and mentees expected their summer work to improve Year 2. Mentors noted, "including the group input at the beginning of the summer session to choose the topics made it so I was engaged..." and "my past experience being a mentor really helped me contribute..." A mentee indicated, "my contributions and my voice have left a positive impact on the program."

While mentors suggested more time for topics that need "breathing room," a mentee suggested shortening summer work. Mentors and mentees recommended increasing focus on implementing prior feedback, neurodivergent leadership, intersectionality, and mental health.

Conclusions: Initial findings suggest bidirectional benefits from autistic college students mentoring autistic high school students, particularly community building. Logistical (e.g., matching mentors-mentees) and conceptual (e.g., developing authentic participatory processes) challenges remain apparent.

427.012 Measuring Stress Improvements Following a Mindfulness Course for Parents of Autistic Children

R. A. Lundwall¹, N. Daines², B. Hughes², A. Jeong², M. Blackham², A. Gould², O. Wirig² and M. Gillies², (1)Psychology & Neuroscience, Brigham Young University, Provo, UT, (2)Brigham Young University, Provo, UT

Background: Parenting a child with autism spectrum disorder (ASD) can be both rewarding and stressful. The stress aspects may arise from added caregiving needs and providing advocacy for their child, making the sometimes stressful job of parenting even more stressful. Mindfulness is growing in popularity as a therapy to manage stress and may be useful to parents, perhaps especially to parents of autistic children.

Objectives: Examine the effects of an 8 week self-guided mindfulness course on stress, quantified using hair cortisol concentration (HCC) levels, for parents of children with and without autism.

Methods: This study was conducted under the framework of a larger study consisting of three unique phases, each of which lasted for at least 8 weeks. Participants were divided into two groups: parents of children with ASD and parents with children with no first-, second-, or third- degree relatives with ASD. At the initiation of each phase, parents had a hair sample taken from the nape of their neck. After completion of all phases, cortisol concentrations were then extracted through high-performance liquid chromatography followed by analysis through enzyme-linked immunosorbent assay (ELISA) techniques. After obtaining HCC levels for both groups, we analyzed differences in HCC measures between groups before and after completion of the mindfulness course.

Results: Results from Phase 1 showed that parents of children with ASD ($n = 19$, $HCC = .83$) had higher stress levels than parents with all NT children ($n = 20$, $HCC = .75$, $p = .3$). Following a mindfulness intervention, cortisol levels between phase 2 and 3 for the ASD group (Phase 2 $n = 26$, Phase 3 $n = 20$) and the NT group (Phase 2 $n = 31$, Phase 3 $n = 26$) showed a significant decrease ($p = .03$). A repeated measures ANOVA showed no significant differences in stress reduction between parents of ASD and NT children, indicating the magnitude of stress reduction was similar for both parents of ASD children and parents of NT children ($p > .05$).

Conclusions: Our results suggest that mindfulness may be a valuable therapy modality in addressing stress in both parents of children with and without autism. It is also interesting to consider parent report of stress as an alternative or adjunct to HCC measures.

427.013 “Unwritten Rules Are Everywhere”: Autistic Adults’ Social Experiences in College and the Workplace
S. M. Wolpe¹ and **I. S. Tien²**, (1)Education: Human Development and Psychology, UCLA, Culver City, CA, (2)UCLA, Los Angeles, CA

Background: In nearly every aspect of adult life, strong social skills are an asset. However, difficulties navigating adult social environments are found to be associated with poorer outcomes for autistic adults. This study examines how autistic adults describe their social challenges and interactions within the context of their transition to adulthood through a series of semi-structured interviews.

Objectives: This study examines how autistic adults describe their social challenges and interactions within the context of their transition to adulthood. Specifically, this project is designed to support the development of neuro-affirming social skills interventions and resource materials that help post-secondary school and work organizations provide accommodations, as well as helping autistic adults cope with the difficulties associated with transitioning to adulthood. Therefore, this study asks the following research questions with the lens of understanding and dismantling compensatory behaviors utilized by autistic adults to assimilate into the social world:

1. How do autistic adults describe the social challenges associated with transitioning into adulthood?
2. What are characteristics of their successful professional or social interactions?
3. What structural changes could educational, vocational, or interpersonal social environments make to promote successful social experiences for autistic students, employees, or friends?

Methods: Seventeen autistic adults (ages 18 to 36) were interviewed. Themes related to social interactions in education and the workplace were analyzed. Data analysis was conducted through the theoretical framework of Critical Disability Theory (Hall, 2019). Data analyses followed the guidelines for reflexive thematic analysis proposed by Braun and Clarke (2006), and a systematic coding consensus approach was then employed (Willms et al., 1990).

Results: Participants expressed **Difficulties with Initial Social** Contact leading to isolation and overstimulation in new environments. Participants recalled difficulties creating **Boundaries** through lack of understanding of appropriate workplace decorum and topics, receiving **Bullying** from coworkers, and experiencing **Growth** in their social and professional identities through employment. Participants struggled and embraced **Disclosure** of autistic identity both in college and in the workplace to coworkers and employers, both wishing to be authentic and known by the people around them and afraid of subsequent discrimination and altered perceptions. Lastly, participants provided **Employer Recommendations** on how to best support their autistic employees, including respecting accommodations, providing expectations upfront for workplace etiquette, and embracing alternate pathways for autistic employees’ success.

Conclusions: The experiences shared by the participants in this study will pave the way for understanding and re-centering of research priorities to reflect the desires of the autistic community, to endow emerging autistic adults with tools for success, and to create collegiate and vocational environments with a greater understanding and acceptance of autistic students, workers, and people.

427.014 Mental Health Challenges in Autistic Teens, Lack of Support, and Impact on the Family

C. M. Anderson¹, **S. M. Colón¹**, **A. O. Iampieri²** and **L. N. Franklin¹**, (1)Health Sciences, Towson University, Towson, MD, (2)Psychology, Towson University, Towson, MD

Background: Limited supports and services for mental health conditions in autistic teens leave these teens and their parents struggling to cope.

Objectives: To explore autistic teens’ mental health challenges and the effect these have on teen and family wellbeing.

Methods: Qualitative interviews were conducted with 46 parents of autistic teens, aged 15-17. Material focused on teen mental health was segregated, then analyzed using the constant comparative method.

Results: Four major themes emerged. **(1) Concerns About Anxiety and Mood.** Parents frequently reported that their teen struggled with anxiety. *She gets extremely anxious and will spiral into a panic attack whenever she feels like she’s done something wrong...* Depression was also mentioned, though less often. *He definitely fights depression and anxiety a lot... He keeps a digital journal for me, so I can track how he’s doing.* **(2) Outbursts and Overwhelm.** Emotional challenges could lead to shutting down. *I guess he gets anxiety, he would just plop himself on the floor and would not move... When he was younger, I could still lift him; as he gets older, it’s hard.* Parents also described meltdowns. *When his anger gets to a certain level, he blanks out, and...can’t control his actions.* Helping a teen return to a regulated state could take time and an emotional toll. **(3) Crisis Points.** Sometimes, the teen had hurt others, injured themselves, or threatened suicide. In certain cases, families reported that extreme behavior had begun at puberty. *He got really aggressive and angry, and was smashing things... leaving the house in the middle of the night, and saying he wanted to kill himself.* Change of school placement, police involvement, or inpatient stays could result. *I feel bad for him because he doesn’t mean it... But he’s like a different person when he’s aggressive... I had to call the police one time... and then they took him to the hospital but I wouldn’t let them keep him because I don’t want him committed somewhere.* **(4) Family Challenges.** Families strove to ease their autistic teen’s difficulties but faced their own issues. *We’ve been through many things of him saying he was going to kill himself... I took eight weeks of family leave to stay home with him.* Parents faced major stressors like dealing with a teen’s aggression. *He actually attacked me... I had to call the cops on him, and it was one of the hardest things I ever had to do.* They ruminated about their teen’s wellbeing. *I’m watching his mood and worrying about him getting down on himself because I can handle almost everything else but when he starts to feel bad about himself, I start to panic.*

Conclusions: As autistic children enter the teen years, mental health challenges can escalate, impacting the wellbeing of teens and families alike. Illuminating the lived experience of autistic teens and their parents is a critical step towards advocating for needed person- and family-centered supports. Future research should focus on further characterizing mental health struggles in this population as well as potential solutions.

427.015 Mental Health Interventions for Caregivers of Autistic Children: An Umbrella Review

T. Chau¹, **Y. S. Budi¹**, **M. Thorbecke²**, **S. Jayasinghe³**, **K. Williams⁴**, **A. Ure⁵**, **G. R. Cox⁶** and **M. Alshawsh⁷**, (1)Department of Paediatrics, Monash University, Clayton, VIC, Australia, (2)School of Psychological Sciences, Monash University, Clayton, VIC, Australia, (3)Monash Health, Cranbourne, VIC, Australia, (4)Paediatrics, Monash University & Monash Health, Melbourne, VIC, Australia, (5)Paediatrics, Monash University Department of Paediatrics, Clayton, VIC, Australia, (6)Department of Paediatrics, Monash University, Melbourne, VIC, Australia, (7)Murdoch Children’s Research Institute, Melbourne, VIC, Australia

Background: Caregivers of autistic children play an important role in supporting and advocating for their child. The time and effort of such support and advocacy, on top of typically-reported parenting stressors, can further contribute to reduced mental health and wellbeing in these caregivers. A number of studies have explored the impact of clinician-delivered mental health interventions for caregivers of autistic children and generally found positive results. However, the studies and types of interventions vary significantly.

Objectives: This umbrella review aims to (1) explore the overall effectiveness of clinician-delivered interventions on mental health and/or wellbeing outcomes in caregivers of autistic children, and (2) evaluate the quality and validity of the systematic reviews that have been undertaken to assess the effectiveness of these interventions.

Methods: The review has been registered on PROSPERO (CRD42024589283). To synthesise the data, between-study heterogeneity will first be assessed in order to inform subsequent meta-analyses of the standardised mean differences between baseline and post-intervention ratings reported for each of the caregiver mental health and wellbeing outcome measures. Publication bias will also be evaluated. For any systematic reviews that report qualitative results, a thematic analysis will be undertaken to provide a descriptive estimate of caregivers' overall mental health and wellbeing before and after receiving the intervention. Sensitivity analyses are planned to assess the robustness of our findings against variations in intervention time and key participant demographics (e.g., child age, parent education level, parent sex). The quality of each systematic review included as part of the umbrella review will be formally assessed using the Risk of Bias in Systematic Reviews (ROBIS) tool.

Results: The review is currently underway with results to be finalised by February 2025. We anticipate approximately 12-15 systematic reviews to be included as part of our study.

Conclusions: It is hoped that these findings will inform the development and refinement of best practice guidelines for the support of autistic children and their caregivers after diagnosis.

427.016 Mindfulness As a Method to Decrease Stress in Parents of Children with Autism Spectrum Disorder

J. Barnum¹, M. Blackham¹, M. Bouton¹, M. San Juan¹, R. A. Lundwall² and M. Gillies¹, (1)Brigham Young University, Provo, UT, (2)Psychology & Neuroscience, Brigham Young University, Provo, UT

Background: Autism spectrum disorder (ASD) is a developmental condition characterized by differences in socialization, communication, and repetitive behaviors. Parents of autistic children often experience heightened stress due to increased caregiving demands. Chronic exposure to these stressors increases psychological strain, with research showing that parents of autistic children, particularly mothers, report greater stress than parents of neurotypical (NT) children. Mindfulness practices have been shown to reduce stress for individuals in a variety of life circumstances. Thus, this study examines the impact of mindfulness-based intervention, specifically self-compassion training, on stress reduction in parents of ASD and NT children.

Objectives: This study aims to (1) compare stress levels between parents of children with ASD and NT children, and (2) assess the effectiveness of a mindfulness intervention in reducing stress, as measured by self-report questionnaires, including evaluating if parents of children with ASD benefit more from the intervention.

Methods: 68 mothers (30 parents of ASD children, 38 parents of NT children) participated in the study. Stress levels were assessed through the Parenting Daily Hassles Questionnaire (PDH) and the Parenting Stress Index (PSI). We further evaluated the quality of life and well-being of parents using the Family Quality of Life Questionnaire (FQOL), the Survey on Flourishing (SURF), and the Neff Self-Compassion Questionnaire-Modified (NSCQ). Parents then participated in a mindfulness-based intervention, "The Gift of Self-Compassion," for approximately eight weeks. Pre- and post-intervention scores on the measures were compared using independent t-tests, paired t-tests, and repeated measures ANOVA.

Results: Parents of ASD children reported significantly higher levels of stress (PDH) compared to parents of NT children ($p < 0.01$, Cohen's $d = -1.44$). Parents of NT children reported a significantly higher quality of life (FQOL) compared to ASD parents ($p = 0.01$, Cohen's $d = 0.87$).

Following the intervention, significant improvements were found in self-compassion ($p = 0.01$) and flourishing ($p = 0.03$) for both groups of parents. However, no significant differences were observed in daily hassles (PDH) or parental stress (PSI) scores. Additionally, parents of autistic children did not experience a significantly greater change in scores following the mindfulness practice than parents of NT children.

Conclusions: The findings suggest that parents of autistic children experience higher stress and lower quality of life compared to NT parents. While the mindfulness-based intervention significantly improved self-compassion and flourishing, it did not impact daily hassles or overall parental stress. These results highlight the complexity of stress management and suggest that self-compassion-based mindfulness helps parents of autistic children as well as other parents. Nevertheless, future interventions targeting the specific needs of parents of children with ASD would be most effective in addressing their unique needs.

427.017 Mixed-Neurotype Interactions in Educational Settings and Their Impact on Autistic Students' Mental Health – a Systematic Review of Qualitative Findings

S. Ophir¹, E. H. Keren², N. Almog³ and Y. Rum⁴, (1)Seymour Fox School of Education, The Hebrew University of Jerusalem, Jerusalem, Israel, (2)Ono Academic College, Kiryat Ono, Israel, (3)Education and Societal Studies, Ono Academic College, Kiryat Ono, Israel, (4)Seymour Fox School of Education, Autism Research Centre - University of Cambridge, Jerusalem, United Kingdom

Background: Within the framework of neurodiversity, social interactions between autistic and neurotypical (NT) individuals are termed “Mixed-Neurotype Interactions” (MiNtI). Considering the continued rise in autism prevalence, and the global trends of inclusion, MiNtI is becoming more common in educational settings. There is a growing body of qualitative research exploring MiNtI and autistic students’ mental health. While qualitative research brings an in-depth and authentic description of experiences, it is, by design, limited in generalizability. A systematic review of this literature could allow for a meta-synthesis of qualitative findings, leading to a broader understanding of MiNtI in educational settings and its impact on autistic students’ mental health.

Objectives: The objective of this review is to synthesize qualitative studies relating to MiNtI in educational settings and autistic students’ mental health from the viewpoints of autistic and NT students, as well as teachers.

Methods: The methodology followed the PRISMA guidelines. We used various combinations of relevant keywords to conduct a search (e.g., *autis**, *teacher*, *student*, *middle/elementary/primary school*, *qualitative*, *inclusion*, *mental health*). This search resulted in 7830 topic-relevant papers, from which papers were excluded if they did not present qualitative findings, were non-peer-reviewed, did not include students/teachers’ perspectives, or referred to MiNtI that did not include autistic students. The final sample included 109 papers describing MiNtI in educational settings from the perspectives of autistic/NT students and teachers (a total of 1847 participants), with references to autistic students’ mental health. The included papers were thematically analyzed. Sub-themes were merged into main themes. Papers were also tested for risk of bias (under PRISMA guidelines): validity was examined by assessing the neutrality of research questions and looking for evidence that deviated from the researchers’ hypothesis (Table 1).

Results: The analysis resulted in four main themes (Figure 1): Main features (loneliness, bullying, friendship), Autistic Identity (camouflaging of autistic traits/behaviors, disclosure of autism diagnosis), Supporting the Interaction (peer interventions, teachers’ scaffolding), and Specific Settings (Physical Education classes, online social interactions). The most prevalent sub-theme was *loneliness*, including self-exclusion by autistic students and shunning by NT students, described as leading to negative mental health outcomes such as depression and self-harm. Camouflaging was also described as leading to adverse mental health outcomes. While perspectives aligned in some themes, discrepancies emerged for others; for example, the definition of “Friendship” differed by perspective. Most of the papers focused on the autistic perspective ($n=72$). Quality assessment indicated a high risk of bias for findings related to friendship, peer interventions, and teachers’ scaffolding.

Conclusions: Both “positive” and “negative” outcomes of MiNtI are recognized from all perspectives. However, themes describing positive outcomes (e.g., friendship) were found to be at a relatively higher risk of bias, while negative themes (e.g., loneliness) were found to be at a relatively lower risk of bias. Findings flag “invisible” outcomes- the experience of *loneliness* and autistic students’ attempts to *camouflage* their autism - as crucial for their mental health. More research is needed on NT students’ perspectives and the impact of online features such as texting and social networks on mixed-neurotype interactions.

427.018 Understanding Autistic Children’s Reports of Social Connectedness

A. Hoffman¹, K. O’Brien¹, A. Eisenhower², N. Hamsho² and J. Blacher³, (1)*School of Education, University of California, Riverside, Riverside, CA*, (2)*Department of Psychology, University of Massachusetts Boston, Boston, MA*, (3)*School of Education, University of California, Riverside, CA*

Background: When measuring the social interactions of autistic children in school settings, most studies prioritize adult reports or observations over or to the exclusion of student self-reports (Losh et al., 2022). Given the double empathy problem (Milton et al., 2022) and consistent with the “nothing about us without us” movement (Kaplan-Khan & Caplan, 2023), it is important to understand autistic students’ self-reports of social connectedness, in order to facilitate their full educational inclusion. It is unfortunate that the field has deemphasized or ignored the perspectives of the youngest autistic children in schools in favor of relational measures that cannot capture internal experience, and this study aims to remedy that exclusion.

Objectives: We examined the self-reported social experiences of young autistic children. We investigated whether and how these early elementary age autistic students’ self-reports of their social connectedness relate to teacher-reported social integration and researcher observations of social behavior in the classroom. We also examined the stability of these three measures of peer interactions over time.

Methods: Participants ($N=18$) were in Kindergarten through second grade and had an autism diagnosis or possible/suspected autism, in a larger study of an autism-focused teacher professional development program (Hamsho et al., 2023). At three time points over a four-month period, teachers were surveyed about the peer social integration of their target student (Social Competence and Behavior Evaluation/SCBE; Skinner et al., 2009), researchers observed student-peer interactions (inCLASS; Downer et al. 2012), and students were interviewed (Loneliness and Social Dissatisfaction Questionnaire/LSOQ; this measure was validated with autistic children by Zeedyk et al., 2016).

Results: Autistic children largely rated themselves as not feeling lonely at school, with 66% reporting that they had lots of friends and 61% reporting that they do not feel alone at school, but teacher and observer reports were less positive. Friedman’s test showed that student-report, teacher-report, and observer scores were stable over time. Kendall’s *tau-b* correlations showed a significant positive correlation between teacher reports of student interaction mean score and inCLASS observer mean of positive peer social interaction domain scores ($\tau_b = .450, p = .012$). Child-reported loneliness was not correlated with either teacher-report social integration ($T=.23, p=.22$) or observed peer communication ($T=.13, p=.49$).

Conclusions: Autistic children consistently reported less loneliness than would be suggested by teacher and researcher observations of their interactions. Relational observation measures are inadequate to capture the internal experience of any person, but are likely to be inherently biased against autistic children, for whom social communication is a core difference from their peers. Autistic individuals have historically been victims of epistemic testimonial injustice (Fricker, 2007) and their voices should be prioritized in assessments of their social behavior. While teachers and observers noted limited peer engagement, neither adult-reported measure correlated with student self-reports. In fact, children felt more socially-connected by their own accounts, suggesting student self-reports must be included in studies that inquire about social connectedness and peer relationships.

427.019 Neurodiversity and Autistic Representation in Children’s Books about Autism

C. E. Venker¹, J. Johnson², G. Corrigan³, E. Lorange⁴, A. Faigin¹, F. Alade¹ and Z. Hesse², (1)*Communicative Sciences and Disorders, Michigan State University, East Lansing, MI*, (2)*Michigan State University, East Lansing, MI*, (3)*Psychological Sciences, University of Connecticut, Storrs, CT*, (4)*Advertising & Public Relations, Michigan State University, East Lansing, MI*

Background: Children's books about autism have the potential to serve as valuable tools for promoting neurodiversity (Barrio et al., 2021; Venker & Lorang, 2024). They may function as mirrors, allowing autistic children to see themselves, or as windows, allowing non-autistic children to learn about autistic experiences (Bishop, 1990). However, the range of mirrors and windows these books provide is constrained by the diversity of the autistic characters they portray. Some backgrounds and experiences may be less well represented than others (e.g., use of augmentative and alternative communication/AAC), which could limit the effectiveness of children's books about autism for broadly promoting neurodiversity.

Objectives: Our primary objective was to characterize the race/ethnicity, sex/gender, and communication of autistic characters in a representative sample of picture books. Our second (exploratory) objective was to examine representation over time.

Methods: Using a keyword search (e.g., autism + juvenile), we identified all children's picture books about autism in the collections of four capital city libraries in the Midwestern United States. This study included books in English with an autistic main character ($n = 93$). Trained coders identified autistic characters' race/ethnicity, sex/gender, and communication modalities. Binomial tests compared the demographic representation of autistic characters to the U.S. autistic population (Maenner et al., 2023; Rose et al., 2016).

Results: Nineteen autistic characters (20%) were non-human (e.g., zebra, train); thus, race/ethnicity codes were not applied. Of the 74 human characters, four were Asian, Southeast Asian, or Pacific Islander (5%); 13 were Black or African American (18%); three were Hispanic, Latino, or Spanish origin (4%); one was Native American or Alaska Native (1%); and 53 were White (72%). White characters were significantly over-represented, and Hispanic characters were significantly under-represented ($ps < .001$; see Figure 1). Twenty-three of the 93 autistic characters were female (25%), and 70 were male (75%); this proportion did not significantly differ from the U.S. population ($p = .156$). Four characters produced immediate echolalia, and four produced delayed echolalia. Eight autistic characters had to AAC. Diversity increased over time (see Figure 2a, 2b). Six of the eight AAC portrayals were from books published in the last eight years.

Conclusions: There were relatively few non-White autistic characters. Though the proportion of female characters resembled the U.S. autistic population, Depictions of AAC were rare. Most non-speaking characters (86%) were depicted without access to a reliable communication system. In addition to normalizing a lack of access to AAC, this may limit non-speaking characters' agency (i.e., decision-making abilities). Future work will investigate the intersectionality of multiple minority identities. The few autistic characters who were Hispanic, Asian, or Native American were all male. Autistic children, families, and educators will best be served by books with characters whose diverse identities represent the broader autistic population.

427.020 Optimizing Social-Emotional Well-Being of Mothers and Infant Siblings of Children with Autism: An Experimental Examination of Mom & Baby Net

C. Holbrook¹, A. Shivar² and K. M. Baggett³, (1)Marcus Autism Center, Children's Healthcare of Atlanta, and Emory University School of Medicine, Atlanta, GA, (2)Georgia State University, Atlanta, GA, (3)Mark Chaffin Center for Healthy Development, School of Public Health, Georgia State University, Atlanta, GA

Background:

Above and beyond the recent advisory on the mental health and well-being of parents in general, mothers of infants, who have sibling with autism, often experience enormous stressors that can lead to maternal depression and reduced resources for enjoyable interactions with their infants. Infants with siblings diagnosed with autism are at high risk for social-communication difficulties. Mom & Baby Net (MBN) is designed to address a crucial gap in accessible parent-mediated interventions with an embedded parental emotional and relational well-being approach, particularly for diverse parents of infants with and at-risk for neurodevelopmental disabilities.

Objectives:

The purpose of this presentation is to showcase a study examining efficacy of the MBN program with culturally diverse mothers and their infants whose siblings were diagnosed with autism. Objectives include providing an overview of the intervention, study approach, results and implications.

Methods:

Following referral from an internationally recognized autism clinic in the Southeast United States, based on an autism diagnosis of a sibling, mother-infant dyads were screened to establish inclusion criteria. Participants included 3 mothers who identified as African American, American Indian, and Latina. Demographic and maternal social-emotional measures were collected to describe the sample.

A multiple-baseline design was used to evaluate efficacy of the MBN program. Participants completed 14 app-based sessions, each consisting of approximately 25 minutes of video-based learning activities. Following each weekly session, mothers participated in a 30-minute coach call with a predoctoral psychology intern with training and experience implementing MBN with high fidelity. Coach calls consisted of co-viewing mother-infant video to facilitate mother reflection on her infant and her use of the positive behavior support strategies. Infant engagement and parent facilitators of infant social engagement were measured using the Indicator of Parent-Child Interaction (IPCI). Data were graphed for visual analysis to assess trends over time. Mother satisfaction was assessed via a rating scale at post-intervention.

Results:

All three mothers demonstrated significant growth in (a) overall positive behavior support of infant social engagement with increases ranging from 42% to 220% and (b) maintaining child's attention with increases ranging from 136% to 440%. All three infants demonstrated significant improvement in aspects of social engagement, including positive social feedback and follow through with increases ranging from 52% to 380%. All mothers reported high levels of stress prior to intervention. At post-assessment mothers reported high intervention satisfaction, particularly the accessibility of the intervention app and the brief, flexible, remote coach support that fit within the lives of these mothers, struggling with complex time and resource demands as the primary caregivers of young children with special needs.

Conclusions:

Use of the MBN program with culturally diverse mothers was found to be both feasible and effective for engaging mothers of infants whose siblings were diagnosed with autism. Digital interventions such as MBN, which infuse parental stress reduction and mood improvement strategies into early parent-mediated approaches, are promising for engaging diverse populations in early intervention, particularly infants at high risk for neurodevelopmental disabilities and mothers at high risk for anxiety and depression.

427.021 Outcomes of Experiencing Interpersonal Violence in Autism: A Mixed Methods Systematic Review and Meta-Analysis

K. Cooke¹, K. L. Ridgway², L. A. Pecora³, E. Westrupp⁴, D. Hedley⁵, M. Hooley⁶ and M. A. Stokes⁶, (1)Healthy Autistic Life Lab; School of Psychology, Deakin University Australia, Melbourne, VIC, Australia, (2)Healthy Autistic Life Lab; School of Psychology, Deakin University - Healthy Autistic Life Lab, Melbourne, VIC, Australia, (3)School of Psychology, Deakin University, Melbourne, VIC, Australia, (4)School of Psychology, Deakin University, VIC, Australia, Melbourne, VIC, Australia, (5)Olga Tennison Autism Research Centre, La Trobe University, Melbourne, VIC, Australia, (6)Healthy Autistic Life Lab; School of Psychology, Deakin University, Burwood, VIC, Australia

Background: Autistic people experience disproportionately worsened outcomes relative to the general population regarding employment, relationships, independent living, and mental health. Autistic females and gender minorities experience particularly elevated mental health challenges. Identifying mechanisms which contribute to these challenges has proven challenging; however, emerging evidence implicates the role of high violence prevalence among autistic people, particularly among females and gender minorities.

Objectives: This mixed-methods systematic review and meta-analysis aimed to examine interpersonal violence and associated impacts on individual factors (e.g., autism, behaviour, mental health) and social variables (e.g., support received, service utilisation, poly-victimisation) among autistic populations of diverse gender identities throughout the life course. We also aimed to summarise the applicability of intersectional and minority stress models for violence outcomes in autism.

Methods: We undertook a systematic database search of the following databases: CINAHL, MEDLINE Complete, PsycINFO, EMBASE, SocINDEX, and Web of Science. Study inclusion criteria were peer-reviewed research of various designs (e.g., qualitative, quantitative, mixed-methods) examining physical, sexual, and/or psychological interpersonal violence among autistic participants diverse in gender, age, and support needs. We conducted a random-effects meta-analysis, pooling data from 9 studies including 3,647 autistic participants (66% males, 24.3% females, 7.1% gender minorities, 2.6% other/non-specified), ranging from one to 80 years. Data not included in our quantitative synthesis were included in a narrative review of 57 studies including 13,127 autistic (71% males, 25% females, 2.4% gender minorities, 1.8% other/non-specified) and 24,291 non-autistic participants (49% males, 51% females, 0.1% gender minorities, 0.1% other n/s).

Results: Analyses found experiencing interpersonal violence was associated with increased mental health and behavioural issues, with the strongest effect found for internalising symptoms ($d = 0.66, p < .001$; CI [0.51, 0.80]), followed by suicidality ($d = 0.63, p < .001$; CI [0.44, 0.82]), post-traumatic stress symptomology ($d = 0.41, p < .010$; CI [0.08, 0.73]), lower self-esteem ($d = -0.35, p = .005$; CI [-0.60, -0.11]), and externalising behavioural difficulties ($d = 0.22, p < .005$; CI [0.07, 0.37]). Narrative synthesis found experiencing violence to be associated with a number of long-standing, adverse individual and social outcomes in relation to health (e.g., mental illness, suicidality, self-harm), functioning (e.g., difficulty accessing support, education, employment, or justice, social challenges) from formative development. These issues were noticeably enhanced among females and gender minorities.

Conclusions: Our findings confirm interpersonal violence incurs longstanding and extensive harm among autistic people, whereby autistic identity and female gender heighten susceptibility towards worsened mental health and behavioural difficulties associated with violence from early childhood. Reviewed findings lend support to the notion that violence incurs a range of mental health and behavioural issues, particularly internalising symptoms (e.g., depression, anxiety) and suicidality, exacerbating intra- and interpersonal difficulties that commonly co-occur alongside autism. Findings implicate a concerning lack of adequate safeguard and response strategies targeted towards violence identification, prevention, and response or treatment among autistic people impacted by violence. This was particularly evident among females and gender minorities from early childhood. Findings raise several considerations for practice, policy, and research

**427.022 Parent Experiences Informing Parent-Child Interactions in Preschoolers with ASD**

R. A. Gordon¹ and A. Dimitropoulos², (1)Psychological Sciences Clinical Psychology, Case Western Reserve University, Cleveland, OH, (2)Psychological Sciences, Case Western Reserve University, Cleveland, OH

Background: Parent-child play represents a critical resource for connection and developmental growth for children with autism spectrum disorder (ASD). However, parents of autistic children may struggle to effectively engage their children during play, demonstrating elevated criticism, questioning, and controlling behaviors (Doussard-Rousevelt et al., 2003; Zlomke et al., 2019). Various factors influence these parenting behaviors, including elevated rates of stress, psychopathology, and reduced coping in this population, such as through experiential avoidance of negative emotions or behaviors in their child (Cheron et al., 2009; Hayes & Watson, 2013). While it is hypothesized that child, parent, and perceptual factors, such as coping, may relate to family functioning, the implications of parent perceptions and experiential avoidance on observed behavior, remain understudied (McCubbin & Patterson, 1983).

Objectives: The aim of the present study was to identify how parents' mental health, stress, and avoidance relate to behaviors during dyadic play interactions with their autistic children. It was hypothesized that parent-child interactions would be lesser in quality when compared to typically developing controls. It was additionally hypothesized that increased parenting stress, depression, and anxiety would relate to worsened parenting skills during parent-child interactions.

Methods: Participants included 15 children with ASD and 23 typically developing (TD) children ages 3-6 and their parents who completed a 5-minute dyadic pretend play task. Play interactions were qualitatively scored across domains of parent, child, and dyadic quality (Vargo et al., 2024). Parents completed questionnaires on child social and behavioral characteristics. Parents also reported their own stress, depression, anxiety, and completed the Parental Acceptance and Action Questionnaire (PAAQ; Cheron et al., 2009) as a measure of avoidance, coping abilities, and controlling parenting behaviors. T-tests directly compared interaction quality scores to those in TD preschool dyads and Pearson's correlations examined relationship between parent and child characteristics and interaction quality.

Results: Dyads in the ASD group showed reduced interaction quality across child, dyad, and total interaction domains in comparison to typically developing dyads (p 's < .001), however, parent domain quality did not significantly differ between groups. Contrary to hypotheses, there were no significant relationships between parenting stress or psychopathology and parent interaction quality within the ASD group. Further, increased PAAQ experiential avoidance and overall PAAQ coping deficits were positively correlated with quality of parenting skills during dyadic interactions ($r = .538$, $p = .047$, and $r = .555$, $p = .039$, respectively).

Conclusions: Results are surprising in suggesting that parental difficulties of reduced coping, controlling behaviors, and in particular, experiential avoidance, may relate to effective parenting behaviors during dyadic play with their child with ASD. These findings may suggest that parents who avoid negativity in parent-child interactions may use alternative strategies, such as redirection or child-led engagement, to maintain effective interactions with their child. Avoidance of negativity may, in turn, be adaptive or act as a buffer against other stressors in promoting more successful parent-child play interactions. This work can inform efforts to enhance parental adaptation and effective parent-child interactions that may contribute to overall family functioning and child socioemotional growth.

427.023 Parent Experiences Post Comprehensive Diagnostic Evaluation for School Age Children and Adolescents Regarding the Diagnostic Process and Accessing Services

J. Hangauer, Psychology, Johns Hopkins All Children's Hospital, St Petersburg, FL

Background: While crucial to begin therapeutic services, the process of obtaining an autism spectrum disorder (ASD) diagnosis has been identified in extant literature as often stressful for parents (Crane, Chester, Goddard, Henry, & Hill, 2016; Makino, Hartman, King, Wong & Penner, 2021). Dissatisfaction with the diagnostic process related to wait times to obtain an evaluation and post diagnostic support has been identified as a barrier to obtaining a diagnosis and services (Siklos & Kerns, 2005). Jashar, et al. (2019) found parents largely left the feedback session without a clear understanding of next steps to obtain services. Extant research examining post diagnostic support are vastly limited to parents of children under the age of five (Makino et al, 2021). A paucity of information exists regarding post diagnostic support for parents of school age children and adolescents at present.

Objectives: To examine the facilitators and barriers as well as lived experiences of parents and children accessing services across therapeutic and educational domains for school-age children and adolescents after a comprehensive diagnostic evaluation for ASD. Three specific questions are addressed: 1) What were parents' experiences before, during, and after the comprehensive evaluation; 2) What were the most helpful recommendations arising from the evaluation process; 3) How easy or difficult was it to access recommendations post evaluation.

Methods: Parents of school-aged children and adolescents who participated in a comprehensive psychological evaluation including cognitive, adaptive, academic, and autism specific measures (e.g., ADOS-2, CARS-2) at an academic medical center were invited to participate. A convergent parallel mixed method design (Teddle, 2007) was employed in order to gather more in-depth information about participants lived experiences. A sample of 60 parents of children diagnosed with ASD per DSM-VTR criteria ages 6 through 17 years of age ($M_{age} = 8.92$; $SD = 11.43$) completed the quantitative survey. A cohort of 15 randomly selected parents individually interviewed using a semi structured approach. Results were analyzed utilizing thematic analysis to address aforementioned questions along with gathering additional information on lived experiences.

Results: Majority of parents report feeling increased stress prior to the evaluation due to extensive wait times and uncertainty regarding the process and eventual outcome. Opportunity to meet with the provider (in person or virtually) prior to evaluation appointment was highly preferred and moderately related to reduced stress. Over 75% of parents report educational navigation recommendations (e.g., assistance with IEP or Section 504 Plan) as highly beneficial while variable results with other recommendations (e.g., social skills training, applied behavior analysis) with regard to access and quality of service. Consistent with extant research, a positive relationship was found with parents of children with comorbidities in addition to ASD (e.g., ADHD) as they reported decreased satisfaction with post evaluation services.

Conclusions: A paucity of information exists regarding post diagnostic support for parents of school age children and adolescents compared to parents of younger children (birth-5). Information gleaned from this study highlights the need for increased post diagnostic support for families to navigate a new autism diagnosis with school age children and adolescents.

427.024 Parent Outcomes of a Mindfulness-Based Intervention for Autistic Adolescents and Their Caregivers

H. Honda¹, M. Mitchell², A. Malligo², S. Boyd¹, B. A. Pagni³, B. B. Braden⁴ and N. L. Matthews¹, (1)Southwest Autism Research and Resource Center, Phoenix, AZ, (2)Southwest Autism Research & Resource Center, Phoenix, AZ, (3)Arizona State University, Tempe, AZ, (4)College of Health Solutions, Arizona State University, Tempe, AZ

Background: Parents raising autistic children experience higher levels of stress than those raising typically developing children or children with other disabilities (Bonis, 2016). In recent years, research on mindfulness-based interventions has highlighted positive impacts on child behavior, family functioning, and both parent and child mental health (Hartley et al., 2019). Among parents of autistic children, higher levels of mindfulness and mindful parenting are associated with lower incidence of depressive symptoms and parental stress (Beer et al. 2013, Conner & White, 2014). The current study builds on this body of work by exploring improvements in parent mindfulness and wellbeing following participation in MINDful TIME (Mindfulness-based Intervention for NeuroDiverse Teens: Telehealth Instruction, Mobile-app Enhanced), a novel group-based telehealth intervention for autistic adolescents and their caregivers.

Objectives:

1. Compare changes in parent mindfulness between the treatment (T_x) and delayed treatment control (DTC) groups.
1. Compare changes in parent wellbeing, stress, and quality of life between T_x and DTC.

Methods: Adolescent-parent dyads ($n=42$) were randomly assigned to T_x or DTC. T_x participants ($n=21$) completed an eight-week telehealth mindfulness and habit formation program, while DTC participants ($n=21$) completed an 8-week wait period prior to intervention. Participants completed pre- and post-outcome measures for the 8-week treatment period or 8-week wait period. For the analysis of parent outcomes, we compared change scores on the Five Facet Mindfulness Questionnaire (FFMQ), Stress Index for Parents of Adolescents (SIPA), the World Health Organization- Five Well-Being Index (WHO-5), and the Beach Center Family Quality of Life Scale (FQOL Scale). Analyses controlled for baseline values for the respective outcome variable.

Results: T_x parents reported greater improvements on the FFMQ ($F(1, 36) = 12.79, p = .001, \eta_p^2 = .26$), the WHO-5 ($F(1, 36) = 7.47, p = .01, \eta_p^2 = .17$), and the parenting domain of the FQOL ($F(1, 35) = 1.27, p = .04, \eta_p^2 = .11$) relative to DTC. T_x parents also reported reduced adolescent-parent relationship dysfunction on the SIPA relative to DTC ($F(1, 36) = 6.36, p = .02, \eta_p^2 = .15$). We did not observe significant group differences on the Family FQOL- Family Interaction or Emotional Well-Being Domains or the SIPA Adolescent or Parent Domains (see Table 1).

Conclusions: Findings support the growing body of literature indicating positive effects of mindfulness interventions for parents of autistic children. Further, they extend existing literature by documenting improvements in adolescent-parent relationship functioning. Significant effects were not observed on variables related to other aspects of family functioning (e.g., spousal and sibling relationships), which is unsurprising given the focus of the intervention. Overall, findings suggest that adolescent and caregiver mindfulness training may improve several, but not all, dimensions of parent and family well-being. Future research with a larger sample size is needed to better understand potential benefits of MINDful TIME for parents and families.

427.025 Parent Views on Primary Care Practices for Children with Autism

I. Lozano¹, M. L. Ayala-Brittain², A. L. Laakman³, M. L. Luu⁴, S. S. Mire⁵, R. P. Goin-Kochel⁶, M. Keller-Margulis³, W. Fan⁷ and J. Contreras-Munoz⁸, (1)School of Education, Baylor University, Waco, TX, (2)Psychological, Health and Learning Sciences, University of Houston, Houston, TX, (3)Psychological, Health, and Learning Sciences, University of Houston, Houston, TX, (4)Meyer Center for Developmental Pediatrics & Autism, Texas Children's Hospital, Houston, TX, (5)Psychological, Health, and Learning Sciences, Baylor University, Houston, TX, (6)Baylor College of Medicine, Houston, TX, (7)University of Houston, Houston, TX, (8)Baylor University, Waco, TX

Background: Family experiences within primary care settings vary widely, contributing to persistent disparities in autism care. Including parents in autism care systems is critical; parents need to know how to access resources, advocate for services, seek personal support, and promote positive child development. However, parents' perspectives are often excluded from collaborative care conversations in medical and school settings. Improving provider-caregiver relationships is essential, as evidenced by parents' dissatisfaction with communication amongst professionals involved in their children's care (Carbone et al., 2013). Within primary care settings, parents frequently report that primary care providers (PCPs) do not address specific concerns raised about autism (Dababnah et al., 2018; Curtin et al., 2020). Unfortunately, parents also report a lack of involvement and support in children's educational planning at school (Shamash et al., 2022), negatively impacting collaboration between parents and school professionals. Enhancing effective cross-system partnerships between parents, PCPs, and school-based professionals can improve the quality of care for children with autism across settings.

Objectives: The purpose of this study was to explore what cross-setting, collaborative goals parents of autistic children view as important for their pediatric PCPs to address in primary care, as well as parent views on supportive primary-care practices when navigating the complexities of an autism diagnosis.

Methods: A total of 228 parents of autistic children (ages 0 – 21 years) participated in a survey study about family experiences in primary care. Participants were recruited via email, social media, and flyers in North America. Descriptive statistics and response frequencies were computed to explore parent views on PCP practices and perceptions of PCPs to provide health-related and school-related supports. Pearson's correlation coefficient was used to examine relationships between child-related factors and parents' views on specific school-related practices in primary care. **Results:** Results revealed variability in expectations for and perceived ability of PCPs to provide autism-specific and school-related care. For example, 46.1% of parents identified it as "important" or "highly important" for pediatricians to address developmental concerns, while 11.8% of parents did not feel this was important. Additionally, 20 participants (8.8%) said their child's PCP never connected them with supports and services and 33 participants (14.5%) reported their family was never connected with community-based services for their entire family system. Forty-seven parents (20.6%) rated their PCP as "very good" at connecting families to school-based services; however, 62 participants (27.1%) either rated their PCP as "fair" or "poor". Overall, 84 participants (38.2%) felt it important or highly important for pediatricians to address educational concerns. Child-related factors (i.e., current age, age of autism diagnosis, presence of medical and behavioral health comorbidities) were significantly associated with parents' perspectives on the importance of PCP's addressing school or academic concerns.

Conclusions: Parents' perspectives on which practices are important in primary care must be investigated to identify ways to improve cross-system collaboration between schools and primary care settings. Results from the current study may provide the foundation for developing ways to efficiently and effectively foster cross-system collaboration between primary care and schools for autistic children and their families, as well.

427.027 Parental Empowerment Experiences and Needs in the Healthcare System for Parents of Autistic Children in Taiwan: A Mixed-Methods Study.

Y. R. Jin¹ and **L. Y. Lin²**, (1)*Institute of Allied Health Science, College of Medicine, National Cheng Kung University, Taiwan, Tainan, Tainan*, (2)*Department of Occupational Therapy, National Cheng Kung University, Tainan, Taiwan, Taiwan*

Background:

This mixed-methods study explores parental empowerment within healthcare systems for autistic children, recognizing parents' pivotal role in their children's development and well-being. Guided by the transformative paradigm and empowerment theory, the research emphasizes amplifying the community's voice to advocate for accessible resources and system changes that empower families and promote inclusivity.

Objectives:

The study aims to bridge the gap between research and action by equipping parents with advocacy skills and fostering collaboration between parents and service providers for transformative change. Highlighting the importance of support networks, the research seeks to strengthen parents' confidence in seeking help and connect findings to actionable improvements in Taiwan's healthcare system for families with autistic children.

Methods:

A convergent parallel mixed-methods design was employed, collecting qualitative and quantitative data concurrently. Four parents of autistic children (three preschool-aged and one school-aged boys) were recruited. The research was conducted in the social welfare community-based settings. All the parents were mother of the child, aged from 37 to 45. Semi-structured interviews gathered qualitative data on lived experiences with different systems, exploring parental empowerment needs in healthcare. Thematic analysis identified key empowerment themes. Quantitative data, collected using the Family Empowerment Scale (FES), Parenting Sense of Competence Scale (PSOC), and Parenting Stress Index (PSI-4-SF), was summarized through descriptive statistics. Integrating both data sets provides a comprehensive understanding of parental empowerment, identifying patterns and connections.

Results:

At the micro-level, quantitative data indicates high empowerment, with parents confident in managing their child's needs and maintaining family stability. Qualitative findings support this, revealing increased maternal self-efficacy. However, both data sets highlight challenges, as parents report needing more support to foster their child's development and manage personal sacrifices. At the meso-level, quantitative data shows a positive sense of agency in interactions with service providers, aligning with qualitative findings that value collaborative partnerships. Nonetheless, the findings underscore the urgent need for more proactive engagement and guidance from providers due to the fragmented healthcare system. At the macro-level, lower and variable scores on community and policy empowerment reflect qualitative findings on stigma, financial strain, and limited resources. These barriers underscore the need for further research to address macro-level challenges effectively.

Conclusions:

This study highlights the multifaceted nature of parental empowerment in healthcare, revealing both strengths and systemic challenges. The findings emphasize the need for interventions and policies addressing micro, meso, and macro-level needs to foster genuine empowerment and transformative change. Centering parental voices, this research contributes to developing more effective, family-centered healthcare services that enhance the well-being of autistic children.

427.029 Parental Influence on the Development of Autistic Masking

C. Rutledge¹ and **M. Botha²**, (1)*Psychology, University of Stirling, Stirling, North Lanarkshire*, (2)*Department of Psychology, Durham University, Stirling, United Kingdom*

Background: Masking is conscious or unconscious social adaptation through the suppression of autistic traits to meet mainstream social norms, to the detriment of an autistic individual's mental health (McDonald, 2020; Pearson & Rose, 2023). Little is known about when masking behaviors start and how relationships impact their development.

Objectives: This study looked at the role parents play in the development of masking, if childhood masking predicts adult masking, and if adult romantic and/or sexual relationships influence masking's relationship with mental health.

Methods: 193 autistic adults completed an online survey on childhood/adulthood masking, perceived parental reactions, parental support behaviors, internalized stigma, expectation of rejection, relationship satisfaction, and mental health. Using a cross-sectional design, mediation analysis examined if parental support behaviors mediated perceived parental reactions and childhood masking; a serial mediation looked at internalized stigma and expectation of rejection on childhood/adulthood masking; and finally, if relationship satisfaction mediates adult masking and mental health.

Results: Negative perceived parental reactions and non-supportive behaviors strongly predicted childhood masking ($p < .001$) and indicated a significant full mediation (figure 1). However, supportive behaviors did not ($p > .05$). Childhood masking was a significant predictor of adult masking ($b = t(184) = 15.21, p < .001$), but was not mediated (nor serially mediated) by internalized stigma or expectation of rejection. Replicating previous work, higher adult masking was associated with higher rates of poor mental health ($p = .012$). However, relationship satisfaction did not mediate this relationship.

Conclusions: Results support the hypothesis that parent/caregiver(s) play a significant role in the development of masking, and that masking behaviors begin in childhood persisting through adulthood. Findings suggest early developmental relationships, such as parents, play a greater role than adult relationships in mental health as a result of masking.

**427.030 Parenting Stress, Social Support, and Affiliate Stigma Among Asian and White Parents of Children with Autism in the United States**

S. Yu¹, **K. Choi¹** and **C. Shivers²**, (1)*Human Development and Family Science, Virginia Tech, Blacksburg, VA*, (2)*Niagara University, Niagara University, NY*

Background: Extensive research has shed light on the elevated parenting stress experienced by parents of children with autism spectrum disorder (ASD). However, existing studies conducted in the United States predominantly featured white parents, thus lacking evidence of the parenting stress and its predictors experienced by racial minority parents raising autistic children. Addressing this gap is essential for advancing our understanding of the determinants of parenting stress theoretically, with a consideration of minority stress. Moreover, this will provide valuable information to guide the development of more tailored and culturally sensitive support programs for parents of children with ASD from diverse racial and cultural backgrounds.

Objectives: The current study aimed to answer the question of what the role of race in parenting stress is and its predictors among Asian and White parents of children with ASD in the United States. Built upon existing literature on parenting stress among families of children with ASD, we hypothesized that Asian parents of children with ASD would experience higher levels of parenting stress, higher affiliate stigma related to ASD, and lower social support. In addition, we raised two research questions to examine the potential differences between two racial groups: 1) Would race moderate the association between social support and parenting stress? 2) Would race moderate the association between affiliate stigma and parenting stress?

Methods: Using an online survey, 129 parents of children with ASD aged between 2-18 years old living across the United States participated in our study. Among them, 76 parents identified themselves as White, and 50 of them identified themselves as Asian. Parents are aged between 23 and 58 years old ($M = 38.83, SD = 6.68$). Regarding parent gender, 77.8% of parents identified as female, 20.6% identified as male, and 1.6% identified as nonbinary/gender expansive. Parents completed questionnaires about their demographics, parenting stress, perceived social support, affiliate stigma, and child behaviors.

Results: We found that Asian parents reported higher parenting stress ($t = 2.13, p = .04$) and higher affiliate stigma ($t = 2.36, p = .02$) than White parents. Yet, no significant difference was found in social support between the two groups ($p > .05$). Furthermore, linear regression models showed that family socioeconomic status, social support, and affiliate stigma were significant predictors of parenting stress. However, race was not a significant predictor after controlling for the covariates. Regarding the research questions, race was not a significant moderator in the association between social support and parenting stress, nor in the association between affiliate stigma and parenting stress.

Conclusions: Consistent with previous literature, the study found higher risks for parenting stress among Asian parents in the United States. Additionally, social support and affiliate stigma are important factors related to higher parenting stress for both Asian and White parents. Given the significantly high levels of affiliate stigma among Asian parents, future studies should examine the mechanisms of stigma and related sociocultural factors. Finally, future studies should continue to explore the determinants of parenting stress using longitudinal designs, particularly among historically underrepresented families raising autistic children.

427.031 Parents of Autistic Individuals and Their Autism Knowledge, Advocacy, Involvement, Awareness of Neurodiversity, and Attitudes Towards Inclusion

V. Y. Kang¹, **S. Awas²**, **M. Mann³**, **A. J. Harrison⁴**, **L. Yu⁵**, **S. Joo⁶**, **J. D. Lee⁶**, **N. Naqvi⁷** and **S. Intepe⁸**, (1)*Counseling, Higher Education, and Special Education, University of Maryland at College Park, College Park, MD*, (2)*University of Maryland, College Park, MD*, (3)*Educational Psychology, University of Georgia, Athens, GA*, (4)*Center for Autism Research, School of Education, Guangzhou University, Guangzhou, Guangdong, China*, (5)*University of Kansas, Lawrence, KS*, (6)*Department of Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA*, (7)*Iona College, New Rochelle, NY*, (8)*Florida State University, College Park, MD*

Background: There is limited research on whether and how parents' perspectives on autism, neurodiversity, advocacy, and inclusion may relate to each other. Understanding these perspectives can be beneficial in providing targeted support to parents in need of resources for advocacy and neurodiversity-affirming and inclusive practices.

Objectives: Two research questions were answered. 1. Do parents' experience in special education, race, primary language, education level, employment status, and family household income predict parents' autism knowledge, advocacy, school involvement, neurodiversity awareness, and attitude towards inclusion? 2. How do parents' autism knowledge, advocacy, school involvement, neurodiversity awareness, and attitude towards inclusion relate to one another?

Methods: 174 parents (92 mothers, 79 fathers, and 3 others) of children with and without disability participated in the study. Parents completed an online survey: (1) Family Demographics & Services Form, (2) Advocacy in Parents of Children with Special Needs, (3) Attitude Survey Inclusive Education – Parents, (4) Neurodiversity Attitudes Scale, (5) Autism Stigma Knowledge Questionnaire-2, and (6) Parent and Teacher Involvement Questionnaire. A descriptive statistical analysis, multiple regression, and path analysis were conducted. See Table 1 for descriptive statistics and Fig 1 for theoretical model tested for path analysis.

Results: Having experience in special education ($R^2 = 2.46$, $t = 2.28$, $p = .024$) and higher income ($R^2 = 3.21$, $t = 4.82$, $p < .001$) and education level ($R^2 = 3.09$, $t = 3.03$, $p = .003$) predicted more neurodiversity awareness. Having no experience in special education ($R^2 = -4.97$, $t = -5.77$, $p < .001$) predicted positive attitudes towards inclusion. Being white ($R^2 = 6.14$, $t = 2.57$, $p = .011$) predicted greater advocacy beliefs/actions. Experience in special education ($R^2 = 5.86$, $t = 2.70$, $p = .008$), being white ($R^2 = 4.64$, $t = 2.16$, $p = .033$) and speaking English ($R^2 = -5.74$, $t = -2.09$, $p = .038$) predicted greater school involvement. Experience in special education ($R^2 = 1.99$, $t = 3.13$, $p = .002$) predicted greater autism knowledge. Autism knowledge had positive direct effect on advocacy ($\beta = .736$, $p < .001$) and awareness of neurodiversity ($\beta = .430$, $p < .001$) and negative direct effect on attitude toward inclusion ($\beta = -.442$, $p < .001$). Advocacy had a positive direct effect on school involvement ($\beta = .940$, $p < .001$). Neurodiversity awareness ($\beta = -.636$, $p < .001$) and attitude towards inclusion ($\beta = -.307$, $p < .001$) both had a negative direct effect on advocacy. See Fig 2.

Conclusions: Targeted support (e.g., parent training) on advocacy, school involvement (e.g., communicating with teachers), and neurodiversity (e.g., talking about it at home) may be beneficial for culturally/linguistically diverse and low-resource parents. More research is needed on what leads parents to develop positive/negative attitudes towards inclusion and ways to promote positive perception of inclusion. Finally, the theoretical model could be revised by adding demographics as moderators.

427.033 Paternal Mental Health Outcomes Related to Sex of Autistic Children

M. Krushena¹, R. S. Factor² and A. Gulsrud³, (1)UCLA Semel Institute for Neuroscience and Human Behavior, Los Angeles, CA, (2)UCLA Semel Institute for Neuroscience and Human Behavior, UCLA Semel Institute for Neuroscience & Human Behavior, Los Angeles, CA, (3)UCLA Semel Institute for Neuroscience & Human Behavior, Los Angeles, CA

Background:

Parents of children with disabilities face unique challenges affecting their mental health and functioning. Evidence suggests parents of autistic children experience increased stress levels (Estes et al., 2009). Dimachkie-Nunnally and colleagues found that child adaptive functioning and repetitive behaviors predicted caregiver stress, with parent executive functioning moderating this relationship (2023). They noted mental health differences between mothers and fathers, with mothers experiencing more anxiety, depression, and caregiver strain. However, the effect of an autistic child's biological sex on parental wellbeing, particularly for fathers, remains largely unexplored.

Objectives:

The current study examines the impact of child sex on parental mental health and extends previous findings by: 1) including balanced samples of males and females, 2) exploring effects on fathers, an understudied population, and 3) by focusing on the intersection of child sex and paternal mental health.

Methods:

Data were collected from the SPARK database via Research Match and, after case controlling for gender, included 116 autistic children and their biological parents, with boys and girls matched by registration age. Notable demographics include race/ethnicity (63.8% White, 12.9% Hispanic, 4.3% African American, 2.6% Asian, 12.9% multiracial, and 4.3% other), child age ($M = 7.09$, $SD = 3.76$), and occupation (38.8% of mothers versus 3.4% of fathers identified as full-time caregivers). Child measures included the Child Behavior Checklist (CBCL), Vineland Adaptive Behavior Scale-Third Edition (VABS-3), and Social Communication Questionnaire (SCQ). Parent measures encompassed the Patient Health Questionnaire (PHQ-9), Generalized Anxiety Disorder (GAD-7), Wellbeing Scale (WBS), and Barkley Deficits in Executive Functioning Scale (BDEFS). Statistical analyses included Pearson correlations, independent t-tests, and multiple general linearized models to compare gender differences and analyze four main interactions: fathers of autistic daughters, fathers of autistic sons, mothers of autistic daughters, and mothers of autistic sons.

Results:

Fathers of autistic girls showed the highest levels of anxiety ($M = 8.22$, $SD = 5.554$, $p = 0.003$) and depression ($M = 7.69$, $SD = 6.004$, $p = 0.02$), greater executive functioning deficits indicated by lower scores in emotion control ($M = 22.19$, $SD = 7.251$, $p = 0.021$) and inhibition regulation ($M = 32.75$, $SD = 10.029$, $p = 0.046$), and lower wellbeing scores ($M = 4.82$, $SD = 0.875$, $p = 0.02$). Conversely, fathers of autistic boys had significantly better outcomes. Mothers showed no significant differences based on child sex; child social communication scores did not significantly affect parent outcomes.

Conclusions:

This study revealed that fathers of autistic girls exhibited significantly poorer overall wellbeing compared to fathers of autistic boys, and mothers of autistic girls and boys. This finding highlights the need for deeper exploration of fathers' experiences of parenting and may inform future interventions and support for parents, with a focus on tailoring these supports to fathers, especially those with autistic girls, to improve their mental health and overall wellbeing. This study highlights the unique challenges faced by fathers in the context of parenting their autistic children, prompting a shift from the traditional focus on maternal caregiving.

427.034 Peer Attitudes, Peer Victimization, and Well-Being in Black and White Autistic Adults

D. R. Jones¹, M. Botha² and N. J. Sasson³, (1)Department of Psychology, University of Maryland, College Park, MD, (2)Department of Psychology, Durham University, Stirling, United Kingdom, (3)University of Texas at Dallas, Richardson, TX

Background: Autistic adults often experience social exclusion and victimization, despite expressing a strong desire for close relationships (Sosnowy et al., 2019). This disparity between social aspirations and actual experiences can heighten the risk of poor mental health outcomes. Additionally, individuals with multiple marginalized identities, such as Black autistic people, may face compounded stigma (Jones et al., 2021), exacerbating mental health challenges. Despite the significance of understanding psychosocial risk factors in autistic adults, no previous study has directly explored the link between peer evaluations, victimization, and mental health status among Black and White autistic individuals. **Objectives:** To characterize interpersonal attitudes and behaviors towards autistic adults, and their impact on well-being.

Methods: 32 Black and White autistic adults ($M_{age} = 26.3$ years, $SD = 6.9$) participated in this study. Participants completed questionnaires assessing their lifetime and recent experiences of peer victimization and cyberbullying, as well as questionnaires related to recent experiences of loneliness, depression, and anxiety, which were used to form a composite measure of well-being. In addition to questionnaires, participants completed videotaped conversations, which were edited to 10-second clips. In the second phase of the study, these clips were shown to non-autistic raters, who evaluated each participant on items assessing traits and social interest. Linear regressions were used to determine the relationships between peer attitudes, peer victimization, and well-being.

Results: Peer evaluations significantly predicted victimization, with more positive peer interest ratings associated with greater lifetime victimization ($b = 15.254$, $SE = 7.071$, $p = .042$). There was a significant interaction between race, cyberbullying, and peer trait evaluations ($b = 5.763$, $SE = 2.566$, $p = .035$), with White autistic people who were rated less favorably by their peers also reporting greater online victimization ($b = -9.821$, $SE = 2.301$, $p = .001$), while this relationship was non-significant for Black autistic people ($b = 1.880$, $SE = 4.671$, $p = .694$). Peer trait ratings were significantly associated with well-being, with autistic people who were rated *less favorably* by peer raters also reporting poorer well-being ($p = .009$). However, the opposite relationship was found between peer interest ratings and well-being, with autistic people whose peers showed *greater interest* in interacting with them also reporting poorer well-being ($p = .001$).

Conclusions: These findings highlight the link between peer attitudes and behaviors and poorer well-being in autistic adults. Interestingly, greater peer interest in future interactions was associated with poorer outcomes, highlighting the complex nature of social relationships for autistic individuals. Differences across races were also observed for the relationship between peer evaluations and online victimization. These results emphasize the need for efforts to improve non-autistic perceptions and behaviors towards their autistic peers, as well as the need for supports that address the social and mental health challenges faced by autistic adults, particularly those with multiple marginalized identities, to improve their overall well-being and social outcomes.

427.035 Peer Support Among Autistic Adults: Different Types of Support Addressing Unique Needs

N. Cusson¹ and I. Courcy², (1)Department of Psychology, Université du Québec à Montréal, Montréal, QC, Canada, (2)Department of Sociology, Université de Montréal, Montréal, QC, Canada

Background: Social support is an important predictor of quality of life for autistic people (Jeanneret et al., 2022; Kamio et al., 2013). A valuable source of social support for autistic adults are autistic peer support groups. These groups fulfill several of their needs, including establishing friendships, sharing their experiences and advice related to everyday life, reflecting on autism and building a sense of belonging to the autistic community (Chan et al., 2023; Crane et al., 2021; Crompton et al., 2022). However, studies rarely analyze in depth the social networks of autistic adults and the support shared between autistic peers from their perspectives. As such, very little is known about the specific types of support exchanged between autistic peers, the importance of peer support in autistic adults' lives, and how peer support differs from the support exchanged with the non-autistic people in their social network.

Objectives: This qualitative study aimed to explore the types of support, satisfaction and meanings autistic participants attribute to peer support within their network.

Methods: Semi-structured interviews using a name generator were conducted with 21 autistic adults (13 women and 8 men living in Canada, aged 18 to 67 years old, who received a diagnosis from a qualified clinician). These participants specifically mentioned having one or more autistic peers in their social network. A thematic analysis (Braun & Clarke, 2006) was used to identify the key themes related to the types and characteristics of support shared between autistic peers as well as the meanings participants attributed to peer support.

Results: Four key themes were identified, namely peer support, mutual acknowledgement, interference in social interactions, and social engagement in the community. More specifically, results showed that several types of support (emotional, informational, companionship and social-related) were shared between autistic peers and that participants considered peer support as important and addressing unique needs. In addition, all participants mentioned experiencing various forms of interference in social interactions with non-autistic people. However, when interacting with autistic peers, the experienced interference decreased, leading to greater ease of communication and mutual understanding. Shared experiences and challenges promoted the emergence of a sense of belonging to the autistic community, and often led to a desire to become socially involved, as manifested by the creation of self-help structures to defend autistic or disabled people's rights and the undertaking of autism awareness initiatives within several settings. As such, social engagement in turn provided the basis for additional sources of support in the community.

Conclusions: The current study offers insight into how autistic participants perceive peer support and the unique place it takes in their everyday life. By highlighting the characteristics of peer support compared to the support provided by non-autistic people in the participants' social network, this study paves the way for reflecting on how to create opportunities and facilitate spaces that promote peer support. Peer support is not a substitute to professional support, but it seems essential for fostering a collective, positive sense of autistic identity and thus improving quality of life.

427.036 Perceived Impact of ASD on Siblings from 9 to 33 Years of Age

M. Micheletti¹, N. E. Rosen¹ and C. Lord², (1)University of California, Los Angeles, Los Angeles, CA, (2)UCLA Semel Institute for Neuroscience and Human Behavior, Los Angeles, CA

Background: Siblings of autistic individuals report diverse experiences related to having a brother or sister with autism spectrum disorder (ASD). Parents of autistic individuals have described negative impacts related to caregiving across financial, social, and emotional domains (Christopher et al., 2023). Less is known about the perceived impact of ASD on siblings over time, and how this relates to sibling engagement later in life.

Objectives: The aim of this study was to identify longitudinal trajectories of parents' perceived impact of ASD on siblings. We also aimed to examine how characteristics of autistic individuals, siblings, and parents predicted trajectory class and sibling engagement.

Methods: Parents were recruited from a longitudinal study of children diagnosed with autism or related developmental disabilities by approximately 3 years old. Inclusion criteria for the present study was parent completion of the Child and Adolescent Impact Assessment (CAIA) at least twice. The sample included 158 parents across four timepoints. Child mean age at T1 = 10.0 (1.1) years, T2 = 13.6 (1.5), T3 = 19.6 (1.3), T4 = 33.9 (3.3). At each timepoint, parents reported the perceived negative impact of their autistic child's problems on their relationship with their other children, the relationships between their children, their other children's behavior, and restrictions on family social activities. A subset of siblings (n=31) described engagement with their autistic sibling as an adult (i.e., living arrangements, how often and who initiates communication or activities). Linear mixed effects models were used to describe change in perceived negative impact over time. To determine trajectory classes, k-means was used to cluster longitudinal data (Genolini et al., 2015). Child characteristics at T1 (ASD symptom severity, cognitive ability, daily living skills, aggression), sibling characteristics (sex), and parent characteristics (social support, race, parent education, divorce) were included as predictors of trajectory class and sibling engagement. Regressions were corrected for multiple comparisons.

Results: From 9 to 33 years of age, we observed decreases in parents' perceived negative impact of ASD on their relationship with their other children ($p<.001$), the relationships between their children ($p<.001$), their other children's behavior ($p=.010$), and restricted social activities ($p<.001$). Longitudinal clustering yielded two impact classes: a high and low impact class, both decreasing over time. More aggression predicted membership in the high impact class for impact on relationships between children ($p=.035$), but this did not remain significant after correction. Higher ASD symptom severity ($p=.014$) and lower daily living skills ($p<.001$) predicted membership in the high impact class for impact on restricted social activities. As adults, 29% of siblings lived with their autistic sibling. Autistic siblings most often initiated activities, and frequency of communication ranged from yearly to daily. Autistic individual, sibling, and parent characteristics did not predict sibling engagement into adulthood in a small subset of siblings.

Conclusions: The current study examines trajectories of parents' perceived negative impact of ASD on siblings over 20 years. As siblings get older, parents reported decreased perceived negative impact on siblings. Future work explores siblings' perspectives, particularly as family systems change and different roles emerge.

427.037 Perceived Stigma and Support from Extended Relatives By Chinese Parents of Autistic Children

J. Li^a, C. Wang^a, F. Cotier^a, M. Washington-Nortey^a, K. C. Chua^a and R. A. Hoekstra^a, (1)Department of Psychology, Institute of Psychiatry, Psychology & Neuroscience, King's College London, London, United Kingdom, (2)Department of Social Psychology, School of Sociology; Autism Research Center, Nankai University, Tianjin, Tianjin, China, (3)Institute of Psychiatry, Psychology & Neuroscience, King's College London, UK, London, United Kingdom, (4)Department of Biostatistics & Health Informatics, Institute of Psychiatry, Psychology & Neuroscience, London, London, United Kingdom, (5)Department of Psychology, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, UNITED KINGDOM

Background: Extended relatives (e.g., grandparents, uncles, aunts, and cousins) can be an important source of support, but also a potential stressor for parents of autistic children. In mainland China it is common to live in extended family households or share childcare responsibilities with the broader family. However, parents of autistic children may encounter stigma, even from their own relatives. To date, few quantitative studies have explored factors associated with stigma and support from extended relatives.

Objectives: We aimed to (1) develop and validate scales measuring stigma and support from extended relatives; (2) describe the levels of stigma and support as perceived by parents; and (3) identify factors linked to stigma and support from extended relatives.

Methods: A total of 233 Chinese parents (87% mothers) of autistic children (mean age = 6.72yrs, SD = 2.43) completed an anonymous Qualtrics survey. Parents provided demographic information about their autistic child, themselves, and their family. Four scales were developed and validated to assess extended relatives' i) stigma against the autistic child; ii) stigma against the parent; iii) frequency and iv) helpfulness of emotional, financial, informational, and instrumental support provided by extended relatives. Using stepwise hierarchical linear regression with 1) child-related factors, 2) parent- and family-related factors, 3) stigma against parents, and 4) stigma against the autistic child as predictors, we examined the relationships among demographic factors, stigma, and support from extended relatives.

Results: Table 1 shows the demographic information; 40% of parents reported they lived with extended relatives; 55% of parents reported their child has daily contact with extended relatives. Figure 1 shows the frequency and helpfulness of support provided by extended relatives. Around 50% of parents indicated receiving instrumental or emotional support at least a few times a month; around 43% found that support at least "generally helpful". Confirmatory factor analyses indicated all four scales were unidimensional, showed good internal consistency and convergent validity. Parents living with extended relatives were more likely to receive more frequent ($p<0.05$) and more helpful support ($p<0.05$). Hierarchical regression models revealed that stigma against the autistic child was significantly associated with lower frequency ($p<0.05$), and reduced perceived helpfulness ($p<0.05$) of extended relatives' support, even when controlling for whether the family and their extended relatives live together. Stigma against parents was associated with support helpfulness ($p<0.05$), but this effect became non-significant after stigma against the autistic child was included in the model. Lower family income significantly predicted stigma experienced by parents ($p<0.05$).

Conclusions: Chinese autistic children have frequent interactions with their extended relatives, with 40% living in extended family households. Extended relatives are a common source of support and their support is considered helpful by many parents. Regardless of whether family members live together, stigmatising attitudes from extended relatives are a factor influencing their support behaviours and whether their support is considered helpful by parents. Future research and practice should recognise the critical role played by extended relatives in caring for autistic children, and focus on addressing stigma within the family network, especially in families experiencing poverty.

427.038 Perspectives and Experiences of Arab Caregivers of Nonvocal Children with ASD and IDD Who Engage in Challenging Behavior

M. Al-Dubayan and G. Yakubova, Counseling, Higher Education, and Special Education, University of Maryland, College Park, MD

Background: Although there has been a rise in the prevalence of both autism spectrum disorder (ASD) and intellectual and developmental disabilities (IDD), especially in families from culturally and linguistically diverse (CLD) backgrounds, these families tend to encounter challenges in obtaining necessary information, assistance, and resources, as well as in navigating healthcare and educational systems. Moreover, with increased levels of challenging behavior among nonvocal and minimally vocal children with ASD/IDD, this is a critically under-researched topic in the field. Therefore, we need more research capturing the unique challenges and perspectives of CLD caregivers of these children, especially caregivers from Arab backgrounds. This study aimed to address this gap by focusing on the unique perspectives and experiences of Arab caregivers.

Objectives: The objective of this study was to qualitatively investigate the perspectives and experiences of caregivers from Arab backgrounds, living in the US, of children with ASD/IDD who are minimally vocal/nonvocal and engage in challenging behavior. Of particular significance was the importance of culturally adapted interventions and coaching for such families.

Methods: This study used semi-structured, in-depth interviews to gather qualitative data from parents of nonvocal and minimally vocal children and adolescents with ASD who live in the U.S. Participants were recruited through network-based snowball sampling using electronically distributed flyers via social media, listservs, and parent advocacy organizations. All interviews were conducted and recorded virtually using Zoom. Afterward, interviews were transcribed and an inductive thematic analysis was applied to the transcripts to identify key themes.

Results: Preliminary findings suggest that Arab caregivers continue to face challenges when supporting their nonvocal or minimally vocal children with ASD. Some common issues include lack of awareness about services available to their children and limited access to workshops or coaching opportunities related to home-based interventions. Some parents expressed the inability to effectively communicate with teachers and administration regarding the service options available to their child both at school and outside of school or about certain cultural norms and expectations that schools may have a hard time understanding. In turn, this makes the burden on parents to teach their children skills outside school even greater. Parents' level of involvement with their child's school or local advocacy organization(s) varied widely with some being extremely involved while others have a difficult time knowing where to start. Overall, some parents also expressed a feeling of isolation or loneliness from their community, whether it be friends and family or the more general Arab community, due to the extreme commitment they have toward their children, both mentally and physically.

Conclusions: This study begins to illustrate and highlight the varying perspectives and challenges faced by Arab caregivers of children with disabilities living in the U.S. The preliminary findings highlight the importance of effective communication and mutual understanding between schools and families to better meet the needs of the children and their families. Future research and interventions should include and take into account the unique perspectives and experiences Arab families have when examining ways to better support their children's communication and behavior needs.

427.039 Pilot Study of an Empirically-Derived Training Program to Enhance Professors' Support for Neurodivergent College Students

S. M. Zeedyk¹ and Y. Bolourian², (1)Child and Adolescent Development, California State University, Fullerton, Fullerton, CA, (2)UCLA Tarjan Center, Los Angeles, CA

Background: Neurodivergent adults are increasingly attending college, yet their likelihood of completing degrees remains lower than their neurotypical peers (Elias & White, 2018). Despite the value of existing programs for neurodivergent students, few initiatives target the professors who teach and accommodate them daily. There is a need for increased educational supports for this population and the professors who teach them (Zeedyk et al., 2019).

We developed a faculty training program, *NeuroPREP*, designed to improve knowledge, applied strategies, and accessibility of resources to enhance experiences and outcomes for neurodivergent college students through neurodiversity-affirming practices. The program was developed in partnership with an Advisory Committee of faculty, neurodivergent students, and disability support staff, whose feedback ensured its relevance and effectiveness (Bolourian et al., 2024).

Objectives: This pilot study aimed to evaluate changes in attitudes, awareness, and knowledge about neurodiversity among university faculty and assessed the socially validity of *NeuroPREP*. Specifically, we sought to explore how neurodiversity-affirming training could facilitate support of neurodivergent college students.

Methods: Participants included faculty and staff ($n=63$; $M_{age}=46.2$, $SD=11.72$) at a four-year university, who were predominantly female (79.4%) and White (42.9%), with 25.4% identifying as Hispanic/Latine.

Participants were given four weeks to complete four asynchronous modules, each including a 20-minute video, handout/exercises, resources, and learning check. The training focused on neurodiversity-affirming strategies, such as recognizing and valuing neurodivergent strengths, implementing inclusive teaching practices, and fostering supportive environments. Data were collected via pre- and post-training surveys assessing neurodiversity knowledge, awareness, and attitudes. At post-training, we also assessed learning satisfaction and perceived impact.

Results: Results revealed significant improvements in knowledge, attitudes, and acceptance from pre- to post-training. For example, correct identification of ADHD characteristics increased from 70.5% to 88.5%, $p<.01$. Participants reported significantly greater comfort in having autistic students in their classroom (45.0% to 77.5%, $p<.01$), and working one-on-one with autistic students (54.0% to 74.0%, $p<.05$). Similar significant improvements were noted for ADHD students. Confidence in teaching autistic ($t(51)=-8.10$, $p<.001$) and ADHD students ($t(51)=-8.97$, $p<.001$) significantly increased, as did understanding of disability support services ($t(58)=-3.40$, $p<.001$).

Participants rated the training highly on seven indicators of learning satisfaction (e.g., "I would recommend this training to faculty members on my campus."), with 76.2% to 95.2% participants either selecting "Agree" or "Strongly agree" on each indicator. Participants also rated the training highly on nine indicators of perceived impact (e.g., "The training has improved my understanding of the unique strengths of neurodivergent college students."), with 78.4% to 93.7% participants either selecting "Agree" or "Strongly agree" on each indicator. The training's perceived impact extended beyond classroom teaching, as 87.3% agreed it would be useful in interactions with students outside the classroom. Qualitative analysis of open-ended responses (e.g., "In your own words, how would you define "neurodiversity?") is underway.

Conclusions: *NeuroPREP* effectively improved university faculty and staff's knowledge, attitudes, and confidence in working with neurodivergent students. Participants rated the training highly, highlighting its value in fostering more inclusive and supportive environments for neurodivergent students.

427.040 Policy Analysis on the Parents and Self Advocacy for Autistic Individuals/Families Access to Federal Funds for Community Based Services, Independent Living, Caregiver Respite.*R. P. Gaines, School of Public Policy, University of Maryland, College Park, MD*

Background: The autism community and general population are not adequately informed on policies that give autistic individuals/families access to federal funds for community-based services, independent living, or caregiver respite. It is imperative to understand these policies, their effects, changes that need to be implemented, and the methodology that can be utilized to implement these changes.

Objectives: Carry out a systematic literature review (using academic, policy, and practice sources) on: Policy advocacy in relation to resource accessibility to people on the autism spectrum and autism-oriented families. (Aim 1) Informing families of policies giving access to federal funds for community-based services, independent living, caregiver respite, etc. This includes exploring information on policies related to autism/family so they know how to advocate for themselves and seek/access services. (Aim 2) Explore relevant policies analyzing the effects of not engaging with said policies on long-term outcomes. (Aim 3) Understand what communities are involved in policy advocacy and the steps needed for change.

Methods: We will collect data and gather research related to autism/family policies and policies giving access to resources like disability advocacy, federal funds, community-based services, independent living, caregiver respite, etc. We will then carry out a systematic literature review (using academic, policy, and practice sources) on tools like PsycINFO, PubMed, etc. This will allow for an analysis of policy advocacy in relation to resource accessibility to people on the autism spectrum and autism-oriented families. We will run a quantitative regression analysis of policy expenditures, including a secondary comparative analysis of long-term outcomes through an application like ANOVA with and without access to monetary funds and policies. This data will then be compiled into a visual analysis of the information gathered.

Results: While the results of my data have not been fully collected, my preliminary data analysis is based on a study done for INSAR by Julie Lounds Taylor, Leann Smith DaWalt, Meghan M. Burke, James C. Slaughter, Meng Xu called: "Improving parents' ability to advocate for services for youth with autism." In this study: "parent advocacy abilities were collected at baseline (before randomization) and post-test (immediately after the treatment group finished the 12-week program) by survey. After taking ASSIST, the treatment condition had greater gains than controls in knowledge of adult services ($B = -1.62$, $CI = -2.33$ to -0.90) and perceived advocacy skills ($B = -0.19$, $CI = -0.33$ to -0.04)" (Taylor, August 8th, 2023).

Conclusions: I have no results; however, said results may be similar to those found in a case from the UK. In the case of the UK, the results show four main takeaways. Partnerships with autistic people, alongside caregivers and stakeholders, throughout the engagement, involvement, and co-production processes improve development. Second, it is important to assess intervention practices and their alignment with a neurodiversity framework and the views of autistic people. Finally, greater regard within intervention programs leads to improved efforts to develop and validate tools to measure autistic prioritized outcomes and the goodness-of-fit between an autistic individual and their environment (Aldred, el. 2004).

427.041 "I See My Child in a New Light": Mindful Self-Compassion for Caregivers of Autistic Children

I. Bharadwaj¹, V. Parnell² and G. Iarocci³, (1)simon fraser university, Burnaby, BC, Canada, (2)Simon Fraser University, Burnaby, BC, Canada, (3)Psychology, Simon Fraser University, Burnaby, BC, Canada

Background: Our study evaluates a digital Mindful Self-Compassion (MSC) intervention for caregivers of autistic children in British Columbia, Canada. In collaboration with community partners, this Zoom-based group program was developed early in the COVID-19 pandemic in response to an urgent need for family-centred, remote interventions. Caregivers often experience high stress, feelings of isolation, and increased financial strain due to additional demands of raising an autistic child, and these challenges were exacerbated by pandemic-related stress (Fong et al., 2020). MSC-based interventions can enhance parental well-being, build caregivers' coping strategies and reduce depressive symptoms (Ruiz-Robledillo et al., 2015; Ahmed & Raj, 2023). Increased parental mindfulness can also benefit children, as parents learn to be responsive rather than reactive in everyday interactions (Kil et al., 2021), reducing their child's emotional distress and efficiently managing challenging behaviour (Siegel, 2007; Siegel & Hartzell, 2013). However, traditional autism interventions primarily target children, and there is a dearth of family-centered interventions despite clear research support for these approaches (Ooi et al., 2016; Gardiner et al., 2020).

Objectives: To investigate the effectiveness of a Mindful Self-Compassion-based intervention for caregivers of Autistic children.

Methods: This mixed-methods study involved forty caregivers ($M_{age}=42.82$, $SD=6.7$; 2 fathers, 1 foster mother) of autistic children ($M_{age}=10.17$, $SD=4.4$). Caregivers participated in one of four offerings of the eleven-week online MSC program between 2021 and 2024. Pre-post quantitative measures assessed the program's impact on parental outcomes, including stress, anxiety and depression, self-compassion, mindfulness, parenting sense of competence, and family quality of life (FQOL). Qualitative surveys explored changes in the parent-child relationship and the perceived benefits of this intervention.

Results: Preliminary analyses through paired samples t-tests on outcome measures revealed significant improvements across all measures except anxiety. Cohen's D effect sizes showed large effects for Mindfulness ($d = 1.04$), Self-Compassion ($d = 0.77$), Parenting Sense of Competence ($d = 0.87$) and Quality of Life ($d = 0.56$) and moderate effects for Depression ($d = -0.61$) and Stress ($d = -0.73$). Preliminary thematic analysis of qualitative survey results showed that participants experienced multiple benefits from this program in addition to learning important mindfulness and self-compassion skills. The following themes were identified: "I learned how to care for myself," "I feel less alone," and "I am a better parent to my child."

Conclusions: Caregivers experienced significant improvements across mindfulness, self-compassion, family quality of life, parenting sense of competence and psychiatric symptoms. Participants also experienced an enhanced sense of community and learned valuable self-care strategies. This program impacted the entire family unit through increased FQOL, with parents reporting improved relationships with their children. The MSC intervention addresses the critical need for research that enhances the lives of autistic individuals and their families, responding to their calls for holistic, neurodiversity-affirming support that enhances family acceptance of autistic individuals. Our study also highlights the need for further research of both MSC-based supports and interventions that support family well-being.

**427.042** Preferences of Spanish-Speaking Individuals from Northern Argentina When Referring to Autism

C. Ruiz-Danegger^a, A. Lambare^a and M. Fernández Miranda^a, (1)Cerebra (Autism Reference Center) / El Pez Volador, Salta capital, Argentina, (2)National University of Jujuy, San Salvador de Jujuy, Jujuy, Argentina

Background: There are numerous studies worldwide exploring the language used to refer to autism, as this can reveal implicit epistemologies related to prevailing paradigms. While there is a substantial body of research conducted primarily in English and French, Spanish-language studies are less common. In Spanish, the terms "autista" (autistic) and "autismo" (autism) are still sometimes used in media and social networks as insults, discriminatory terms, or part of ableist practices. Conversely, within the autistic community, often under the neurodiversity paradigm, there are reflective movements aimed at changing assumptions, practices, and the language associated with these concepts. Given the territorial, historical, and sociocultural diversity within Argentina, we focused on the NOA region, corresponding to the northern Andean region. Our perspective in engaging in this research is the interest in this topic within inclusive education, as the epistemology implied in the preferred terms for talking about autism involves positions and cuts that are related to educational assumptions and practices.

Objectives: To understand the preferences of speakers from northern Andean Argentina regarding terms used to refer to autism. To analyze similarities and differences compared to the results of similar studies conducted in other regions and linguistic contexts.

Methods: This is a "mixed method" study - commonly understood in the context of autism studies as the coordinated use of qualitative and quantitative strategies. Data was collected online using ad hoc forms. Participants were given options to express their preference for various terms, indicating one, all, or none of the options. Some examples of items were: "Autistic person or person with autism?", "Child with ASD, child with autism, or autistic child?". The qualitative inquiry aimed to understand the semantic fields assigned by speakers to preferred or non-preferred terms, in the words of the participants.

Results: The results of the research in the context of Spanish spoken in northern Argentina generally do not agree with the trends found among English and French speakers in various countries. The results so far indicate a preference for person-first language (person with autism), and to a lesser extent identity-first (autistic person), which is found to a greater extent in other regions or linguistic contexts. Additionally, there is still a preference for forms that associate autism with forms of disorder (ASD) or forms that include a reference to the autism spectrum (ASD or ASC).

Conclusions: This work is in the process of data collection and analysis. It can be advanced that, although it is found that activist movements seem to be emerging and there are some samples of their expression in the studied context, the preferred forms of expression centered on aspects of autistic identity or its valuation from neurodiversity or neuro-affirmation perspectives do not show the consensus that studies find in other regions or linguistic contexts. This could be due to a lack of knowledge of these relatively new points of view, at a general level, in our region, and especially among non-autistic people, the phenomenon known in Argentina as "centralismo porteño" (Buenos Aires-centrism) could also influence.

427.043 Priority of Autism Research, Services, and Public Education Among Autism Community Stakeholders in Hong Kong

G. Y. H. Lam and **W. Chan**, *Department of Educational Psychology, The Chinese University of Hong Kong, Shatin, NT, Hong Kong*

Background:

Development of autism research and services have traditionally been directed by academicians and policymakers. There needs to be greater involvement of community members in research to set priorities that can directly impact their lives. However, existing priority setting exercises have been conducted only in Western countries, leaving the voices from non-Western societies unheard.

Objectives:

To understand the needs and priorities in autism research, services, and public education among autism community stakeholders in Hong Kong

Methods:

Participants included 31 autism community stakeholders locally recruited in Hong Kong representing three groups: 13 autistic adults, 12 parents of autistic individuals, and 6 professionals with experience working with autistic individuals. We held 3 in-person and 4 online groups, followed by two surveys. The group processes were focused on answering three questions: What do you wish for the future development of Hong Kong autism (1) public education, (2) research, and (3) services or support? Nominal Group Technique (for question 1) and Modified Delphi Method (for questions 2 and 3) were used to guide the discussion and consensus processes, which involved brainstorming and discussing ideas, synthesizing common themes, and individual voting and ranking. Two rounds of survey received 31 (100% response rate) and 28 (90%) valid responses, respectively.

Results:

Among the top-rank themes of public education, autistic adults hoped others understand their different needs and strengths. They also wanted the mainstream society to critically reflect and create an autism-friendly environment, so they can be accepted rather than normalized. Parents sought for others' understanding of autistic individuals' special needs, while not stigmatizing autistic differences. Parents also desired the public to forgive autistic behaviors and know how to appropriately interact with them. Professionals noted the wide spectrum of autistic individuals, but were more focused on the role of adequate support and education that can help autistic individuals thrive. They also stressed that the public needs to understand how autistic brain processes information and their sensory needs.

Summary of top 5 rankings of research and service themes can be found in Tables 1 and 2. Among the top priorities of research themes and service themes, more parents endorsed research about autistic behavioral and psychological presentations and services about providing trainings to autistic individuals to improve their social and adaptive skills, reflecting parents' desire to seek the right strategies to deal with autistic symptoms and behaviors. More autistic adults and professionals prioritized research reflecting autistic perspectives or strengths and advocated for increasing public understanding towards autism, reflecting more neurodiversity-affirming perspectives. Adult research was ranked by all stakeholder groups as important. Autistic adults desired more involvement in service development.

Conclusions:

This is the first priority setting exercise focusing on autism in Asia region. Despite the small sample size, anecdotal feedback from participants praised the meaningful research engagement in determining directions for future development of autism. Findings can directly inform priorities in autism research and policies. Differences across groups can also inform public education campaigns to target the narratives and beliefs of specific subgroups.

427.044 Professional Development Training in Inclusive Practices for Staff in Informal STEM Learning Settings

N. L. Matthews¹, **H. Honda¹**, **K. Schimmel¹**, **M. Mann¹**, **A. Boglio²**, **J. Koke²**, **M. Verbeke²**, **J. Babendure³** and **C. J. Smith⁴**, (1)Southwest Autism Research and Resource Center, Phoenix, AZ, (2)Institute for Learning Innovation, Beaverton, OR, (3)SciTech Institute, Tempe, AZ, (4)Southwest Autism Research & Resource Center, Phoenix, AZ

Background:

Informal learning settings like museums and science centers are associated with higher engagement for learners, even when topics are challenging or less preferred (Bell et al., 2009). However, autistic learners and their families report that some aspects of museum visits can be stressful and overwhelming (Fortuna et al., 2024), which may result in reduced inclusion, engagement, and impact (Matthews et al., in press). Research is needed to develop and implement inclusive practices in informal learning settings to increase inclusion and accessibility for autistic learners.

Objectives:

To examine feasibility of a professional development (PD) training in inclusive practices for museum staff.

Methods:

An existing training and consultation program in inclusive practices was adapted based on stakeholder feedback and delivered to 79 staff members at four STEM-related museums in the Greater Phoenix area (see Table 1). Each museum designated a core team of 4 to 5 administrative leaders ($n = 19$) to work closely with the consultant conducting the professional development (PD) training. Members of each core team completed an inclusion checklist (adapted from Kids Included Together Checklist for Inclusive Programs) to provide insight into the state of the respective museum's inclusive practices before the PD training. This information was used to tailor the training to staff at each museum. Core team members ($n = 15$) also completed the checklist after staff training was complete.

Staff at each museum, which included an additional 51 forward-facing staff (18 front desk employees, 28 educators, and 5 volunteers), attended a didactic presentation that included an introduction to autism and inclusion. Then, two Board Certified Behavioral Analysts used Behavioral Skills Training (BST) to teach seven core competencies (Composure; Connection; Engagement; Inclusive Language; Accommodations and Accessibility; Active Listening, and Visual Supports) to forward-facing staff. Each staff member practiced the respective competency until fidelity of implementation (FOI) was achieved (mastery criterion = 80% or greater) across a minimum of three interactions. Additionally, up to four probes were collected across the study (baseline, two time points during training, and training exit) to measure FOI of inclusive practices (pre- and post-training probes were completed for $n = 44$).

Results:

Reported in Table 2, there was a significant increase from baseline to post-training in ratings on the inclusion checklist by core team members (Wilcoxon Signed Rank Test $z = 3.11$, $p = .002$). There was also a significant increase in fidelity of implementation of inclusive practices (Wilcoxon Signed Rank Test $z = 5.91$, $p < .001$). FOI mastery criterion of 80% or greater was achieved by 98% of participants with pre- and post-training probes.

Conclusions:

This study represents the first phase of larger project that aims to build capacity for improved inclusion and accessibility in informal STEM learning settings. Findings demonstrate feasibility of an individualized PD training for forward-facing staff. The second phase of this work is underway and will adapt the training to increase scalability. We will also examine autistic learners' perceptions of inclusion and accessibility during visits to museums whose staff engaged in the PD training.

427.045 Psychosocial and Financial Burden and Coping of Families of Children with Autism Spectrum Disorder - Indian Experience

B. Koshy^a, S. Beryl^b, K. Sathish^c and J. Prasad^d, (1)Developmental Paediatrics, Christian Medical College, Vellore, INDIA, (2)Developmental Paediatrics, Christian Medical College, Vellore, Tamil Nadu, India, (3)Community Health, Christian Medical College, Vellore, Tamil Nadu, India

Background:

Autism spectrum disorder (ASD) is a complex neurodevelopmental disorder and can have significant psychosocial and financial impact on families. There is a dearth of evidence from India on these impacts and associated coping mechanisms.

Objectives:

Objectives were to assess the psychosocial burden of families with children with ASD, the out-of-pocket (OOP) expenditure towards support and the different coping mechanisms for psychosocial and financial burdens.

Methods:

This prospective study was conducted in a tertiary hospital in India between August 2020 and December 2021. Children aged 2-18 years of age with a prior diagnosis of ASD of at least 6 months were included and those with neuro-metabolic or neuro-progressive conditions excluded. Semi-structured questionnaires on sociodemographic and financial analysis were administered along with the Family Burden Interview Schedule. Financial burden was assessed by calculating medical, non-medical and indirect costs.

Results:

The study enrolled 115 children with a median age of 4 years, 83.5% males. Socio-economic status evaluation showed that 31.3% families were in the lower middle-income group, 13.9% in the upper lower, 46.1% in upper middle and 8.7% in the upper income strata groups (by modified Kuppuswamy scale). Majority of the parents in our study were graduates which included 89 (77.4%) mothers and 77 (67%) fathers. The median monthly family income was 40,000 INR. Severe autism was seen in 55% of our children as evaluated by Childhood Autism Rating Scale -Second edition.

Evaluating family burden pattern, subjective burden was reported by 95.7% of families. The highest burden was noted in the mental health domain (49.5%), followed by physical health (41.8%). Problem-focused coping methods (43%) were most noted followed by finding comfort in religion (28%).

Median total costs for autism support for the last 6 months were 63745 INR (range 5550 – 9,34,395) and were out-of-pocket (OOP). Median total direct costs were 43745 and indirect costs 20000. Though 13.9% families had insurance, no ASD support services were covered. A multivariate logistic regression model showed that severity of autism and co-morbidities were associated with moderate to severe financial burden. Predominant financial coping mechanisms included using monthly salary (85.2%) and savings (64.3%).

Conclusions:

There is high psychosocial and financial burden for families of children with ASD, with predominant OOP expenditure. Problem-solving coping was utilized, with a financial coping strategy of drawing from savings. These results highlight the need to develop further psychosocial and financial support for these families.

427.046 "I Want to be a Voice for Not Only Myself, but Also the Autistic Community": Experiences of Autistic Community Partners in Post-Secondary Education Autism Research in Canada

M. Pabia¹, **H. M. Brown**², **C. Hack**³, **E. Coombs**⁴, **C. Bendavis**⁵, **C. Devlin**⁶, **A. Crerar**⁷, **T. Ksiazek**⁸, **P. Dwyer**⁹, **J. Ryan**⁹, **N. Pogue**¹⁰, **M. Janse van Rensburg**¹¹, **L. Ripley**¹, **H. Santilli**², **I. Weigel-Mohamed**¹, **H. Ma**¹, **A. Wang**¹, **H. Nelson**³, **B. Di Rezze**¹², **D. B. Nicholas**¹³, **T. Connolly**¹¹ and **S. Thompson-Hodgetts**¹⁴, (1)University of Alberta, Edmonton, AB, Canada, (2)Educational Psychology, University of Alberta, Edmonton, AB, Canada, (3)University of Calgary, Calgary, AB, Canada, (4)Counselling Psychology, University of Alberta, Calgary, AB, Canada, (5)First Nations Technical Institute, Elphin, ON, Canada, (6)Ryerson University, London, ON, Canada, (7)Alberta Health Services, Edmonton, AB, Canada, (8)Olga Tennison Autism Research Centre, La Trobe University - OTARC, Melbourne, VIC, Australia, (9)Rehabilitation Medicine, University of Alberta, Edmonton, AB, Canada, (10)Vancouver Island University, Nanaimo, BC, Canada, (11)Carleton University, Ottawa, ON, Canada, (12)McMaster University, Hamilton, ON, Canada, (13)University of Calgary, Edmonton, AB, Canada, (14)Occupational Therapy, University of Alberta, Edmonton, AB, Canada

Background: Autistic advocates have long called for more equitable partnerships and greater decision-making power in autism research, which has traditionally prioritized the perspectives of allistic researchers, clinicians, and caregivers with neuronormative agendas.¹ With recent shifts towards a neuro-affirming paradigm, there is growing implementation of Autistic advisory boards and participatory research methods in recognition of the harm past research has done to Autistic people.² The Campus Belonging Network (CBN) employs a participatory approach to explore the experiences of Autistic post-secondary (PS) students in Canada.³ This approach emphasizes inclusivity, transparency, and a focus on enhancing the quality of life, as defined by Autistic individuals.⁴ To further amplify Autistic perspectives, particularly those most marginalized within our community, reflexivity on the experiences of Autistic people as researchers is critical amongst a history of research-based violence.⁵ Seligman's **PERMA** model of well-being—Positive Emotions, Engagement, Relationships, Meaning, and Accomplishment⁶—provided a lens to evaluate the impacts of serving as an Autistic Community Partner (ACP) within the CBN.

Objectives: To explore the perspectives of ACPs on the impact of their involvement in an Autistic-led research project focused on fostering belonging for Autistic PS students in Canada.

Methods: ACP members were recruited through social media and the project team's networks. Eligibility criteria included being Autistic, aged 18+, a Canadian citizen or Permanent Resident, current or former PS student, and being available to complete required tasks, meetings, and training. Pre/post survey questions collected information on what the ACP members predicted they would gain, and ultimately gained from participating in the CBN. A hybrid analytical approach was used. Data were analyzed using a deductive codebook approach; responses were divided into thought units and categorized according to one or more **PERMA** pillars. Then, data were inductively coded into sub-themes within each pillar using a six-step thematic analysis process.⁷

Results: Four applicants (aged 27 to 46) who represented diverse backgrounds, including Indigenous and queer communities, were selected as ACP members. Aligned with the **PERMA** model, they reported enhanced well-being through participation with the ACP, noting Positive emotions such as passion, gratitude, and enjoyment. Deep Engagement emerged from 1) a psychologically safe environment and 2) active research participation. They valued the sense of community (Relationships) as 1) a safe space to be authentically Autistic and 2) to connect with like-minded peers. ACPs felt a sense of Meaning because 1) they believed they were making a difference, deepening their conviction that Autistic-led autism research is vital, and 2) felt they could now envision new directions for their future. They also experienced overlapping Accomplishment and Meaning through 1) empowerment to create positive change, 2) accessing typically excluded spaces, and 3) developing new research skills. Relationships also contributed to a sense of Accomplishment by 1) expanding their neuro-affirming perspectives and 2) by growing their social network, which led to new opportunities.

Conclusions: ACP involvement benefited participants' well-being, where amplifying Autistic perspectives within our project empowered ACPs personally and professionally as they collaborated on research on Autistic PS students' belonging.

**427.047** "Diagnosis As an Instrument": The Lived Experiences of Autistic Adolescents in Taiwan

C. H. Liu^{1,2}, **W. C. Lin**³ and **M. C. Lai**⁴, (1)Department of Psychiatry, Chang Gung Memorial Hospital at Linkou, Taoyuan city, Taiwan, Canada, (2)Institute of Medical Science, University of Toronto, Toronto, ON, Canada, (3)Graduate Institute of Behavioral Science, Chang Gung University, Taoyuan city, Taiwan, Taiwan, (4)Campbell Family Mental Health Research Institute, Centre for Addiction and Mental Health, Toronto, ON, Canada

Background: Autistic people tend to experience longstanding difficulties navigating the social world. In Taiwan, most autistic people receive their autism diagnoses in childhood or adolescence. However, little is known about what an autism diagnosis means to Taiwanese autistic adolescents themselves and how the diagnosis influences their social navigation.

Objectives: To explore the experiences of Taiwanese autistic adolescents receiving autism diagnoses, and how the diagnoses affect their life and social navigation.

Methods: We enrolled 8 autistic adolescents aged 14-18 years (3 assigned-male-at-birth and 5 assigned-female-at-birth; Table 1), who received their autism diagnoses between the ages of 8 and 18 (0-7 years prior to the interview). In-depth individual interviews were conducted using an interview guide (Table 2). All interviews (average duration 43 minutes) were audio-recorded, transcribed verbatim, and analyzed by thematic analysis. Initial codes were generated from the data according to their explicit and implicit meanings. Categories were generated from codes with similar meanings, and related categories were integrated into themes. Data collection and analysis occurred concurrently, while new participants were enrolled until saturation was reached.

Results: We identified four themes across participants. The autistic adolescents in Taiwan identified their autism diagnoses serve the roles of: (a) explaining their past life experiences, with both positive and negative stereotypes; (b) understanding own behaviors and providing a framework for modifying own behaviors; (c) articulating their difficulties and facilitating their family members' and peers' understanding of them; and (d) negotiating with the regulations of the Taiwanese educational system to meet their needs. These Taiwanese autistic adolescents were already aware, to varying degrees, of their differences from others before receiving a formal autism diagnosis. Receiving the autism diagnosis provided explanations for previously unarticulated feelings of social unalignments. While the autism diagnosis carried risks to experiencing stigma and reinforcing stereotypes, it could in fact reduce stigma and highlight positive traits. With the diagnosis as a label, autistic adolescents found a keyword for searching information, understanding themselves, recognizing their differences from others, and modifying their social behavior to mask their difference. The diagnosis also served as a gateway to the autistic community, enabling autistic adolescents to connect with peers and access a shared language to describe their difficulties, facilitate greater understanding and acceptance. The diagnosis may be used by autistic adolescents to negotiate with the Taiwanese education system (which can be inflexible with strict regulations) for their needs to be met. Some adolescents received autism diagnoses through referral from the education system to the medical system initially, and the confirmed diagnosis in turn increased (both superficially and actually) the flexibility of the educational system to accommodate their differences.

Conclusions: Our findings highlight the instrumentality of an autism diagnosis in Taiwan, and how autistic adolescents make use of their diagnosis to understand themselves and to interact with their environments.

427.048 Quality of Life of Parents of Children on the Autism Spectrum: A Cross-Country Comparison

R. Aishworiya^{1,2}, S. Erdembileg^{3,4}, N. Kamal Nor⁵, S. Liang⁶, W. W. Yang⁷ and Y. Q. Kang^{1,2}. (1)Paediatrics, National University Hospital, Singapore, Singapore, (2)Paediatrics, National University of Singapore, Singapore, Singapore, Singapore, (3)National University Hospital, Singapore, Singapore, Singapore, (4)Centre for Holistic Initiatives for Learning and Development (CHILD), National University of Singapore, Singapore, Singapore, Singapore, (5)Paediatrics, Universiti Kebangsaan Malaysia Specialist Children's Hospital, Petaling Jaya, Selangor, Malaysia, (6)National University of Singapore, Singapore, Singapore, Singapore, (7)Faculty of Medicine, Universiti Kebangsaan Malaysia, Kuala Lumpur, Federal Territories, Malaysia

Background: Parents of children on the autism spectrum often face unique challenges that can impact their quality of life (QoL). Cross-cultural differences and nation-specific health systems may influence how parents experience these challenges. Singapore and Malaysia are neighboring countries that have similar multicultural populations but with distinct healthcare systems that may influence QoL.

Objectives: To examine and compare the QoL of parents of children on the autism spectrum in Singapore and Malaysia and factors associated with them.

Methods: Cross-sectional studies were conducted in each country's tertiary developmental pediatric clinics, each with a study sample of children diagnosed with autism based on DSM-5 criteria. Parents completed the Quality of life in Autism Questionnaire (QoLA), which contains 2 sub-scales: Part A measures parental self-rated QoL (score range 28-140, higher scores denote greater perceived QoL); Part B measures perceived problems due to child's autism-related behaviors (score range 20-100, higher scores denote fewer perceived problems). Parents also completed a demographic questionnaire and provided information on co-occurring conditions and medication use. Independent T test was used to compare the total QoLA scores, while Chi-square test was used to compare the individual questions. General Linear Model was used to identify differences in QoLA responses and factors associated with QoLA by testing the interaction effects between country and the factors of interest. When significant interaction was detected, a subgroup analysis by country was conducted.

Results: The sample comprised of 300 parents ([N=134 from Singapore, child mean age: 6.1 years, 79.8% male] and [N=166 from Malaysia, child mean age: 7.68 years, 81.3% male]). Total QoLA scores were high in both countries with no significant difference between the them (103 vs 101.63 for Part A, $p = .156$ and 70.08 vs 69.77 for Part B, $p = .887$ respectively). For QoLA Part A scores, parents from Singapore reported higher scores in life satisfaction, financial stability, and safety while parents from Malaysia reported higher stress and feelings of guilt but better scores for adopting a healthy lifestyle and perceived better community support (Table 1). For QoLA Part B scores, parents from Singapore perceived less difficulties with their child's ability to socialize, and in managing their anger while parents from Malaysia perceived fewer challenges with their child's obsessive interests, inappropriate emotional reactions, repetitive behaviors, ability to understand other's feelings and the child's actions being seen as embarrassing (Table 2). Subgroup analysis showed that QoLA part A score was higher in Malaysia for parents who were from a non-low-income family ($p = 0.075$), were married ($p = 0.009$), and when either the father or mother had tertiary education ($p = 0.064$; $p = 0.036$). However, in Singapore none of the study factors was significantly associated with QoLA part A score.

Conclusions: Parents from both countries had similar overall QoL scores although differences were present in specific aspects of QoL and factors associated with QoL. These can inform targeted interventions to improve QoL. Further research should focus on the role of healthcare structures impacting QoL while remaining culturally sensitive.

427.049 Racial-Ethnic Differences in Prolonged Autism Diagnosis Process & Diagnoses Received Prior to Autism in 23 States
V. I. Underwood Carrasco^{1,2}, **C. Charlesworth**³, **K. Watson**³, **O. J. Lindly**⁴, **J. McConnell**¹ and **K. Zuckerman**¹, (1)Division of General Pediatrics, Oregon Health & Science University, Portland, OR, (2)OHSU-PSU School of Public Health, Portland, OR, (3)Oregon Health & Science University, Portland, OR, (4)Health Sciences, Northern Arizona University, Health Sciences Department, Flagstaff, AZ

Background: Autism spectrum disorder (herein: autism) symptoms are known to overlap with other developmental conditions, leading to diagnostic delays. Prior research showed that children from minoritized racial and ethnic backgrounds experienced high rates of diagnostic delays and acquired other developmental diagnoses before their autism diagnosis. Even so, these diagnostic trends and disparities have not been recently investigated as racial and ethnic disparities in autism prevalence decrease.

Objectives: Replicate previous assessment of prolonged autism diagnosis process and diagnoses received before autism, in a national dataset of children with Medicaid/CHIP insurance.

Methods: Using Transformed Medicaid Statistical Information System Analytic Files (TAF) from 23 states with sufficient claims volume and complete data, we conducted a retrospective cohort analysis of children ages 2-8 entering specialty mental healthcare (SMH) during 2017 who ultimately received an autism diagnosis within 2 years. We assessed prolonged diagnosis process (PDP), defined as >90 days between initial SMH entry and subsequent autism diagnosis to account for the multiple visits often needed to diagnose younger children. Unadjusted and adjusted (by sex and age; further, by rurality and state) Ordinary Least Squares Regression models were used to assess racial and ethnic differences of children with PDP. Among those with PDP, mental health diagnoses received in SMH before an autism diagnosis were also evaluated and modeled by race and ethnicity.

Results: Of 21,782 children with an autism diagnosis in our sample, 4,585 (21.2%) had a PDP. In contrast with previous research, PDP was most common among white children (22.8%) and least common among Asian children (15.1%). In adjusted models, Asian and American Indian/Alaska Native (AI/AN) children were significantly less likely than white children to have PDP (Figure 1). Though there was substantial variation in PDP by state (14% to 31%), there were no notable differences in effect estimates after adjusting models for age, sex, or residence rurality. Among children who experienced a PDP, ADHD was the overall most commonly received diagnosis prior to autism (38.6%), followed by speech and language disorders (21.0%), and the non-specific “other neurodevelopmental disorders” diagnosis (20.4%). Similar to prior research, frequency of prior diagnoses received prior to an eventual autism diagnosis varied by race and ethnicity (Figure 2). Even in adjusted models, there were significant racial and ethnic disparities for prior diagnoses acquired. For example, AI/AN children were significantly more likely, while Hispanic and Asian children were significantly less likely, to have a prior diagnosis of ADHD compared to white children.

Conclusions: More than 1/5 of Medicaid-enrolled children with autism in our sample experienced a PDP after SMH entry; however, findings suggest prior trends of increased PDP in children from minoritized racial and ethnic backgrounds have decreased or reversed. Racial and ethnic differences remain in diagnoses received prior to an autism diagnosis, particularly for ADHD, speech and language disorders, and non-specific signs of developmental delay.

427.050 Re-Negotiating the Asian American Autism Family Relationships Among Non-Autistic Adult Siblings: A Data-Driven Theoretical Model

T. P. Nguyen¹ and **K. L. Suyemoto**², (1)University of Washington, WA INCLUDE & Seattle Children's Autism Center, Seattle, WA, (2)Psychology, University of Massachusetts Boston, Boston, MA

Background: “Autism” is as much of a family experience as it is an individual one. For families of individuals on the autism spectrum, the shared familial experience of living with and adjusting to the autistic family member’s disability can have profound impact on the collective family unit, as well as the nested sub-units. For Asian American families of Confucian-ethnic heritage, the centrality of familism and the integral role of relationship-oriented family dynamics are profoundly important. Asian Americans represent one of the fastest growing populations in the United States. Yet, relatively little is known about the Asian American family relationship processes, in general—and even less among those with an autistic family member. Within the Eurocentric mainstream autism research and clinical practice, the voices and perspectives of individuals from marginalized family backgrounds, such as immigrants, lower socioeconomic status, and limited-English-speaking households, remain largely absent. This lack of diversity and inclusion is especially problematic, as any innovation made towards future autism-related interventions run the risk of imposing ethno-culturally incongruent practices. Regardless of the autism family’s sociodemographic background, non-autistic siblings are uniquely situated and can possess one of the longest lasting relationships with the autistic child-family member. For the non-autistic Asian American child-family member of immigrant parents, involvement in various aspects of the family life is common and expected.

Objectives: This qualitative grounded theory study sought answers to the research question: *How do adult individuals who have an autistic sibling within Asian American immigrant families from Confucian-ethnic heritages experience their family relationship processes over time?* Participants’ narratives informed the data-grounded theoretical model on the Asian American autism family relationship processes among non-autistic siblings from an immigrant and Confucian-ethnic family background. The emerged theoretical model was presented pictographically, alongside with select quotes to illustrate the family relationship processes and shifts across the developmental course.

Methods: Using a constructivist and critical-ideological lens as the guiding research paradigm, semi-structured interviews were conducted with twelve Asian American non-autistic adult siblings. Data collection was completed once data saturation was reached. A constant comparative data analysis approach was utilized to produce the data-grounded theoretical model. The practice of bracketing, memoing, external and internal auditing, as well as member checks were also implemented to ensure research rigor/trustworthiness.

Results: The emerged theoretical model illuminated the Asian American autism family relationship processes as dynamic and embedded within the autism and cultural contexts. The model also demonstrated the influence of the non-autistic siblings’ internal “paradigm shift” and developmental familial shifts on the ways in which these family relationship processes are re-negotiated over time.

Conclusions: Findings from this study both supported and expanded the existing, albeit scarce, published research on the Asian American autism families. The lived experiences of family relationships among non-autistic Asian American adult siblings undergo on-going processes of negotiating and adapting across their developmental course and family life cycle. Findings from this study calls for individual- and family-level support and resources that can promote positive meaning-making of the Asian American autism family relationships. Implications for future research will be further discussed.

427.051 “Creating a Socially Acceptable Version of Myself”: A Qualitative Exploration of the Female and Nonbinary Experience of Navigating the Autism Diagnostic System

I. S. Tien¹, S. M. Wolpe², K. Seers³ and A. Pearson¹, (1)UCLA, Los Angeles, CA, (2)Education: Human Development and Psychology, UCLA, Culver City, CA, (3)Charles Sturt University, Bathurst, NSW, Australia

Background: Early diagnosis for autistic youth is critical in improving quality of life. However, diagnosis is typically delayed for AFAB and gender diverse individuals, with their autism-related struggles being overlooked.

Objectives: The current study utilizes semi-structured interviews with autistic adults to explore how gender identity and socialization impacts diagnostic odysseys. As such, we examined the following research questions: 1) What are the female and nonbinary experiences with pursuing an autism diagnosis? 2) What was the experience like receiving and coping with an autism diagnosis?

Methods: Qualitative interviews were conducted with 24 autistic adults identifying as nonbinary, agender, or genderfluid (n = 14), female (n = 8), and male (n = 2). Coding used reflexive thematic analysis, informed by tenants of gender socialization roles and feminist disability model.

Results: Participants reported experiencing clinician bias within the mental health system, being mislabeled, having difficulties navigating the diagnostic system, and masking to compensate prior to diagnosis.

Conclusions: This study provides a greater understanding of diagnostic trajectories and the intersection of gender socialization with their coping strategies for navigating life without a diagnosis. This informs future practices in reducing diagnostic biases and the toll of compensatory mechanisms used in the interim.

427.053 Represent AIM: A Systematic Review and Meta-Analysis of the Sample Demographics in Autism Intervention Research

J. I. Feldman¹, J. E. Markfeld¹, R. A. Millager², S. C. LaPoint³, D. Agojci⁴, K. McClurkin⁴, Y. C. Syu⁵, I. Kim⁶, Z. J. Williams⁶, M. Sandbank⁷, K. Bottema-Beutel⁸ and T. G. Woynarowski¹, (1)Department of Hearing and Speech Sciences, Vanderbilt University Medical Center, Nashville, TN, (2)Department of Hearing and Speech Sciences, Vanderbilt University, Nashville, TN, (3)University of North Carolina-Chapel Hill, TEACCH Autism Program, Carrboro, NC, (4)Vanderbilt University, Nashville, TN, (5)University of North Carolina at Chapel Hill, Chapel Hill, NC, (6)Medical Scientist Training Program, Vanderbilt University School of Medicine, Nashville, TN, (7)The University of Texas at Austin, Austin, TX, (8)Lynch School of Education and Human Development, Boston College, Chestnut Hill, MA

Background: There has been an immense amount of research conducted on potential intervention approaches for autistic children. However, primary studies of candidate interventions often do not include representative samples; thus, findings for the efficacy of interventions may not generalize to the broad population of autistic children.

Objectives: With REPRESENT AIM, we aimed to explore the demographic makeup of participants in early childhood autism intervention research and to compare the makeup of samples to demographic data from the US Census and the Autism and Developmental Disabilities Monitoring (ADDM) Network. We hypothesized that past studies would have a greater proportion of white, male, non-Hispanic or Latino/a/x participants than would be expected given US Census and ADDM Network estimates.

Methods: The Autism Intervention Meta-Analysis for Studies of Young Children (Project AIM; a systematic review autism early childhood intervention research) is a large meta-analytic dataset containing 290 reports. All reports were double coded for the available frequency count of race using NIH categories (i.e., American Indian or Alaska Native, Asian, Black or African American, Native Hawaiian or Other Pacific Islander, White, Other, Multiracial); ethnicity (i.e., Hispanic or Latino, Non Hispanic or Latino); and parent-reported sex or gender (hereafter, referred to as sex). In a series of planned analyses, the proportion of each demographic category was calculated for each eligible study and we generated the 95% highest-density credible intervals (95% CrIs). The 95% CrIs were compared to data for the autistic population (i.e., 2020 data from the ADDM Network).

Results: There were 130 studies in Project AIM conducted in the US; 119 (91.5%) of these studies reported participants' sex, 97 (74.6%) reported at least some information on participants' race, and 65 (50%) reported at least some information on participants' ethnicity. Compared to ADDM estimates, male participants were significantly over-represented (95% CrI = 81.2%-83.6%; Mdn = 82.4%) compared to ADDM estimates (79%). White participants were also significantly over-represented (95% CrI = 56.7-68.3%; Mdn = 62.3%) compared to estimates from the ADDM (55.5%). All other demographic groups were significantly under-represented compared to ADDM estimates for example, Hispanic participants were significantly under-represented (95% CrI = 10.5%-21.6%, Mdn = 15.5%) compared to the ADDM estimate (27.4%).

Conclusions: Patterns of reporting participant demographic information across primary studies testing effects of autism interventions are poor. Results suggest that females and all racial and ethnic minority groups are underrepresented when compared to the demographic data in the ADDM network. This result, sadly, accords with findings for representation across broader biomedical and social sciences research. The lack of representative samples indicates that we cannot generalize results from extant studies to the full population of autistic individuals. This study has important implications for autism intervention research and leads to calls for great improvements in representative sampling and cultural adaptations of interventions that may be assessed in diverse populations.

427.054 Research on the Experience of Psychiatric Drug Use in People with Autism: From a Parent Perspective.

K. M. Kim¹ and **C. E. Lee²**; (1)*SANGDO-RO 369, DONGJAK-GU, DEPT OF SOCIAL WELFARE, Soongsil University, SEOUL, Seoul, Korea, Republic of (South)*, (2)*SungKyunKwan University, Seoul, Korea, Seoul, Korea, Republic of (South)*

Background:

While behavioral interventions remain a cornerstone in supporting individuals with autism, psychotropic medications are often prescribed worldwide to address associated symptoms, such as anxiety, aggression, and hyperactivity (Alfageh et al., 2020). Overall, 35% of patients used at least one psychotropic medication, most commonly stimulants, neuroleptics and/or antidepressants (Rosenberg et al., 2010). To develop better outcomes, it is imperative to examine parental perspectives as they are pivotal advocates for ensuring the judicious use of psychotropic medications in the autism community.

Objectives: The purpose of this study is to understand the status of psychotropic medication use among autistic individuals and how South Korean mothers perceive its effects and communication process.

Methods:

The current study employed a qualitative design and conducted individual interviews with 19 parents of autistic individuals. To be included in the study, participants are required to be over 18 years old, have an adult child diagnosed with autism, and currently receive psychotropic medication. Overall, parents' ages ranged from 50 to 72 years ($M = 55.39$, $SD = 1.88$), and 38.9% had received psychotropic medication for depression or panic disorder. The age of autistic individuals ranged from 20 to 35 years ($M = 25.89$, $SD = 1.71$), and the age of onset of medication ranged from 4 to 32 years ($M = 11.61$, $SD = 6.42$). Each interview lasted between 59 and 138 minutes ($M = 94.05$ mins, $SD = 24.23$). All nineteen interviews were recorded and transcribed verbatim. Constant comparative analysis (Glaser & Strauss, 1967) and emergent coding (Patton, 2002) were used to code the interview transcripts and field notes as well as to triangulate additional data sources.

Results:

The patterns of psychotropic medication use were grouped according to age at the initiation of psychotropic medication use, reasons for psychotropic medication use, effects of psychotropic medication use, dose of psychotropic medication used, and experience of psychiatric hospitalization. Experiences of psychotropic medication use were grouped based on skepticism toward the effects of medication, psychotropic medication adherence, and environmental factors. Lastly, communicating psychotropic medication use was grouped according to communication with psychiatrists, with an autistic child, and with other professionals.

Conclusions:

Once autistic individuals initiate a psychotropic medication prescription, they maintain it for a longer duration. As Rosenberg et al. (2010) mentioned, children were more likely to receive a greater dosage as they grew older. Given the higher dosages of medication at younger ages, parents were concerned about side effects (e.g., diabetes and obesity) and pessimistic about halting the medication. Consequently, Asian parents present skepticism toward taking medications (Lee, 2014). Further, limited accessibility to healthcare due to communication between healthcare providers and patients with disabilities and their families was observed. Overall, future practices are warranted for developing educational programs on medication use including foundational knowledge of medications, correct dosages, and strategies for managing side effects. Indeed, ongoing communication among stakeholders is essential. Finally, mental healthcare providers should prioritize the voices of individuals with autism, as well as team approaches based on social models.

427.055 Role of Religion in Service Access for Muslim Parents of Children with Autism

H. Alkhatib¹ and **A. C. Stahmer²**; (1)*University of California Davis, Davis, CA*, (2)*UC Davis MIND Institute, University of California at Davis MIND Institute, Sacramento, CA*

Background: While there is a reliance on Muslim religious leaders for mental health concerns (Humam et al., 2023), the extent that Muslim parents rely on religious leaders when making decisions about their child's development has not been investigated. Furthermore, the impact of religious beliefs on decisions related to diagnosis and service access remains understudied. Specifically, research about autism in the Muslim community is relatively limited, heavily qualitative, and primarily focused on families living outside of the United States despite the population of 3.45 million Muslims in America (Hussein et al., 2019; Masri et al., 2020; Pew Research Center, 2018; Tareh et al., 2020).

Objectives: This research aims to identify the religious, etiological beliefs that Muslim parents in the United States have about autism, the support they receive from their religious community, and their beliefs in spiritual interventions. Furthermore, this project aims to identify differences in the experiences of Muslim caregivers who were born in the United States and Muslim caregivers who were born outside of the United States.

Methods: Using a descriptive approach, Muslim parents were recruited to complete surveys asking about religious beliefs about autism, knowledge of autism intervention and stigma, acculturation levels, and support from their religious organizations. Preliminary data analyses were conducted using survey results. Inclusion criteria included: Muslim caregivers of a child who had been diagnosed with autism in the United States. Fliers were sent to mosques throughout the United States and posted in relevant online groups.

Results: The current sample ($n = 24$) is composed of Muslim parents whose children received an autism diagnosis in the United States. 50% identified as Southeast Asian, 29.16% as Arab, and 20.84% as Caucasian, African American, and East Asian. The average age of diagnosis was 4.92 years ($SD = 4.33$, range = 1.5, 17). 88% of the sample did not endorse stigma, and 71% showed adequate understanding of autism intervention. Although only 27% endorsed evil eye as a potential cause of autism, 58% reported that autism could be treated through Quranic recitation. Moreover, only 18% reported becoming more active in their mosque since their child with autism was born.

Conclusions: The median age of earliest known diagnosis across 11 states in the United States is approximately 49 months (Maenner et al., 2023), which is lower than the average age of diagnosis in this study. Furthermore, some parents may seek out Quranic recitation as an intervention for their children. Together, these data suggest the need for integration of autism education and information about early intervention in the Muslim community, potentially in a religious setting such as the mosque. Further data analysis will investigate relationships between acculturation, religious beliefs, and support from religious organizations and intervention choices. Additionally, potential differences in experiences between Muslim parents born in the United States and Muslim parents born outside of the United States will be explored.

427.056 Self-Determination in Racially and Ethnically Minoritized Autistic Youth and Adults in the Transition to Adulthood: Individual Traits and Social Drivers of Health

K. Greene-Pendelton¹, **A. Escobedo²** and **T. M. Girolamo³**; (1)*Johns Hopkins University, Baltimore, MD*, (2)*California State University University, Santa Barbara, Santa Barbara, CA*, (3)*Psychological Sciences & CT Institute for the Brain and Cognitive Sciences, University of Connecticut, Storrs, CT*

Background:

Self-determination, or how well individuals feel they can set and reach goals as causal agents, indicates person-environment fit and predicts post-secondary outcomes (Shogren & Shaw, 2017). Unfortunately, many U.S.-based autistic youth face poor post-secondary fit (Lai et al., 2020), especially if racially and ethnically minoritized (hereafter, minoritized) or with structural language (grammar) impairment (Johnson et al., 2010; Shogren et al., 2018). Poor fit is partly due to loss of child-/school-based services upon high school exit ("IDEIA of 2004," 2018), yet knowledge gaps remain. Autism research primarily: a) attributes outcomes to individual traits and overlooks social drivers of health (services access, sociocultural capital; Anderson et al., 2018), and b) collapses heterogeneity (using categorical labels like language impairment versus continuous scores, white-minoritized comparisons, or only caregiver report; Plaut, 2010; Schaeffer et al., 2023). Understanding self-determination requires examining social drivers of health and heterogeneity.

Objectives:

This cross-sectional study examined self-determination in minoritized transition-aged autistic individuals, asking:

1. Do social drivers of health (sense of community, unmet service needs, barriers to

services) predict Self-Determination Inventory (SDI) self-report and SDI caregiver scores, respectively, given continuous individual trait scores (language, nonverbal IQ, autism traits)?

1. Do effects differ when using a categorical approach to clinical traits (language impairment, intellectual disability, high level of autism traits)?

Methods:

Per participatory guidelines (Wallerstein & Duran, 2006), we worked with community partners (5 self-advocates, 3 caregivers, 3 speech-language pathologists, 2 psychologists, 2 teachers) and recruited 73 minoritized U.S.-based autistic participants (ages 13-30 years; 55% with language impairment; 29% NVIQ <70 to 84) and 51 caregivers. All used primarily spoken English. Participants and caregivers completed assessments using Zoom and Qualtrics. Self-determination was measured using SDI scores. Social drivers of health measures were: Brief Sense of Community Scale overall score (Peterson et al., 2008), number of unmet service needs, and number of barriers to services (Newman et al., 2011; Taylor & Henninger, 2015). Individual trait measures were: SRS-2 for autism traits (continuous: total *t*-scores, categorical: high, or ≥ 75), Raven's 2 for NVIQ (continuous: standard scores; categorical: intellectual disability, or <70), and CELF-5 core language (continuous: standard score; categorical: language impairment, or <81). Data were analyzed using descriptives and mixed-effects modeling.

Results:

SDI self-report ($M=68.6$) and SDI caregiver scores ($M=59.6$) were moderately, positively associated, $rs=.41$, $p=.003$. There were: a) small negative effects of CELF-5 language scores ($\beta=-.17$) and medium negative effects of SRS-2 total *t*-scores ($\beta=-.42$) on SDI self-report scores; and b) large negative effects of SRS-2 total *t*-scores ($\beta=-.83$) and large positive effects of sense of community ($\beta=.9.54$) on SDI caregiver scores. Using a categorical approach, there were large negative effects of high levels of autism traits ($\beta=-15.96$) and large positive effects of sense of community ($\beta=11.09$) on SDI caregiver scores. Overall, predictors differed by approach and respondent.

Conclusions:

Findings support the importance of heterogeneity in self-determination. Future work should examine the role of additional social drivers of health in self-determination and factors in caregiver-self differences.

427.057 Should Educators Prioritize Observed Employment-Related Skills or Self-Reported Attitudes? Insights from Games Made By Autistic Youth in Game Design and Employment Workshops

T. Antony¹, A. Hayes², S. O'Brien³, E. Grossman⁴, C. Edano⁵, S. Shevchuk-Hill⁶, A. R. Arista⁷, J. R. Marcotte⁸ and K. Gillespie-Lynch⁹, (1)College of Staten Island CUNY, Staten Island, NY, (2)College of Staten Island; CUNY, New York, NY, (3)2800 Victory Blvd 4s-103, College of Staten Island; CUNY, Staten Island, NY, (4)Psychology, CUNY Graduate Center, New York, NY, (5)Wilf Family Department of Politics, New York University, New York, NY, (6)College of Staten Island, Staten Island, NY, (7)Center for Children and Technology, Education Development Center, New York, NY, (8)Soft Chaos, Montréal, QC, Canada, (9)Department of Psychology, CUNY Graduate Center, Staten Island, NY

Background: Autistic people are underemployed due to systemic discrimination and potential mismatches between skills, interests, and job demands (Black et al., 2020). Through iterative curricular revisions across three summers of online Game Design and Employment workshops, we sought to help Autistic youth develop skills and attitudes they can use for employment success. Computational thinking (CT), solving problems systematically using pattern matching and abstraction (Wing, 2011), is a 21st century workplace skill but is difficult to assess (Martins-Pacheco et al., 2021). Self-efficacy, easier to assess, is the focus of many projects seeking to improve employment for Autistic people.

Objectives:

1. Assess observed employment-related skills by coding video games produced by Autistic students in our workshops;
2. Examine if students' games are associated with CT scores, video game design self-efficacy, and/or engagement with workshop activities.

Methods: Masked coders used content analysis to code games produced by diverse Autistic youth in Year 1 ($n = 32$; $Mage = 16.8$) and 3 ($n = 28$; $Mage = 17.3$) workshops. Games were not coded in Year 2 as students did not use a consistent game platform. Pre- and post-test surveys assessed video game design self-efficacy, CT, and other constructs.

In Year 1, we assigned students to one of two abbreviated versions of the Computational Thinking Abilities –Middle Grades Assessment (CTA-M). In Year 3, all students completed a revised version of the abbreviated CTA-M (after removing items exhibiting ceiling effects in Year 1) and one multi-part item from Exploring Computer Science (ECS). During each workshop, students' rated their cognitive and affective engagement with select workshop activities (Figures 1 and 2).

Results: In Year 1, one version of the CTA-M had unacceptable internal consistency ($\alpha = .57$) while the other had acceptable consistency ($\alpha = .74$). The number of elements in students' games was associated with pre-test CTA-M scores and student-rated cognitive engagement with a game-making activity ($ps \leq .01$) but **not** video game design self-efficacy ($p = .38$).

In Year 3, the adapted CTA-M had acceptable internal consistency ($\alpha = .83$). The adapted ECS did not ($\alpha = .59$). Students who made games with more interactive elements and levels had higher pre-test CTA-M scores ($ps \leq .05$). Games and CT scores were again **not** associated with video game design self-efficacy ($ps > .10$). Students who reported higher cognitive engagement with self-advocacy activities made more complete games with more interactive elements, levels, and clear objectives than their less engaged peers ($ps < .04$).

Conclusions: Our findings suggest that it may be more important for educators to help students develop observable skills, like CT, and context-specific adaptations, like engagement with self-advocacy activities, than it is to focus on helping students increase self-efficacy, which is easy to measure but may lack validity and be prone to social desirability. This aligns with recommendations to help Autistic people develop an understanding of their strengths, interests and challenges to help them find jobs well-matched to their full selves (Goldfarb et al., 2019). Findings highlight the importance of learning from student-reported engagement and student-generated products.

427.058 Social Validity of a Parent Psychoeducational Program to Support Parents of Autistic Preschoolers

B. Ayalew^a, L. B. Jahromi^a and M. Brassard^b, (1)Teachers College, Columbia University, New York, NY, (2)Brassard Practice, New York, NY

Background: A growing number of evidence-based psychoeducational programs have been developed to support the needs of parents of autistic children. The Incredible Years parent program-ASLD (Webster-Stratton, 2021), is an adaptation of the program's original curriculum (IY-BASIC; Webster-Stratton, 2015) to address the specific needs of parents of young autistic children. The program's group-based, social-support-oriented structure and curriculum aims to promote parents' positive psychosocial wellbeing while preparing parents to address developmental topics such as child-directed play and self-regulation coaching. There is a need to better understand the perceptions of families with regard to the program's social validity (Meadan, et al., 2022) which could inform the program's contextual and cultural relevance when applied across different community settings.

Objectives: This study examines various indices of social-validity from a community-research partnership study of IY-ASLD.

Methods: The study included N = 58 caregivers of preschool aged children with autism or language delays with an IEP or IFSP who met criteria for autism and/or language delays who engaged in a waitlist-controlled RCT of IY-ASLD. The curriculum was implemented using a telehealth approach in 14 weekly sessions in groups of 5-8 parents. The study will report quantitative (IY-ASLD-Program Satisfaction Questionnaire) and qualitative data (open-ended questions; in-depth interview) on parents' perceptions of likes/ dislikes, perceived key benefits, and suggested program improvements. The in-depth interview addresses parents' perceptions of ecological-cultural validity.

Results:

What was the preschool community's reported need? Through a needs-assessment conducted by the community-research partnership team, caregivers reported a desire for support facilitating interactions with their children in different parenting/teaching situations (48.5%), virtual group webinars or online information sessions (44.1%), and well-being support groups for mothers and fathers (42.6%). Notably, 40% of parents reported that despite their need for parent support, barriers preventing them from participating included work schedules, childcare, and distance and/or transportation.

IY-ASLD's response to community need. The team first conducted a pilot telehealth implementation of IY-ASLD (N = 17) which provided support of the need, feasibility, and acceptability of the telehealth IY-ASLD program. Pilot data revealed that 82% of parents enjoyed the convenience of the telehealth program, 82.3% of families reported that the program was "appropriate" or "greatly appropriate" for strengthening their child's social and emotional behaviors, and 70.6% of families indicated they felt "positive" or "very positive" about the program achieving their goals for their child and family. Finally, parents rated the utility of the following aspects of the program highest: content, skills demonstrations through video vignettes, group discussions, and coaching/practice of skills. Data from these measures as well as in-depth interviews following the waitlist control RTC will be analyzed to further explore parents' perceptions of the program.

Conclusions:

Our findings demonstrate a clear need for supportive programming among caregivers of autistic children, and feedback about elements of the IY-ASLD program that can inform future iterations of the program across socio-demographic and community settings. While the preliminary findings indicate a positive experience with IY-ASLD, there was nevertheless variability in parents' experiences, which will be important to unpack from interview narratives to inform necessary adaptations.

427.059 "Engage Him First, Instead of Assuming That the Engagement Is Lacking Because of 'autism'": Themes in Clinician Identification of Effective Communication with Autistic Individuals

E. Venkatesh¹, J. Heinly², L. Morgan³, D. Delgado^{2,4}, S. Bowers², S. Jager-Hyman⁵, B. B. Maddox² and D. S. Roubinov¹, (1)Psychiatry, University of North Carolina at Chapel Hill, Chapel Hill, NC, (2)TEACCH Autism Program, University of North Carolina at Chapel Hill, Carrboro, NC, (3)Autism and Suicide Prevention Workgroup, Kittery, ME, (4)Psychology, University of Georgia, Athens, GA, (5)Psychiatry, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA

Background: Autistic individuals experience heightened risk of mental health concerns, including elevated suicidality, anxiety, and depression; however, their engagement in treatment is limited. Amongst the most commonly identified barriers to accessing mental health care for autistic individuals are clinicians' lack of autism-specific knowledge and clinical competence. These factors may be exacerbated by communication barriers or missteps on the part of the clinician. While numerous training modules have been developed to educate clinicians on autism-centered communication, little work to date has examined the resulting impacts on clinician competency or knowledge.

Objectives: The present study examined clinicians' understanding of effective communication with their autistic clients following a training to deliver a safety planning intervention tailored for autistic youth (SPI-A).

Methods: Participants included 277 clinicians who work frequently with autistic individuals and completed the SPI-A training and post-training evaluation. This training was co-led by autistic community members and researchers, and included information regarding best practices for communicating with autistic individuals. The post-training evaluation involved free response prompts in response to staged videos modeling delivery of SPI-A, such as "what did the clinician do well in this section?" Data from the first six questions of the evaluation, which assessed clinician competence with autism-centered communication, were analyzed using reflexive thematic analysis (Braun & Clarke, 2022).

Results: Preliminary analysis revealed the following themes:

Respecting autistic communication styles and preferences. Many clinicians referred to the need for more direct or concrete language when interacting with autistic individuals, accommodating for potential differences in processing speed, or respecting their sensory and communication preferences (e.g., not forcing eye contact).

Actively working to foster autistic communication. Several clinicians endorsed incorporating non-verbal or visual modes of communication or ensuring sensory friendly spaces for their clients. Additionally, some clinicians suggested actively asking about communication preferences before starting SPI-A, though this was not a commonly endorsed response.

Presumption of a lack of understanding. Many clinicians' responses suggested that they believed that the video's client did not understand the content or purpose of SPI-A, despite lack of explicit indicators of confusion.

Centering neurotypical communication styles or preferences. Many clinicians suggested therapeutic tactics, coping skills, or methods of engagement that, while potentially effective for neurotypical clients, are likely not as effective for autistic clients.

Conclusions: These findings reveal that clinicians understand and can identify autism-centered communication strategies at the surface level. However, without knowing the intent behind clinicians' answers, it is unclear if these clinicians respect their clients' uniquely autistic ways of being or if their approaches continue to be colored by a neurotypical lens. Given that these potential biases persist after attending a training that extensively covered autistic-centered communication and was co-developed and co-led by autistic individuals, it is possible they are a byproduct of institutionalized ableism, rather than indicators of individual clinicians' beliefs. Future research should identify methods of enacting systemic change in the ways clinicians are taught to view and interact with autistic individuals.

427.060 Sound Sensitivity and Autistic Quality of Life

A. Minniss¹, R. Batra², T. Q. Boucher¹, N. E. Scheerer³, G. Iarocci¹ and E. Birmingham⁴, (1)Psychology, Simon Fraser University, Burnaby, BC, Canada, (2)Psychology, Simon Fraser University, Burnaby, BC, (3)Psychology, Wilfrid Laurier University, Waterloo, ON, Canada, (4)Faculty of Education, Simon Fraser University, Burnaby, BC, Canada

Background:

Misophonia (sensitivity to specific sounds) and hyperacusis (decreased tolerance to sound) have previously been shown to be more prevalent in autistic adults and related to their quality of life (QoL; Scheerer et al., 2024). However, autism-related factors associated with QoL (e.g., supports/barriers, sensory challenges, friendship difficulties, being authentic/unmasking) have not been studied in relations to decreased sound tolerance (DST), despite autistic experiences with DST and QoL often diverging from the experiences of non-autistic adults (Scheerer et al., 2024; McConachie et al., 2018). Using autism-specific measures of QoL can provide insight into the effect that DST has on the well-being of autistic adults.

Objectives:

Examine the relationship between autism-specific quality of life factors and misophonia and hyperacusis.

Methods:

A total of 61 autistic adults (Mean age = 33.33, SD = 11.53; 5 non-binary, 2 gender queer, 3 transgender, 10 men, 40, women) from the community participated in an online study examining experiences with sounds and hearing, mental health, and QoL. All participants self-reported a diagnosis of autism, and completed the Autism Spectrum Quotient (AQ; Baron-Cohen et al., 2001) assessing autistic traits, Misophonia Questionnaire (MQ; Wu et al., 2014), Inventory of Hyperacusis Symptoms (IHS; Greenberg & Carlos, 2018) the World Health Organization Quality of Life–Brief (WHOQOL-BREF; WHOQoL Group, 1998), and the Autism Quality of Life Questionnaire (ASQoL; McConachie et al., 2018). The ASQoL is a 9-item addendum to the WHOQOL-BREF inquiring about factors relevant to autism (i.e., support, ability to “be yourself”, financial security, friendships, sensory issues, and barriers) on a 5-point Likert scale (Never to Always). Pearson correlations were conducted to examine the relations between autistic traits, misophonia, hyperacusis, and quality of life.

Results:

Within the sample, 55.7% and 42.7% of participants scored above the cutoff for clinical presence of hyperacusis symptoms and misophonia symptoms, respectively. Autistic traits were significantly positively correlated with hyperacusis symptoms ($r(59) = .31, p = .015$). Hyperacusis symptoms were significantly negatively associated with the ASQoL ($r(59) = -.31, p = .014$), but not misophonia symptoms. Misophonia symptoms were significantly positively correlated with hyperacusis symptoms ($r(59) = .72, p \leq .001$).

Conclusions:

Hyperacusis symptom severity, but not misophonia, was negatively correlated with the autism-specific quality of life measures. This difference resulting from the outcome of measures could be due to hyperacusis symptoms becoming more difficult to manage in a person's environment, as hyperacusis is defined by a lower tolerance for experiencing “loudness”, and everyday sounds may be hard to avoid and manage. In contrast, QoL may be associated with misophonia as triggers may be comparatively easier to avoid. Using autism-specific measures increases specificity when investigating the effect of DST on autistic adults, and also helps us understand the unique relations between QoL and DST in autistic adults.

427.061 Specifying Social Strengths: Mental Health and Demographic Correlates in Autistic Youth

J. K. Richards¹, J. A. Gates², M. L. McNair² and M. D. Lerner^{1,2}, (1)A.J. Drexel Autism Institute, Drexel University, Philadelphia, PA, (2)Department of Psychology, Stony Brook University, Stony Brook, NY

Background: A dramatically understudied dimension of strength in autistic youth is social strengths (SSs). Autism is often defined in terms of social deficits and such strengths are often ignored or even considered anathema to autism itself (see Gates et al., 2023a for review). A recently developed method that isolates SSs among broader social profiles of youth has revealed that autistic youth *do* possess SSs like their non-autistic peers (Gates et al., 2023b). However, examination of SSs while accounting for challenges, including their relative contributions to autism traits, behaviors, and mental health outcomes, and how they vary as a function of demographic differences, has never been explored.

Objectives: To examine how SSs relate to demographics, behavior, autism traits, and mental health outcomes in autistic youth; to evaluate patterns in these relationships in context of one's full profile of social challenges and strengths.

Methods: Parents of 106 autistic adolescents ($M_{age}=14.10$, 78% male) completed questionnaires as part of a study on social interaction. Alternative scoring on the SSIS (Gresham & Elliot, 2008) calculated social acquisition, performance, and strengths scores (Gresham et al., 2010; Gates et al. 2023b). SSs' correlations with mental health and behavioral outcomes, autism traits, and demographic variables were explored (see Table 1). For each significantly correlated outcome, commonality analyses (Nimon et al., 2008) were performed to tease apart the relative contributions of SSs, acquisition and performance deficits (individually, and in combination with each other) in explaining their variance.

Results: SSs negatively correlated with ODD symptoms ($p=0.002$), hyperactivity ($p<0.001$), attention problems ($p<0.001$), autism traits ($p<0.001$), and parental education ($p<0.049$). Greater SSs were reported for youth with higher social skills, Black racial identity, and by parents reporting not seeking work (p 's <0.001 ; see Table 1). All commonality models were significant overall (p 's <0.001). SSs most uniquely predicted parental education and Black racial identity (Table 2) while acquisition deficits most uniquely predicted autism traits, ODD, and hyperactivity. SSs and social performance, combined, best explained the variance in social skills as well as parental employment (Table 2).

Conclusions: Examining social strengths provides explanatory power and nuanced understanding of a variety of outcomes in autistic youth which may have been underestimated in deficit-focused research. SSs' negative associations with parent-reported ODD symptoms, hyperactivity, and autism traits emphasize SSs as a potential treatment target in youth; however, commonality analyses suggest the importance of considering SSs in conjunction with challenges when trying to impact such targets in this population. Additionally, after accounting for acquisition and performance deficits, parents of Black children, those who report not seeking employment, and those who report less formal education each reported higher levels of SSs, suggesting parents of these backgrounds may have a particular propensity for attending to the SSs – rather than deficits – of their children. Overall, results attest to the importance of better understanding how, when, and why parents observe and see value in the SSs of their autistic children. Consequently, this method may facilitate personalization of intervention to best build upon one's existing strengths and target their desired social goals.

427.062 "Everything and Nothing": Exploring the Perceived Salience of Gendered Cues at the Intersection of Autism and Gender Diversity Via Measure Validation and Analysis

M. I. Pascoe^{1,2}, **A. I. van der Miesen**³, **K. Cooper**⁴, **W. Wang**^{5,6}, **R. W. Tafari**⁷, **D. P. VanderLaan**⁸ and **M. C. Lai**⁹, (1)Psychology, University of Toronto, Toronto, ON, Canada, (2)Margaret and Wallace McCain Centre for Child, Youth & Family Mental Health, Campbell Family Mental Health Research Institute, Centre for Addiction and Mental Health, Toronto, ON, Canada, (3)Department of Child and Adolescent Psychiatry, Center of Expertise on Gender Dysphoria, Amsterdam University Medical Centers, Location Vrije Universiteit, Amsterdam, Netherlands, (4)Department of Clinical, Educational and Health Psychology, University College London, London, London, United Kingdom, (5)Biostatistics Core, Centre for Addiction and Mental Health, Toronto, ON, Canada, (6)College of Public Health, University of South Florida, Tampa, FL, (7)Department of Psychology, University of Toronto, Toronto, ON, Canada, (8)Department of Psychology, University of Toronto at Mississauga, Mississauga, ON, Canada, (9)Campbell Family Mental Health Research Institute, Centre for Addiction and Mental Health, Toronto, ON, Canada

Background: Autism and gender-diverse identities often intersect, and many autistic individuals experience a unique gender identity phenotype which includes a sense of disinterest in gender as a construct. In the general population, unless gendered cues (the indicators of the various gender groups) are salient to an individual, one is not motivated to self-categorize in terms of gender. We hypothesized that autistic individuals perceive gendered cues as less salient than nonautistic individuals, which could explain why autistic individuals present with disinterest toward the utility of gender. Investigating the perceived salience of gendered cues might, therefore, help us better understand autistic gender-diverse experiences. We define gender salience as being aware of, paying attention to, and placing meaning in gendered cues.

Objectives: 1) To develop and validate a self-report measure of gender salience that is applicable across autistic and nonautistic adults and cisgender and gender-diverse adults, with two versions, present-day and retrospective at age 10-13 years; 2) To investigate how levels of gender salience differ in accordance with autism-status, gender diversity-status, and sex-assigned-at-birth.

Methods: Working with a group of six autistic, gender-diverse individuals, we developed a set of self-report items to capture gender salience. Data were collected via Prolific for autistic-gender-diverse ($n = 484$), autistic-cisgender ($n = 469$), nonautistic-gender-diverse ($n = 358$), and nonautistic-cisgender ($n = 523$) adults. Participants responded according to present-day and retrospective experiences. A series of exploratory factor analyses (EFA) were first performed on the present-day data to select robust items, and a confirmatory factor analysis (CFA) then performed on the retrospective data. The alignment method was used to examine measurement invariance across autism-status, gender diversity-status, and sex-assigned-at-birth groups. We then used multivariate hierarchical regression to investigate the effects of autism-status, gender diversity-status, and sex-assigned-at-birth, alongside their interactions on gender salience factor scores as three dependent variables, for each timepoint.

Results: Three factors were identified via the EFAs, including 16 items explaining 53.8% of total variance (Table 1). The factors were named Gender Awareness, Gender Categorization, and Gender Rumination. The CFA on retrospective items indicated good model fit. The measurement invariance testing indicated 9.38% noninvariance in the present-day data and 3.13% noninvariance in the retrospective data, suggestive of measurement invariance. Being autistic ($p = .002$) and being gender-diverse ($p < .001$) were associated with higher present-day gender salience scores (indicating higher levels of perceived salience of gendered cues) on the omnibus tests. Being autistic ($p = .003$), gender-diverse ($p < .001$), and assigned-female-at-birth ($p = .003$) were associated with higher retrospective gender salience scores on the omnibus tests. See Table 2.

Conclusions: One explanation for greater gender salience is that those who have most actively thought about gender rules to fit in (i.e., gender-diverse, autistic, or assigned-female-at-birth people) are more likely to have greater gender salience. Following a Bayesian explanation of autistic cognition, priors of traditional gendered constructs might be attenuated for autistic individuals, leading to reduced adaptation to gendered cues and thus subjective greater salience. The findings inform a “difference-and-not-delay” framework of the development of autistic gender identity experiences.

427.063 Stress and Coping Experienced By Mothers with Autoimmune Diseases While Parenting Children with Autism

C. M. Dillon, *Children's Services, Walden University, Petoskey, MI*

Background: The number of individuals diagnosed with autoimmune diseases (AD) continues to rise with the majority being women of childbearing age. Quantitative studies regarding the effect of the maternal immune system on the developing fetus have shown an increase in both pregnancy and birth complications for women with ADs and a higher incidence of both AD and autism in children born to mothers with ADs.

Individuals with ADs report increased emotional, medical, and financial burdens resulting from symptoms associated with their AD.

There has been a concurrent increase in the number of children diagnosed with autism and mothers are often the primary caretaker. AD and autism have been researched separately through quantitative studies with similarities regarding potential etiology and heritability. The gap identified in the literature was the need for qualitative study regarding stress and coping among mothers with AD parenting children with autism.

Objectives: The purpose of this qualitative study was to understand the stress and coping experiences of mothers with AD while parenting children with autism. We used the transactional model of stress and coping as the conceptual framework for this study to understand what was needed to support these mothers in parenting their children.

Methods: Inclusion criteria for this study required mothers between 30 and 60 years of age diagnosed with one or more AD's, parenting a child diagnosed with autism between the ages of three and 18. Semi structured interviews were conducted with 10 mothers with ADs aged 35 to 52 parenting children with autism. Interviews were conducted virtually on a secure platform and audio recorded with consent. Recordings were securely stored and reviewed repeatedly for line-by-line transcription, coding, and theme development for thematic analysis.

Results: We identified 11 themes including delayed AD diagnosis, delayed autism diagnosis, chronic pain and fatigue, time management, challenging autism concerns, lack of resources, bidirectional stress, relationship issues, school issues, emotional cost, financial cost, and judgement from others. Symptoms associated with ADs were reported to create barriers at times to caring for their children. When their child experienced emotional dysregulation resulting in increased behaviors, this increased the mother's emotional burden and AD symptoms. Mothers reported using coping strategies including managing their diet, seeking social supports, pacing and planning daily activities, and time for rest. Engaging in their own therapies and adhering to sleep routines were reported to be beneficial. These mothers emphasized the need for medical practitioners, school staff, family members, and people in their communities to listen to them regarding symptoms and needed supports for themselves and their children.

Conclusions: Comprehensive education for medical professionals is needed regarding ADs to allow for faster identification and provision of supports and services. Recognizing ADs in pregnant mothers may provide support for the mother and child while the child is still in utero. Comprehensive education for medical and school professionals is needed regarding autism supports. Practitioners and school systems would benefit from creating collaborative, whole family approaches that may lead to better patient outcomes, and stress reduction for mother and child.

427.064 Supporting Families: Insights into the Transition Experience for Parents Whose Autistic Child Is Moving to an Independent Living Setting

M. Argumedes Charles¹, **I. Préfontaine²**, **M. M. Dufour³** and **D. Ummel¹**, (1)Psychoéducation, Université de Sherbrooke, Sherbrooke, QC, Canada, (2)Psychoéducation, Université Laval, Quebec, QC, Canada, (3)Psychoéducation, University of Montreal, Montreal, QC, Canada

Background: An increasing number of autistic adults are seeking independent living arrangements, as many continue to live with their aging parents. The transition from the family home for an autistic adult who is unable to live independently is a significant event for their families (Longtin, Soulières, Gagné, & Lapointe, 2017). This change represents a major disruption to family dynamics, requiring parents to adapt to a new reality (McNavish, 2019). Consequently, this transition raises important questions about how parents experience and cope with this adjustment. The Véro and Louis Foundation opened an autism-specifically designed group home environment in Canada, housing 16 residents. In order to better meet the needs of families whose children are moving to the Véro and Louis House, the research team investigated their transition experience.

Objectives: The aim of this research is to describe the experience of parents following the move of their child from the family home to a suitable living environment for autistic adults.

Methods: To understand the experience of parents, we conducted semi-structured interviews, which were recorded and subsequently transcribed. The sample consisted of 3 couples who participated in the interview together and 11 parents who had individual interviews. We employed a thematic analysis approach (Braun & Clarke, 2021). The interviews were first analyzed inductively to identify themes and patterns, and then deductively to confirm categories and to closely examine cases that did not align with the overall analysis (Patton, 2015).

Results: The results address their thoughts, emotions, and experiences before the move to the new home and during the transition period, as well as the information received about the house program before, during, and after their child's move. Six themes emerged from the analysis: perception of the child's well-being, quality of interventions by practitioners, frequency and modalities of communication with the child, quality of interactions between parents and practitioners, overall satisfaction with the new living environment, and the significance of parental involvement in the child's intervention plan.

Conclusions: The results highlight that the child's well-being is central to parental concerns, as it serves as a measure of the quality of the transition. The relationships established between parents and practitioners significantly influence their levels of stress or comfort regarding the move to the new living arrangement. This study emphasizes the importance of considering the realities of parents during the relocation of their autistic child, as they are significant actors in their child's life. A key aspect of supporting the transition is to promote the continuity of the relationship between the parent and their child, as well as with practitioners. Consequently, practitioners must involve parents in decision-making processes regarding their child to maintain the quality of the relationship.

427.065 Supporting Rural Families: Outcomes of a Virtual Parent Support Program

E. McRae and L. Stoppelbein, University of Alabama at Birmingham, Birmingham, AL

Background: Parenting stress among caregivers of autistic children negatively impacts child adjustment and contributes to the risk of adverse outcomes. These caregivers often experienced elevated stress associated with the demands of navigating extensive supports and interventions. Understandably, this stress is exacerbated in rural, under-resourced areas where access to healthcare, support services, and community resources is limited. In the southeastern US, many regions lack specialized programs and services, leaving caregivers with minimal opportunities to access support networks. For many families, barriers like transportation, childcare, and financial resource further limit their ability to access the few resources that exist. Thus, parents in these regions are tasked with navigating not only the needs of an autistic child but with doing so in the absence of supportive services. This dearth of resources is concerning for ongoing disparities in low-income, rural, and/or minority families of autistic children. The needs of these families in the face of such barriers necessitates innovative approaches to providing resources to autistic children and their caregivers.

Objectives: This study examined the effectiveness of an 8-week parent support and psychoeducation group delivered via telehealth throughout the rural southeastern US. The goals of the program were to decrease parenting stress and enhance parents' perceived social support and satisfaction in the parent-child relationship. We also examined parent- and child-related factors that influenced response to intervention.

Methods: The intervention was based on a semi-structured curriculum that was administered virtually for 8 consecutive weeks. Each session included a hybrid approach involving the provision of didactic information and a semi-structured, facilitated support group model. Variables of interest were measured before and after the intervention. Data collection throughout a follow-up period is ongoing. Variables of interest included parenting stress, perceived social support, and satisfaction in the parent-child relationship. We also assessed the broad autism phenotype (BAP) in parents and child-related factors (i.e., autism symptom severity, internalizing and externalizing problems) as factors influencing response to intervention.

Results: Participants ($n=43$) included mothers (80.9%) and fathers of autistic children (M age = 9.30; $SD = 4.30$) who participated in the intervention. At baseline, BAP traits in parents were positively associated with satisfaction in the parent-child relationship ($r = .54, p < .01$). Parenting stress was negatively associated with perceived social support ($r = -.56; p < .01$). Outcomes were analyzed for participants who completed at least 6/8 sessions ($n=35$). Child age was the only significant predictor of attrition. Results of an ANCOVA showed a significant increase in perceived social support post-intervention after controlling for child age and autism symptom severity ($F[1,34]=20.15, p < .01$). An increase in satisfaction in the parent-child relationship approached significance.

Conclusions: Social support can be difficult for parents of autistic children to access, yet it is known to mitigate parenting stress and to enhance overall wellbeing in parents. In rural areas, garnering social support can be particularly challenging. This study shows that a virtual parent education and support program is effective for increasing parents' perceived social support, which represents a meaningful way by which providers in under-resourced areas can support families of autistic children.

427.067 "They Believed in Me": A Community-Partnered Participatory Study Exploring the Outcomes of Adult AAC Users

L. Fischbacher¹, D. J. Su², G. Blasko³, J. Zimmerman⁴ and M. Piette⁵, (1)Baylor University, Waco, TX, (2)University of Pittsburgh Medical Center, Pittsburgh, PA, (3)self-advocate/ community participatory researcher, Seattle, WA, (4)self-advocate/ community participatory researcher, OH, (5)community partnered researcher, CO

Background: In 2020, around five million Americans and 97 million people globally used or could benefit from AAC (Beukelman & Light, 2020). Research on AAC users, especially those with autism and intellectual and developmental disabilities (I/DD), is limited and mostly focused on young children. This study aims to explore the outcomes, transitions, and special education experiences of AAC users with autism and/or intellectual disabilities through a multiple-case study approach.

Objectives: The study aims to explore the outcomes, transitions, diagnoses, communication, and special education experiences of AAC users with autism and/or intellectual disabilities. Using community-partnered participatory methods involves interviews with AAC users, parents, educational history questionnaires, and quality of life and self-determination measures. The research seeks to understand what AAC users consider fulfilling and successful outcomes, challenging traditional perspectives. Grounded in the social model of disability, it aims to provide insights into the unique needs and experiences of AAC users, contributing to the limited knowledge about their outcomes and informing future research and practice.

Methods: This study uses a community-partnered participatory research (CPPR) approach to conduct multiple case study research on AAC users with I/DD who qualified for special education under autism and/or intellectual disability. After a lengthy recruitment process, three participants qualified and participated. Data collection methods included interviews, questionnaires, surveys, and document reviews. The analysis involved within-case and cross-case phases (Creswell, 2018) using QCAmap software for qualitative content analysis (Mayring, 2021). CPPR fosters trust, mutual respect, and shared decision-making, ensuring relevance and benefit to the community. The study's three CPPR phases were vision (goal setting and design), valley (data collection and analysis), and victory (dissemination of findings) (Jones et al., 2009) were done in collaboration with a team of community stakeholders who are fellow authors on this presentation.

Results: The within-case and cross-case analyses revealed that friendships were a strength for all three participants (see table and figure below). Communication was a strength for Billy and Jessica but a challenge for Emma. Day programs provided social and academic support for Jessica and Emma. All participants lived with their parents, relying on them for support. Employment was a strength for Billy and Emma. Participants continued to grow in adulthood, with high quality of life scores. Self-determination was an area for growth. Talents like running, dancing, and swimming helped them connect with others. Good outcomes included being loved, included, respected, and having continued support.

Conclusions: This study emphasizes the importance of understanding AAC users' outcomes, particularly those with autism and intellectual and developmental disabilities. The study addresses community-specific needs by involving stakeholders and individuals with lived experience in the research process. Key findings highlight the necessity of providing ongoing support and training for day programs, employers, and job coaches. The research underscores the need for tailored educational strategies and policy changes to improve service delivery. It also identifies barriers such as lack of awareness and access to specialists, advocating for better support across the lifespan for AAC users. This study serves as a foundation for future research and practice improvements.

427.068 Teachers' Knowledge, Beliefs, Experiences, and Needs in Sex Education for Autistic Students with Intellectual Disabilities in China

Q. Pan¹, Y. Yang², M. Y. S. Bak¹, X. Liu³ and H. Qiu⁴, (1)Educational Psychology, University of Minnesota - Twin Cities, Minneapolis, MN, (2)Special Education, Lingnan Normal University, Zhanjiang, Guangdong, China, (3)Educational Psychology, University of Minnesota, Minneapolis, MN, (4)Psychology, University of Minnesota - Twin Cities, Minneapolis, MN

Background:

School-based sex education (SBSE) is crucial for sexual health and safety for all students. In China, there is a significant lack of SBSE for students with disabilities. Special education teachers are key to developing and delivering SBSE specifically tailored to students' needs. Although some studies suggest a growing awareness of SBSE among special educators, little research has examined their knowledge, beliefs, experiences, and needs in providing SBSE for autistic students with intellectual disabilities.

Objectives:

Phase 1 involved a survey investigating 51 special education teachers' knowledge of sexual and reproductive health (SRH) and beliefs about SBSE. Phase 2 involved focus groups with 17 participants from Phase 1, exploring teachers' experiences and needs for SBSE for autistic students with intellectual disabilities.

Methods:*Phase 1*

Fifty-one special education teachers recruited via online teacher groups completed an online survey on SRH knowledge and beliefs. The knowledge section covered categories in physiological health, sexually transmitted diseases, conception, and sexual violence. The belief section asked questions regarding importance, timing, and self-competency in delivering SBSE. Descriptive statistics were generated using SPSS.

Phase 2

Participants were selected from Phase 1 based on student grade level and school locations. Thus, 17 teachers participated in three focus groups, each with five to six participants. Two-hour interviews explored teachers' experiences delivering SBSE and the need for SBSE. Transcriptions were analyzed using NVivo, employing thematic analysis to identify themes.

Results:*Phase 1*

Knowledge: The participants demonstrated an overall high knowledge level (Mean = 26/30). However, knowledge level varies across categories such as conception.

Belief: Nearly all teachers (98%) agreed SBSE is essential and should be tailored for autistic students with intellectual disabilities. Over 75% believed elementary school is the best time to introduce SBSE. Around 90% supported involving caregivers and professionals in developing SBSE, though fewer (55%) endorsed the involvement of school administrators or government entities. While 98% recognized teachers' key role in improving students' sexual health, only half felt confident in delivering SBSE.

Phase 2

Three themes emerged from focus groups: 1) current state of SBSE, 2) barriers to delivering SBSE, and (3) desired content and format of ideal SBSE.

Experience: Teachers reported gaps in current state of SBSE at student, school, and teacher levels. Barriers are shared regarding student needs, teacher training, school support, caregiver collaboration, and cultural taboos.

Need: Teachers identified three key content areas for SBSE in physical knowledge, psychological support, and safety protection. Teachers also highlighted needs in format for clear and direct content delivery, multi-sensory teaching methods, as well as teacher support and guidance.

Conclusions:

Autistic students with intellectual disabilities are at significant risk of sexual violence and exploitation due to the absence of SBSE. Special education teachers may acquire relatively high SRH knowledge levels and recognize SBSE's importance, but are confronted with multiple implementation barriers. Their insights on content and format of SBSE provided a foundation for future development of SBSE tailored to these students' needs.

427.069 The Enduring Differential Impact of Family Resources and Needs on the Strengths of Children with Intellectual and Developmental Delay: A Longitudinal Study of the Family Advocacy and Support Tool

A. Farrey¹, X. Tong², S. Leon³, O. Vsevolozhskaya², M. Lardner⁴, J. McAllister⁴ and **M. R. Altschuler⁵**, (1)Kentucky Injury Prevention and Research Center, University of Kentucky, Lexington, KY, (2)Biostatistics, University of Kentucky, Lexington, KY, (3)Psychology, Loyola University Chicago, Chicago, IL, (4)Center for Innovation in Population Health, University of Kentucky, Lexington, KY, (5)Center for Innovation in Population Health, Department of Health Management and Policy, and Department of Psychology, University of Kentucky, Lexington, KY

Background:

Considerable effort has been spent assessing the predictors of positive long-term outcomes for children on the autism spectrum and with intellectual and developmental delays (DD). However, the role of family and caregiver resources and needs in supporting children with DD and profound autism is less understood. A lack of comprehensive community or public support programs for families and caregivers of children with DD may lead to prolonged parental caregiving obligations as well as a disproportionate need to play a more active role in supporting their children. Drawing on our lived experiences as family members of individuals with profound autism, we examined whether family needs and resources may be differentially impactful for promoting strengths of DD children.

Objectives:

To (1) center our lived experiences as family members of individuals with profound autism; (2) assess whether the impact of family resources and needs on child strengths is moderated by DD; (3) examine its enduring differential impact across 24 months.

Methods:

This study utilized Family Advocacy and Support Tool (FAST) survey assessments ($N=165,011$) from families ($n=27,086$), caregivers ($n=54,264$), and children ($n=59,775$) with DD ($n=3,817$) and without DD ($n=55,958$) conducted by Child Protective Services (CPS) during hotline calls and follow-up visits across 24 months. Children were between 1 to 21 years old (5 or younger: 33.8%, 6-10: 28.0%, 11-15: 27.6%, 16-21: 10.6%) with diverse racial backgrounds (White: 48.6%, Black: 37.8%, Other: 13.6%). A total family/caregiver wellness score (FCW) at baseline was calculated from the FAST items to reflect having fewer needs and more resources. Generalized models were used to assess the moderating effect of DD, controlling for age and race, and accounting for the repetitive, nested nature of the data (see Table 1 and Figure 1).

Results:

Higher baseline FCW was more strongly associated with baseline child strength in DD children relative to non-DD children ($p=0.003$). In non-DD children, baseline child strength was 0.531 higher per unit increase in baseline FCW score ($p<0.001$). For DD children, the increment was 0.650 ($p<0.001$). Baseline FCW also had an enduring differential impact on child strength over 24 months moderated by DD. Higher baseline FCW was associated more strongly with DD child strength relative to non-DD children 6 months later ($p<0.001$), 12 months later ($p<0.001$), 18 months later ($p=0.001$), and 24 months later ($p=0.003$).

Conclusions:

Our results demonstrate an enduring differential impact of FCW on strengths of children with DD and suggest the importance of focusing resource allocation on family engagement. DD children consistently showed more benefit in their strength development from baseline family wellness than non-DD children, suggesting families with fewer unmet needs may play a more active role in promoting DD child strengths. Results also mirror our collective lived experiences, which support the notion of a disproportionate effect of FCW on DD children compared to non-DD children. Practice and policy efforts aimed at building strengths among DD children should focus on identifying and addressing the needs of families. Centering the lived experiences of the family will help bridge the existing research, practice, and policy gap.

427.070 The Impact of Coping on the Mental Health of Mothers of Children with Autism Spectrum Disorder, Children with Other Disabilities, and Typically Developing Children in Japan

N. Porter^a, T. Yamane^a, E. Suzukida^a and K. A. Loveland^a, (1)Department of Early Childhood Education, Hokuriku Gakuin University, Kanazawa, Ishikawa, Japan, (2)Graduate School of Developmental and Environment, Kobe University, Kobe, Japan, (3)Doshisha University, Kyoto, Kyoto, Japan, (4)Louis A Faillace, MD, Department of Psychiatry and Behavioral Sciences, McGovern Medical School, University of Texas McGovern Medical School, Houston, TX

Background:

Coping strategies are crucial to how families manage stress, especially to families of a child with Autism Spectrum Disorder (ASD) (Benson, 2010). Problem-focused coping is associated with better mental health, while avoidance-oriented coping is associated with poorer outcomes (Dabrowska & Pisula, 2010). However, it is unclear if coping strategies effective for families of typically developing children (TD) or families of those with other disabilities (OD) are equally effective for parents of children with ASD.

Objectives:

This study examined coping strategies used by mothers of children with ASD, OD, and TD in Japan, and to compare how these strategies impacted mothers' mental health.

Methods:

One hundred fifty-nine mothers of children with ASD, 88 with OD, and 172 with TD, aged 2 to 12 participated. Average age of children was 94.83 ± 37.91 months for ASD, 93.75 ± 36.02 for OD, and 76.67 ± 31.76 for TD. Socioeconomic status (SES) was calculated using an index based on the mother's education, occupation, and family income. Participants completed online surveys using Japanese versions of the Brief COPE (Engagement, Disengagement, Distraction, Cognitive reframing), WHO Well-Being Index (WHO-5), and Kessler Psychological Distress Scale (K10) to assess maternal characteristics, and the Social Communication Questionnaire (SCQ) and Strengths and Difficulties Questionnaire (SDQ) for child characteristics, along with life stress (LS). ANOVA was used to examine differences in psychological well-being and effects of coping strategies across the three groups. Multiple Group Path Analysis was used with SCQ, SDQ, and LS as observed variables, controlling for child age and SES, to explore how coping strategies influenced well-being across groups.

Results:

Disengagement coping was significantly higher in the TD group compared to the OD group ($p < .001$) (Figure 1). In the multiple-group simultaneous analysis, after examining the model without equality constraints, we analyzed the model with equality constraints on paths with significant and non-significant and positive and negative path coefficients in any group (Figure 2). The resulting model fit indices were adequate (CFI = .85, RMSEA = .05, AIC = 810.85, and BCC = 888.99). Key findings in the model without equality constraints included significant positive paths from SCQ to Disengagement in the ASD and TD groups ($\beta = .18$; $\beta = .19$). Additionally, Cognitive Reframing negatively predicted K-10 in the ASD and OD groups ($\beta = -.22$; $\beta = -.40$), while Distraction positively predicted K10 in the ASD and TD groups ($\beta = .15$; $\beta = .21$).

Conclusions:

Disengagement coping was positively associated with social communication difficulties (SCQ), suggesting mothers of children with stronger ASD traits may be more likely to use less adaptive coping strategies. Interventions should aim to reduce disengagement coping and promote active coping in this group. Cognitive reframing emerged as a significant protective factor in the ASD group. Fostering cognitive reframing skills could be particularly beneficial in alleviating distress among these mothers.

**427.071 The Impact of Environmental Factors on Autistic Young People's Mental Health**

S. Hampton¹, K. Cooper^{2,3}, E. Midouhas³, E. Flouri³ and W. Mandy³, (1)Research Department of Clinical, Educational & Health Psychology, University College London, London, UNITED KINGDOM, (2)University of Bath, Bath, UNITED KINGDOM, (3)Research Department of Clinical, Educational & Health Psychology, University College London, London, United Kingdom

Background: Autistic people experience high rates of depression and anxiety and this can have a detrimental impact on their lives. An evidence-based understanding of how and why these difficulties develop in childhood and adolescence is lacking, leading to a paucity of evidence to inform the development of much needed mental health support for autistic people. In particular, there is a lack of research into how autistic young people's social and physical environment influences their mental health. Greater research is needed into these environmental factors as they are likely to impact heavily on mental health, and many such factors may be amenable to modification and therefore important targets for intervention.

Objectives: To better understand why autistic young people commonly develop anxiety and depression, and to identify potentially modifiable environmental factors that can form targets for intervention.

Methods: Given the study's focus on lived experience, a qualitative approach was taken. This approach allowed the amplification of autistic young people's voices, who are seldom heard in research. Semi-structured qualitative interviews were conducted with 23 parents and 14 young people (mean age 11.70 years (range 5-17); 13 males, 10 females, 1 non-binary; 19 white, 5 belonging to an ethnic minority). Interviews are due to be conducted with 50 participants (20 young people, 30 parents) in total. Interviews were analysed using Framework Analysis. An analytic framework was created drawing upon categories of environmental variables known to impact mental health, underpinned by Bronfenbrenner's ecological systems theory. Transcripts were coded by multiple coders. The study was conducted in collaboration with autistic young people and other stakeholders.

Results: Nature, trajectory and impact: Internalising issues were a significant and daily challenge for many, with issues often increasing in severity with age and leading to isolation and sometimes debilitating difficulties completing daily activities. **Family relationships:** Supportive and understanding family members were a key protective factor, with young people valuing family who facilitated a positive sense of their autistic identity. Parents described modifying their parenting to lower demands and boost their child's autonomy and thereby ease their anxiety. **Social and academic environment outside the home:** School often represented a deeply pressurising environment and school refusal was common. The weight of academic expectations was a significant source of stress, as were difficulties with peers by whom young people commonly felt misunderstood and victimised. Young people often internalised these stressors, impacting their sense of self-worth and leading to exhaustion and burnout while attempting to meet others' social and academic expectations. **Physical environment:** Access to greenspaces represented an important protective factor, facilitating emotion regulation. Young people described the importance of safe spaces, most often their bedroom, in which they could control their sensory environment and engage in their passions and interests.

Conclusions: Autistic young people face significant internalising issues, often as a result of unaccommodating environments and pressure to meet neurotypical expectations. Environmental factors such as academic expectations, parenting styles, understanding of autism among family, teachers and peers, and access to low sensory demand spaces may be important targets for mental health interventions.

427.072 The Impact of Visible and Invisible Stigmatized Identities on the Transition to Adulthood: Qualitative Perspectives of Autistic Young Adults, Caregivers, and Service Providers

M. Adebogun¹, J. S. Wilson², W. Feng³, J. S. Eilenberg⁴, A. Chu⁵, K. M. Guthrie⁶, G. I. Orsmond⁷ and K. Long¹, (1)Clinical Psychology, Boston University, Boston, MA, (2)Department of Psychological and Brain Sciences, Boston University, Boston, MA, (3)Lehigh University, Bethlehem, PA, (4)Boston University, Boston, MA, (5)Brown University School of Public Health, Providence, RI, (6)Brown University, Providence, RI, (7)Department of Occupational Therapy, Boston University, Boston, MA

Background: The transition to adulthood for autistic adolescents and young adults (AYAs) is a crucial period marked by a paucity of adult services and AYAs' unique vulnerability to discrimination and disempowerment as a societally stigmatized group. Few studies have explored how discrimination due to different forms of stigmatization can impede transition-related goals as families prepare for AYAs to navigate the world with increased independence. Stigmatization can occur due to visible or readily apparent socially devalued characteristics (i.e., race) and invisible or concealable identities (e.g., autism) that may become consequential through perception or disclosure (Turnock et al., 2022). AYAs and caregivers from marginalized backgrounds often must navigate both visible and concealable stigmatized identities throughout the transition process, especially in the context of encountering potential discrimination. Understanding how families manage stigmatizing experiences is necessary to improve transition outcomes.

Objectives: This qualitative study sought to (1) explore how AYAs and caregivers navigate experiences of discrimination due to visible and invisible stigmatized identities, and (2) examine how these experiences pose additional challenges for families during the transition to adulthood.

Methods: English, Mandarin, and Cantonese-speaking autistic AYAs ($N=8$, 14–22-year-old), caregivers ($N=22$), and service providers ($N=5$) participated in individual semi-structured interviews. Interviews explored experiences of AYAs and caregivers during the transition to adulthood, with particular attention to barriers related to experiences of discrimination, service provision, and resource access. Data collection continued until thematic saturation was achieved. Data were transcribed verbatim, cleaned, and systematically coded, then organized conceptually using framework matrices. Data were further analyzed using applied thematic analysis.

Results: Three primary themes were identified. First, AYAs and caregivers encounter barriers in the transition process related to their visible and invisible identities, with those who exist at the intersection of multiple stigmatized identities experiencing additional, unique barriers. Second, due to the increasing threat of discrimination, caregivers attempt to protect and prepare AYAs for success in navigating the world with increased autonomy. Third, there is variability in the decision-making process regarding concealing or disclosing AYAs' autism diagnosis. The decision maker weighs the costs and benefits of disclosure or concealment depending on the specific social context. To illustrate, Black caregivers and AYAs consider preemptive autism disclosure in encounters with law enforcement due to the increased risk of adverse or life-threatening outcomes. In contrast, there are situations wherein it may be advantageous to conceal autism, which stems from a fear of discrimination, e.g., on college applications.

Conclusions: Understanding how AYAs and caregivers navigate discrimination due to visible and invisible stigmatized identities during the transition process is crucial to mitigating resulting barriers. This is especially true for AYAs and caregivers from marginalized racial, ethnic, and cultural backgrounds with intersecting stigmatized identities. Discrimination-related challenges can limit the environments AYAs can independently navigate. This study identifies the identity concealment or disclosure process as a significant experience during the transition period that warrants deliberate consideration for families. Future research should examine how systems can help families navigate the cultural and social implications of the transition to adulthood and improve outcomes for AYAs and caregivers.

427.073 The Mediating Role of Psychological Capital in the Relationship between Family Sense of Coherence and Caregiver Stress Among Parents of Children with Autism Spectrum Disorder

M. A. Zoromba^a, H. El-Gazar^a, A. Ali^b, M. Atta^c and S. Amin^d, (1)Psychiatric Nursing, mansoura university, Port Said, Port Said, Egypt, (2)Port Said University, Port Said, other, Egypt, (3)Mansoura University, Mansoura, Other, Egypt, (4)Alexandria University, Alexandria, other, Egypt, (5)Damanhour University, Damanhour, other, Egypt

Background: Caregiving for children with autism spectrum disorder (ASD) is a challenging role that often imposes a significant psychological and emotional burden on parents. The stress experienced by these caregivers can arise from various sources, including the high demands of caregiving, family-related concerns, and financial strains. As children with ASD often require specialized care and support, caregivers frequently face difficulties in managing the associated responsibilities, leading to elevated stress levels. Furthermore, the unique behavioral, social, and communication challenges presented by children with ASD can exacerbate feelings of frustration and helplessness among caregivers. Therefore, understanding the factors that can mitigate caregiver stress is of paramount importance to enhancing the well-being of these individuals. Previous studies have identified that psychological resources, such as resilience, hope, optimism, and self-efficacy, play a pivotal role in reducing stress levels among caregivers. Psychological Capital, which encompasses these four key dimensions, has been shown to buffer against stress and improve mental health outcomes. Additionally, the concept of Family Sense of Coherence, which refers to the family's ability to perceive life events as comprehensible, manageable, and meaningful, has been associated with positive mental health and reduced stress in various caregiving contexts. However, limited research has explored the combined impact of these two constructs—Family Sense of Coherence and Psychological Capital—on caregiver stress, particularly in the context of caring for children with ASD.

Objectives: This study investigates the interplay between Family Sense of Coherence, Psychological Capital and caregiver stress in this context.

Methods: A total of 205 caregivers of children with ASD participated in this cross-sectional study. Data were collected on Family Sense of coherence, Psychological Capital (encompassing hope, resilience, optimism and self-efficacy) and caregiver stress. Structural equation modelling was employed to test the mediation effect of psychological capital between family sense of coherence and caregiver stress.

Results: The results indicated a strong positive correlation between family sense of coherence and all subdomains of psychological capital, with coefficients ranging from 0.541 to 0.610. Conversely, psychological capital demonstrated significant negative correlations with various domains of the Kingstone Caregiver Stress Scale, including caregiving, family issues and financial issues (coefficients from -0.443 to -0.427). Furthermore, family sense of coherence showed a direct negative effect on stress ($\beta = -0.384, p < 0.001$). Notably, the study revealed a significant mediating role of psychological capital in the relationship between family sense of coherence and caregiver stress, with an indirect effect of family sense of coherence on stress through psychological capital ($\beta = -0.127$). The findings underscore the crucial role of family sense of coherence and psychological capital in enhancing psychological resources and mitigating stress among caregivers of children with ASD.

Conclusions: These results suggest that interventions aimed at strengthening family coherence and building psychological capital could be effective strategies in alleviating stress among caregivers of children with ASD. Healthcare professionals should consider incorporating family coherence approaches and psychological capital techniques in their support programs for these caregivers.

427.074 The Relationship between Early Child Temperament and Parenting Stress in Young Children with Autism Spectrum Disorder: Changes over a 12-Month Period

T. L. Lin^a, S. P. Hung^a, H. Y. Hung^a and C. H. Chiang^a, (1)Institute of Behavioral Medicine, National Cheng Kung University, Tainan City, Taiwan, (2)Center of Teacher Education, National Cheng Kung University, Tainan City, Taiwan, (3)Department of Nursing, National Cheng Kung University, Tainan City, Taiwan, (4)Department of Psychology, National Chengchi University, Taipei, Taiwan

Background: Autism Spectrum Disorder (ASD) is a highly heterogeneous neurodevelopmental condition, and parents of children with ASD often experience elevated levels of parenting stress, which can vary based on the severity of symptoms and children's developmental level. While temperamental factors are recognized as important contributors to individual differences and influences on parenting stress in typically developing children from an early age, research on parenting stress in ASD has rarely explored the impact of early child temperament, particularly in longitudinal studies. Understanding these factors could inform interventions and support for families.

Objectives: This study aims to examine changes in the relationship between early child temperament and child-related parenting stress in young children with ASD over 12 months, while controlling for children's developmental level and ASD symptom severity.

Methods: A total of 35 young children with ASD (mean age = 34.40 months) and their parents participated. Data were collected at three timepoints (T1, T2, and T3) over two 6-month intervals. Early child temperament (negative affectivity, effortful control, surgency/extraversion) was assessed at T1 using the Early Childhood Behavior Questionnaire (ECBQ), and child-related parenting stress was measured at all timepoints using the Parenting Stress Index, Third Edition (PSI-3). Children's developmental level (developmental quotient [DQ]) was assessed at all timepoints using the Mullen Scales of Early Learning (MSEL), and ASD symptom severity (calibrated severity score social affect [CSS-SA] and restricted and repetitive behaviors [CSS-RRB]) was measured at all timepoints using the Autism Diagnostic Observation Schedule (ADOS). Hierarchical regression analyses assessed the contributions of child temperament to parenting stress over time.

Results: After controlling for developmental level and ASD symptom severity, hierarchical regression revealed that at T1, both DQ and negative affectivity significantly predicted parenting stress ($p = .026$ and $.004$, respectively), with temperament variables accounting for 24% of the variance (Step 1, $R^2 = .241, p = .034$; Step 2, $\Delta R^2 = .238, p = .013$). At T2, negative affectivity was the sole significant predictor of parenting stress ($p = .005$), with temperament variables contributing 32% of the variance (Step 1, $R^2 = .064, p = .555$; Step 2, $\Delta R^2 = .323, p = .007$). At T3, both CSS-RRB and negative affectivity significantly predicted parenting stress ($p = .018$ and $p < .001$, respectively), with temperament variables accounting for 38% of the variance (Step 1, $R^2 = .168, p = .121$; Step 2, $\Delta R^2 = .375, p = .001$).

Conclusions: This study underscores the importance of considering child temperament in understanding parenting stress among parents of young children with ASD. The findings reveal a growing influence of temperament on parenting stress over time and indicate a consistent impact of emotion-regulation-related aspects of temperament on parenting stress, independent of developmental level and ASD symptom severity. Moreover, factors affecting parenting stress may change over time: initially, parents may be more concerned with developmental delays, while later stress may stem more from children's restricted and repetitive behaviors. Targeted interventions that consider temperament and adapt to evolving concerns are needed to better support families of young children with ASD.

427.075 The Relationship between Parental Self-Efficacy and Parent-Child Relationships: The Moderating Roles of Family-Based Factors

W. C. So, Educational Psychology, The Chinese University of Hong Kong, Hong Kong, NA, Hong Kong (China)

Background: It is challenging for parents to establish and maintain positive relationships with their autistic children (e.g., McDaniel, 2005), which is important for the children's developmental competence. Since parent-child relationships (PCR) are influenced by parental self-efficacy (PSE) in families with neurotypical children (Coleman and Karraker, 1998), it is crucial to understand how PSE influences the parent-child relationships PCR in autism families, given that parents play a crucial role in training their autistic children. Yet, such issue is understudied in the literature. Additionally, through identifying the protective and risk factors moderating the relationship between PSE and PCR, therapists would have better ideas which families would have a higher risk of having relatively poor PCR at a certain level of PSE.

Objectives:

The present study aimed to investigate the relationship between PSE and PCR, and more importantly, the potential protective factors and risk factors that could moderate such relationship. Given family is viewed as a system composed of interrelated parts (e.g., main caregiver, spouse, children; Bowen, 1978), the potential moderators were autistic children's behavioral problems, parent's endorsement of stigma toward autism, and the support provided by the parent's spouse. We hypothesized that PSE would be positively associated with PCR (H1) and risk factors (behavioral problems and endorsement of stigma) would weaken the PSE's impact of on PCR, while protective factors (spouse support) would strengthen it (H2).

Methods:

A community sample of Chinese caregivers of autistic children (N=198; 180 mothers; mean age=40.23, SD=6.49; median income=USD3750-6250) who were attending routine parent and child interventions participated. Their children's (mean age=6.43, SD=2.17; male-to-female ratio 3.21:1) autism diagnoses were confirmed. Caregivers completed the Chinese Versions of the Parenting Sense of Competence Scale (C-PSOC; Yang et al., 2014), Child-Parent Relationship Scale (CPRS; Zhang & Chen, 2010), Endorsement of Autism Stigma (KAS-C; Yu et al., 2020), Conners Parent Symptom Questionnaire, Chinese Version (PSQ-C; Su et al., 2001), and Experiences in Close Relationship Scale (ECR-CS; Zhao & Hao, 2019).

Results:

All variables were centered. Each model had PSE, the predictor, PCR, the criterion variable, and a hypothesized moderator. PSE significantly and positively predicted PCR ($ps < .001$). Behavioral problems (conduct problems, impulsivity-hyperactivity, hyperactivity) negatively predicted PCR, $Bs \geq -.38$, $SEs \geq .10$, $ps < .0003$ while lack of endorsement of autism stigma positively predicted PCR, $B = 1.75$, $SE = .56$, $p < .002$. Only the interactions of PSE and behavioral problems (psychosomatic problems¹) and lack of endorsement of autism stigma² were statistically significant (¹ $B = -.08$, $SE = .02$, $p < .001$; ² $B = .11$, $SE = .05$, $p < .04$). Figures 1 and 2 show the patterns. PSE and PCR relationship was weakened when there were more psychosomatic problems. In contrast, the relationship between these two variables was strengthened when parents tended not to endorse the autism stigma.

Conclusions: Our first hypothesis was supported, and second hypothesis partially supported. Chinese parents' lack of endorsement of autism stigma appears to serve a protective role for parent-child relationships, while autistic children's psychosomatic problems serve as a risk factor. Toward that end, our study reveals important avenues for supporting Chinese parents of autistic children, such as delivering an intervention for helping them understand autism and accept their children.

427.076 The Role of Burnout on Early Intervention Providers' Self-Efficacy Delivering Evidence-Based Parent-Mediated Interventions

M. S. Valdivia Acosta¹, N. Islam², J. L. Kuhn³ and K. Pickard¹, (1)Emory University School of Medicine, Marcus Autism Center, Atlanta, GA, (2)Marcus Autism Center, Children's Healthcare of Atlanta, Atlanta, GA, (3)Pediatrics, Boston Medical Center, Boston, MA

Background:

Part C Early Intervention (EI) systems serve a large number of toddlers with or at high likelihood of autism. Although EI systems provide a critical access point to services and have been a focal point of implementation efforts, intervention quality is variable.¹ Early intervention quality may be driven by providers' varied backgrounds and experiences,² in addition to turnover and other internal challenges, such as emotional exhaustion^{3,4} and burnout.^{3,4} However, limited work has been conducted on the role of burnout in providers within early autism intervention service systems. Our study attempts to bridge this gap by examining factors that drive EI provider burnout and the impact of burnout on the implementation of an evidence-based parent-mediated intervention, Project ImPACT.⁵

Objectives:

- (1) How do provider characteristics and support systems predict EI provider burnout?
- (2) How does EI provider burnout relate to their self-efficacy delivering Project ImPACT?

Methods:

Preliminary data from the current study comes from an ongoing contract with Georgia's Department of Public Health and Part C system. Sixty-nine participating EI providers were trained in Project ImPACT, an evidence-based parent-mediated intervention supporting social communication skills in toddlers with autism.⁵ Prior to training, providers completed measures of (1) demographic characteristics, including years of experience in the EI field and age, (2) providers' sense of cohesion⁸ and organization support,⁹ and (3) burnout and strain.⁶ Post training, providers completed measures of (1) their self-efficacy delivering Project ImPACT⁵ and (2) their attitudes towards Project ImPACT.⁷ Research staff kept records of providers' training participation as measured by percent attendance in training activities. Linear regression models were calculated using R Studio and SPSS to evaluate the extent to which provider characteristics predicted variance in EI providers' reported burnout and self-efficacy delivering Project ImPACT.

Results:

Although provider burnout was related to perceptions of organizational support ($\beta = -0.66$; $p = 0.03$), provider age, sense of cohesion, and years of experience in the EI field were not. The full regression model did not explain a significant amount of the variance in EI provider burnout ($F(4,14) = 1.590$, $R^2 = 0.312$; $p = 0.23$). Similarly, although providers' years of EI experience related to their sense of self-efficacy in delivering Project ImPACT ($\beta = 0.60$; $p = 0.03$), providers' age, sense of cohesion, burnout, and organizational support did not. The full model also did not predict a significant amount of the variance in Project ImPACT self-efficacy ($F(5,13) = 1.285$; $p = 0.33$).

Conclusions:

Preliminary findings revealed that higher levels of perceived organizational support were associated with lower burnout among EI providers. Additionally, years of experience in EI was associated with higher self-efficacy delivering Project ImPACT. Linear regression models evaluating the role of several provider characteristics on provider burnout was not significant, nor was a model evaluating the role of burnout on provider self-efficacy. Further analyses will include a larger sample of providers and the relationship between burnout, training participation, attitudes, and Project ImPACT fidelity. Study limitations and implications will be discussed.

427.077 The Role of Meta-Dehumanization and Autistic Community Connectedness on Autistic People's Mental Health

M. Botha, *Psychology, Durham University, Durham, Durham, United Kingdom*

Background: Dehumanization is a process by which a person or a group of people are denied human uniqueness or human nature by another person or group of people whereby they are considered as literally sub-human – more as a robot (mechanistic) or animal (animalistic) than person (Haslam, 2006). Previous research has identified that non-autistic adults dehumanize autistic people, including denying them human uniqueness (traits which distinguish human-animals from non-human animals) (Cage et al 2019), but to date, there has little to no research investigating the impact of such dehumanization on autistic people. Meta-dehumanization refers to the concept that a person or group perceives themselves to be dehumanized (Bustillos et al., 2023), and it predicts significantly worse personal and interpersonal outcomes for victims of dehumanization (Bastian & Haslam 2011; Čehajić et al, 2009). For autistic people, it might contribute to the drive they experience to “mask” autistic traits, so as to avoid dehumanization – yet masking is associated with poor mental health and suicidality (Miller et al, 2021) – and so also compound the effect. Lastly, autistic people experience a seemingly unique rapport with other autistic people with autistic community connectedness potentially buffer against some of the effects of discrimination on mental health (Botha 2020).

Objectives: Give this, the aim of this study was to investigate whether 1) autistic people experience higher meta-dehumanization and worse mental health than non-autistic 2) masking mediates the relationship between meta-dehumanization and poor mental health outcomes in the autistic cohort, and 3) whether autistic community connectedness moderates the relationship between meta-dehumanization and masking in the autistic cohort.

Methods: A cross-sectional purposive-sampling study with autistic ($n=149$) and non-autistic people ($n = 99$) was employed. Measures of meta-dehumanization, masking, mental health, and autistic masking were administered.

Results: Autistic people ($M = 32.6$, $SD = 8.74$) experienced significantly meta-dehumanization than non-autistic people ($M = 19.5$, $SD = 8.33$), ($t(246) = 11.75$, $p < 0.001$). Autistic people ($M = 21.7$, $SD = 7.1$) also experienced worse mental health than non-autistic people ($M = 16.7$, $SD = 6.13$); ($t(246) = 5.78$, $p < 0.001$) For the autistic group, the results show that meta-dehumanisation significantly positively predicts worse mental health ($\beta = 0.37$, $t = 4.9$, $p < 0.001$). When including masking behaviour (mediator) into the model, the effect of meta-dehumanisation on mental health did not change ($\beta = 0.31$, $t = 3.96$, $p < 0.001$) Mediation analysis via bootstrapping revealed a significant indirect effect of masking behaviours on the association between meta-dehumanisation and mental health (mean bootstrapped indirect effect = 0.07, with a 95% confidence interval between 0.02 and 0.13, $R = 0.44$, $R^2 = 0.2$). Autistic community connectedness had a significant direct effect on mental health through belongingness with higher belongingness predicting better mental health ($p = .01$), but no moderation effects.

Conclusions: masking and mental health may be in part driven by perceived dehumanization, while belongingness to the autistic community predicts better mental health, it does not buffer against the impact of meta-dehumanization on mental health for autistic people.

427.078 The Roles of Communal Coping and Social Support in Family Functioning According to Primary Caregivers of Autistic Youth

R. L. Harmon¹, **O. F. Ward^{1,2}**, **L. K. Baker³** and **T. S. Tomeny¹**, (1)Psychology, The University of Alabama, Tuscaloosa, AL, (2)Department of Psychology, The University of Alabama at Birmingham, Birmingham, AL, (3)Hassenfeld Children's Hospital at NYU Langone, New York, NY

Background: “Family functioning”, commonly understood as the way in which families interact and operate (Crindland et al., 2014), has generally been found to be poorer among families of autistic individuals compared to families of non-autistic individuals (e.g., Pisula & Porebowicz-Dörsmann, 2017). Factors that have been identified to influence caregivers’ perceptions of family functioning, specifically within families of an autistic individual, include parental gender (e.g., Gau et al., 2012), marital status (e.g., Johnson & Simpson, 2013), socioeconomic status (e.g., Zaidman-Zait et al., 2018), and autistic child’s behaviors (e.g., Brown et al., 2019). Given a greater focus on including family members, especially caregivers, in autism-focused interventions (e.g., Crindland et al., 2013), understanding factors that may influence family functioning and how they interrelate is becoming increasingly important.

Objectives: The present study aimed to explore how primary caregiver distress, communal coping during family challenges (i.e., communal coping), and social support relate to overall family functioning within families of autistic youth.

Methods: 106 primary caregivers ($M_{age} = 41.4$; 87% biological mothers; 88% female, 85% White, 77% married) of autistic youth ($M_{age} = 11.47$; 87% male; 82% White) completed an online or paper survey. Primary caregivers reported demographic information related to themselves, their autistic child, and their family in addition to completing measures assessing their overall distress (i.e., DASS-21; Lovibond & Lovibond, 1995), communal coping (i.e., The “communal coping during family challenges” scale; adapted from Afifi et al., 2015), social support (i.e., Multidimensional Scale of Perceived Social Support; Zimet et al., 1988), and family functioning (i.e., McMaster Family Assessment Device; Epstein et al., 1983). Primary caregivers also completed measures assessing their autistic child’s overall severity of symptoms and broadband adjustment.

Results: Linear regression analyses using The PROCESS tool (Hayes, 2018) for SPSS revealed significant direct and total effects of overall primary caregiver distress on family functioning (i.e., higher scores indicated poorer family functioning) across both models. When examining communal coping as a mediator, analyses also revealed a significant indirect effect of primary caregiver distress on family functioning through communal coping (see Figure 1). Similarly, when examining social support as a mediator, analyses revealed a significant indirect effect of primary caregiver distress on family functioning through social support (see Figure 2). However, significant direct effects of primary caregiver distress on family functioning remained when probing for each mediator, indicating that communal coping and social support may partially explain the relationship between primary caregiver distress and family functioning. All results were controlling for autism symptom severity and broadband adjustment of the autistic child.

Conclusions: Results reiterate that primary caregiver distress relates to poorer family functioning. Additionally, results indicate that both communal coping and social support may mediate this relation between primary caregiver distress and family functioning, providing additional points of intervention to improve family functioning among families of autistic youth. More specifically, family-based interventions should focus on increasing effective communication and coping efficacy among families and bolstering social support for caregivers in hopes of improving overall family functioning and autistic child outcomes.

427.079 The Social Impact of Experiences with Strength-Based Inclusive Employment: Autistar's Influence on Public Attitudes Toward Autistic People

H. Park¹, **S. Lee²**, **S. Y. Kim³** and **J. Na⁴**, (1)AUTISTAR, Seoul, Korea, Republic of (South), (2)Special Education, EWha WOMANS UNIVERSITY, Seoul, Korea, Republic of (South), (3)Korea University, Seongbuk-gu, Seoul, Korea, Republic of (South), (4)Special Education, Ewha Womans University, Seoul, Korea, Republic of (South)

Background: Social inclusion and connectedness are critical determinants of the quality of life for all individuals, including those with disabilities. However, people with disabilities often face exclusion and marginalization due to persistent prejudice and negative societal attitudes. Autistic people, who frequently experience challenges in social communication, are particularly vulnerable to such exclusion. Exploring public experiences with autistic individuals can help identify strategies to reduce social distance and improve community acceptance. Recently, AUTISTAR, a South Korean design company that employs autistic designers and provides strength-based, individualized support, has gained recognition as a successful employment model that may positively influence public perceptions of autism.

Objectives: This study aimed to assess how experiences with AUTISTAR influence social distance and public attitudes toward autistic people.

Methods: We used a mixed-methods design comprising an online survey and focus group interviews (FGIs). The online survey assessed social distance toward autistic people and familiarity with AUTISTAR among three subgroups (no exposure, some familiarity, and high familiarity), with a total of 138 participants (46 per group). For quantitative data, t-tests were used to examine associations with gender and having a family member with a disability, correlational analysis for age, and ANOVA for familiarity with AUTISTAR to explore how these factors were associated with social distance toward autistic people. Additionally, FGIs were conducted with 11 participants purposefully recruited for their extensive contact with and familiarity with AUTISTAR. These interviews included open-ended questions on their experiences with AUTISTAR and its autistic employees. Content analysis was used to examine participants' interview responses.

Results: The quantitative analysis revealed no significant differences in social distance based on age, gender, or having a family member with a disability (all p s > 0.05). However, prior familiarity with AUTISTAR was significantly associated with social distance ($p < 0.0001$), with post-hoc tests indicating that participants familiar with AUTISTAR reported lower levels of social distance compared to those with no or limited familiarity. Furthermore, 96% of respondents viewed AUTISTAR positively, suggesting a favorable perception of its employment model and its potential role in promoting positive attitudes toward autistic individuals. Qualitative findings showed that participants with experience in AUTISTAR recognized its positive impact on autistic people, their families, and the broader community through strength-based employment support. They reported a decrease in social distance, attributing this to positive interactions and an increased understanding of autistic individuals' abilities. Before their experiences with AUTISTAR, participants often held negative or indifferent views about autistic people. However, after interacting with AUTISTAR, they observed that autistic people could contribute meaningfully to the community when provided with appropriate support. Participants expressed confidence in working alongside autistic individuals and supporting their community participation.

Conclusions: The findings suggest that AUTISTAR may reduce social distance toward autistic people by providing opportunities for the public to engage with autistic individuals in meaningful ways, challenging misconceptions about their abilities, and highlighting their strengths. Reducing social distance and stigma requires both frequent and high-quality interactions, which can be promoted through inclusive employment and community activities to foster a more accepting society.

427.080 The State of Affairs of Existing Service Outcome Measure According to Autistic Adults, Service Providers and Academic Researchers: What to Improve and How to Do It

R. Caldwell¹, **M. J. Baker-Ericzen**², M. Scharer³, I. Moura⁴, R. K. Schuck⁵, J. Maslak⁶, S. K. Kapp⁷, A. Joyce⁸ and C. Nicolaidis⁸, (1)San Diego State University Research Foundation, San Diego, CA, (2)Administration, Rehabilitation and Post-Secondary Education, San Diego State University, San Diego, CA, (3)Academic Autism Spectrum Partnership in Research and Education, Portland, OR, (4)Lurie Institute for Disability Policy, Brandeis University, Waltham, MA, (5)Department of Psychiatry and Behavioral Sciences, Department of Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA, (6)Academic Autism Spectrum Partnership in Research and Education (AASPIRE), Portland, OR, (7)School of Psychology, Sport and Health Sciences, University of Portsmouth, Portsmouth, Hampshire, United Kingdom, (8)School of Social Work, Portland State University, Portland, OR

Background:

Although autism research for autistic adults has proliferated over recent years there remains a critical void in outcome measurement tools that are accessible, understandable, and usable by the autism community. The majority of instruments used in services and research programs were not developed for nor with autistic adults. This contributes to a higher likelihood that instruments do not function as intended, and this may also introduce measurement bias leading to inaccurate ratings.

Objectives:

The current study aimed to address the following research questions:

- (1) What are the common problems of existing measurement tools according to stakeholders?
- (2) What types of measurement adaptations address these issues?

Methods:

Researchers from the longstanding AASPIRE team used a community-based participatory research (CBPR) approach throughout the project. We collected and combined data from three related sources: 1) surveys from a CBPR-nested Delphi process with 52 participants, including autistic adults, leaders from community organizations, healthcare systems, disability service systems, and academic researchers (categories not mutually exclusive), who reviewed a set of existing measures that assess high priority outcomes for the autism community 2) an institutional ethnography of workgroup meeting notes and artifacts from the AASPIRE 22-member team process adapting or creating a set of 22 instruments; and 3) Cognitive Interviews with 37 autistic adults. Delphi survey responses were calculated per endorsed problem type: 1) autism-related issue, 2) problematic language, 3) accessibility, 4) understanding construct difficulties and 5) usability issues. Participants were given the option to say no issues were present, select types of issues, or state an issue using an open-ended response. Transcripts and field notes from meetings were coded to identify recommended adaptations. After adapting or creating a set of 22 instruments, we conducted cognitive interviews to assess the instruments' content validity and determine what additional changes might be needed. This iterative process continued until all measures were considered accessible, understandable, and usable.

Results:

52 Delphi panelists reviewed 51 potential measures for 26 outcomes, and identified challenges across the measurement tools, indicating a variety of concerns (see Table 1 for full list of response options). The most frequently endorsed concerns were adaptability (n=324 reported issues; e.g. clarify instructions), accessibility issues (n=317 reported issues; e.g., confusing terms or imprecise response options) and autism-specific issues (n=197 reported issues; e.g., failing to capture autism-related aspects of constructs). No measure was exempt from issues; the majority of participants indicated that every measure would need at least minor adaptations to be usable in one or more identified challenge area. Based on this feedback, we adapted or created twenty-two measures. Workgroup meetings and cognitive interviews identified 15 specific recommendations for adaptations, such as visual aids response options, hotlinks with definitions and examples, and simplified language (see Table 2 for full list of adaptations).

Conclusions:

Results from this study indicate the pervasive issues in accessibility and functionality when using measures that are not designed with a CBPR approach. These conclusions have wide-ranging implications across research and services, emphasizing the importance of meaningful inclusion of target populations when creating outcomes measures.

**427.081 The Struggle for Meaningful Employment Among Autistic Adults in Canada**

G. Pontarollo¹, N. G. Van Esch² and N. E. Scheerer², (1)Wilfrid Laurier University, Mississauga, ON, Canada, (2)Psychology, Wilfrid Laurier University, Waterloo, ON, Canada

Background: The employment rate for autistic individuals in Canada is estimated to be below 15%, leaving many either unemployed or underemployed. With most services and supports for autistic individuals ending at age 18, the difficulty in securing stable employment significantly jeopardizes the quality of life for both autistic adults and their caregivers, further marginalizing an already vulnerable population.

Objectives: This study aims to understand the experiences of autistic adults in employment settings in Canada, while exploring factors that might relate to the staggering low employment rate for autistic people.

Methods: Twenty participants between the ages of 19 and 53 years (Age M(SD) = 35.12 (11.73) years; 9 males, 11 females) from Ontario, Canada took part in semi-structured interviews that explored their employment related experiences. Autistic traits were assessed with the Autism-Spectrum Quotient with scores ranging from 23-41 (AQ M(SD) = 30.56 (4.51)). Report of participant's highest level of education indicated that 10 participants had post-secondary degrees, 3 were currently pursuing post-secondary degrees, 6 completed high school, and 1 had some high school. During the interview participants provided information regarding their job history; their experiences in the workplace; their thoughts on their future employment; and accommodations received at the workplace.

Results: Across the participants interviewed, 6 were currently employed full-time, 5 were employed part-time, 3 were seeking opportunities, 3 were students, 1 was a stay-at-home parent, and 1 was on long-term disability. In terms of the employment positions reported, the majority of the jobs described were in retail (e.g., clothing or grocery stores), food service (e.g., barista, fry-cook, etc.), or entry-level administrative positions (e.g., receptionist, file clerk, etc.), with only 3 participants reporting employment related to their education or specialized skills (e.g., IT consultant, marketing manager, learning consultant). The average duration of employment ranged from one day to 20+ years, with only 4 participants reporting steady employment for more than 5 years. When participants were asked to rate their confidence in their ability to keep a job, the average rating was 55.7% (SD = 30.8%) confident. When asked about accommodations received in the workplace, 10 reported receiving no accommodations. For those who did report accommodations, they included flexible hours, noise cancelling headphones, breaks, patience from employers, remote work, and personalized support.

Conclusions: This study highlights the grim reality of employment for autistic adults in Canada. Despite many participants being well-educated, with half holding post-secondary degrees, meaningful employment remained elusive for most. The majority of jobs held were low-wage, entry-level positions in retail, food service, or administration, with only three individuals employed in roles related to their education. Confidence in job retention was also low, with an average self-rated confidence of just over 55%. Additionally, half of the participants reported not receiving any workplace accommodations, further illustrating the systemic barriers that prevent autistic individuals from securing and maintaining meaningful employment. This bleak landscape underscores the need for more inclusive and supportive workplace environments for autistic people, particularly those with higher education.

427.082 The Views and Experiences of Autistic Adults Regarding Early Autism Interventions: A Systematic Review, Thematic and Descriptive Narrative Syntheses

E. Nosova¹, K. Leadbitter², N. Humphrey³ and A. Sturrock⁴, (1)Manchester Institute of Education, University of Manchester, Manchester, Lancashire, United Kingdom, (2)University of Manchester, Manchester, UNITED KINGDOM, (3)University of Manchester, UK, Manchester, United Kingdom of Great Britain and Northern Ireland, (4)Human Communication, Hearing and Development, The University of Manchester, Manchester, United Kingdom

Background: In the last two decades, autistic adults have become more and more involved in different areas that affect autistic people's lives. The idea that autistic voices should be heard when discussing autism research is consistent with overall values in healthcare, research and education (e.g. Patient and Public involvement in healthcare). However, the research on early autism interventions typically focuses on parental views and priorities, and the perspective of autistic people has not been asked until very recently. Autistic people expressed concerns regarding the potential of specific types of interventions to cause harm and voiced their priorities on intervention goals. New studies are constantly emerging, and this systematic literature review aims to synthesise the latest evidence. To our knowledge, this is the first systematic literature review on the topic.

Objectives: To identify and synthesise the evidence regarding views and experiences of autistic adults regarding psychosocial early interventions for autistic children, including specific intervention goals, practices and contexts.

Methods: Four electronic bibliographic databases (Web of Science Core Collection, Education Resource Information Centre, Education Database and PsycInfo) were searched together with additional search strategies: reference searching and cross-checking via Google Scholar. Quality appraisal was performed using the Quality Assessment with Diverse Studies (QuADS) appraisal tool. 13 studies were identified, 5 quantitative or mixed-methods (all surveys) and 8 purely qualitative. A results-based convergent synthesis design was used: the qualitative and quantitative data were originally treated separately and then cross-checked. Qualitative data was originally analysed using thematic synthesis. Quantitative data was analysed using descriptive narrative synthesis. Goals, practices and context were summarised using textual description and tabulation, and goals were additionally synthesised using data transformation and a visual representation.

Results: Among qualitative studies, three main themes were developed – A child's voice, which explores how the interventions can take into account the child's perspective, Accept our disability, which combines autism acceptance with acknowledgement of autistic difficulties and Damage done, which talks about negative experiences of autistic people who underwent early autism interventions. In quantitative studies, autistic people consistently rated quality of life and reducing harmful behaviours as the top priorities for the interventions and goals involving reducing autism symptoms as the lowest priorities. Overall, the findings between quantitative and qualitative studies were consistent. More studies are needed about intervention practices and contexts, as well as studies that ask autistic adults with higher support needs.

Conclusions: Across the studies, autistic adults consistently emphasised the need to consider the child's inner perspective, as well as making the early interventions autism-affirming. Autistic adults also consistently disagreed with goals that target autism symptoms and discussed their previous negative experiences with early interventions and the impact of those experiences on their lives.

427.083 The Voice of the Autism and Related Rare Genetic Condition Community: Treatment Preferences within the European Autism Genomics Registry (EAGER) Study

C. J. Molloy^{1,2}, K. Jordan³, A. Lautarescu⁴, M. Bloomfield⁵, S. Douglas⁶, M. Absoud⁷, C. Rush⁸, K. Van den Bosch⁹, P. Violland¹⁰, J. R. D. Plas¹¹, A. Ghosh¹², C. O'Neill¹³, M. V. Montiel¹⁴, M. Background: Autism is a prevalent neurodevelopmental condition with a complex genetic basis. Many autistic individuals face unaddressed healthcare challenges that could be informed through genomics research and clinical trials. This includes support for co-occurring conditions, along with autism features. A focus on personalised, multidisciplinary approaches to clinical care in autism and associated rare genetic conditions (RGCs) is necessary to address specific individual needs. Precision medicine approaches informed by specific biological mechanisms may benefit individuals with a known genetic etiology.

Objectives: To understand the key health and developmental concerns among autistic individuals and individuals with related RGCs, and identify participant reported priorities for target interventions, which will help to inform future research and clinical trials.

Methods: The European Autism GENomics Registry (EAGER) aims to create a registry of up to 1,500 autistic individuals and individuals with RGCs associated with autism across 13 sites, who will all have undergone whole-genome sequencing. Medical history and development were assessed using a set of questionnaires, completed either by participants themselves or by their parents, depending on age and ability. The Voice of the Community questionnaire was used to examine current health and developmental concerns, their impact on participants, and participant preferences for target interventions.

Results: Preliminary results were based on a UK sub-sample from two EAGER sites (King's College London, KCL, and Guy's and St Thomas', GSTT) included in the current descriptive analysis. To date, 31 autistic (mean age = 28.9 ± 21.0 SD; gender = 20 male: 11 female) and 28 RGC (mean age = 12.3 ± 7.3 SD; gender = 11 male: 17 female) have taken part in the study (Table 1). Greater than half of the autistic group reported developmental and health concerns related to difficulty with social interaction (77.4%), anxiety (77.4%), sensory issues (71.0%), attention issues (64.5%) and sleep problems (61.3%), while the RGC respondents, 65.5% of whom had Tuberous Sclerosis Complex (TSC), reported highest concerns related to intellectual disability or learning delays (67.9%), attention issues (53.6%) and epilepsy/ seizures (57.1%). The top three target interventions reported as important to the autistic group were to improve mood irritability or anxiety (41.9%), sleep (32.3%), and social interaction abilities (29.0%), while learning and cognitive ability (46.4%), seizures (35.7%) and speech and language (28.6%) were the highest priority for target interventions for the RGC group (Table 2).

Conclusions: We report preliminary data on a sub-sample of the EAGER cohort, which suggest that there are differences in reported concerns and intervention preferences between the autistic and RGC cohorts. It is critical to note that the majority of the RGC cohort to date is comprised of a single condition, TSC, warranting caution in generalising treatment target priorities to other RGC communities. The full cohort from 13 sites will be added for further analysis to understand health and developmental concerns and establish priorities for target therapeutics for a European autism and RGC cohort. The EAGER registry will support recruitment for future clinical trials and studies, leveraging genetic, clinical, and phenotypic data, alongside participant priorities.

427.084 Toward Overcoming the Double Empathy Problem: Bridging Autistic and Neurotypical Minds through Science and Art
G. J. Cardon, Communication Disorders, Brigham Young University, Provo, UT

Background:

The *Double Empathy Theory* proposes that empathy gaps between autistic and neurotypical (NT) people arise from breakdowns in *mutual* consensus, rather than failures by autistic people. Unfortunately, empathy gaps are linked to myriad personal and societal challenges. Thus, improving cross-neurotype connection could result in greater compassion and inclusion, impacting autistics and NTs alike.

All people experience challenges with various types of stress and reactivity when faced with social and environmental demands. The degree of such reactivity varies by context. Common high-demand scenarios might include public speaking and high-stakes conversations, among others. However, some, including many autistic people, experience elevated reactivity to situations typically considered less demanding (i.e., classroom, grocery store, library, etc.). By drawing on their own patterns of reactivity during demanding situations, NT individuals might more readily empathize with autistic persons' reactions to seemingly less extreme scenarios.

Objectives:

Thus, we scientifically examined overlaps in reactivity to common scenarios between autistic and NT individuals, hypothesizing that commonalities would occur across different, not within the same, scenarios. Then, we worked with artists to translate scientific findings into artistic representations of the thoughts, feelings, and experiences (i.e., "minds") of autistic and NT people. We propose that allowing autistic and NT people to "see" each other's minds side-by-side, via artistic depictions, could facilitate greater autistic-neurotypical empathy.

Methods:

Phase 1 (Quantitative): Participants were 35 autistic individuals (17 female) and 300 NT people (150 female), ages 18-26. Each subject completed a survey, which included an original questionnaire consisting of questions about their reactivity to eight scenarios, each differing in its level of social/environmental demand. The survey also included standardized questionnaires, measuring sensory processing, mental health, and autistic traits. Statistical analysis included: i) Between-group comparisons of reactivity scores within- and between-scenarios; ii) correlational analysis between standardized and scenario questionnaire scores.

Phase 2 (Qualitative): We conducted semi-structured interviews with six autistic and six NT young adults (3 male/3 female, respectively). Interviews explored participants' experiences with comfortable and uncomfortable social interactions and environments. We then performed thematic analysis.

Finally, we collaborated with four illustrators to convert our findings into artistic representations of the "minds" of autistic and NT participants.

Results:

Phase 1 results showed significant between-group differences in most comparisons of reactivity scores within the same scenario (autistic > NT). In contrast, many similarities were found between scores associated with less intense scenarios in autistic participants vs. those for more demanding scenarios in NT subjects. Phase 2 analyses revealed themes consistent with, yet providing deeper insights into, quantitative findings. Artistic representations of the combined results will be presented and discussed.

Conclusions:

Diagnoses aside, there appear to be common, yet context-dependent patterns of human reactivity. While cross-neurotype empathizing can be difficult, building mutual understanding on inter-group similarities may facilitate this process. Using artistic means, based on scientific findings, to elucidate similarities in reactivity across scenarios simultaneously provides rigorous technical understanding and could encourage viewers to do the hard work of empathy, which, has the potential to improve quality of life, clinical/educational practice, family relationships, and society at large.

**427.085 Train: Trauma Recovery for Autistic, Intellectually Disabled, and Neurodivergent Adults**

A. Layton, J. Bonatakis, K. Hirsch, E. L. Saich and R. Elias, Penn State College of Medicine, Hershey, PA

Background: The impact of Adverse Childhood Experiences (ACEs) is well documented in the research, showing far reaching impacts on physical and mental health throughout the lifespan. However, the impact of ACEs on individuals with autism has not been as thoroughly studied. This lack of research stands in stark contrast to the data that suggests individuals with developmental disabilities may have up to three times the risk of trauma exposure compared to neurotypical peers. As a result of the lack of research on impacts of trauma in autistic individuals, there is a subsequent gap in effective trauma therapies for this population. To address this gap, a training program for licensed therapists was developed to adapt known Trauma-Focused Cognitive Behavioral Therapy (TF-CBT) techniques to use with autistic adults.

Objectives: To develop a training program for licensed therapists who already treat autistic individuals to support the unique needs of this population who have experienced trauma using assessments, measures, and techniques adapted from current evidence-based TF-CBT.

Methods: A 12-week didactic training program was developed combining self-paced learning and instructor-led discussions. At the end of the program, participants complete surveys on their experience with the materials. 6 month follow up surveys are being completed with all therapists who complete the program in order to gather information on their knowledge, attitudes, and potential behavior change.

Results: To date, 73 licensed therapists have completed the 12-week program with 52 of those completing the initial post-training survey. 77% of respondents indicated the program exceeded or greatly exceeded their expectations. 94% of respondents rated the quality of content as above average or exceptional. 96% of respondents rated the quality of the presentation as above average or exceptional. 85% of respondents indicated the program helped them professionally and 100% of respondents would recommend the program to a fellow therapist.

Conclusions: The overwhelming majority of respondents indicated the program materials and content were of high quality and were already of benefit to them in their professional practice. It is important to note that while some respondents did not rate some aspects of the course favorably, they all did indicate they would recommend the program to fellow therapists, highlighting the importance and usefulness they ascribe to the program.

427.086 "It's Part of Me": Exploring Autistic Adolescents' Thoughts & Feelings Towards Their Autistic Identities/ Autism**Diagnoses**

K. E. Sharp¹, C. C. Neuman², J. R. Bertollo³, E. Carel⁴, A. Lopez⁵, M. Taylor⁶, A. Verbalis⁶, L. Kenworthy⁴ and L. Baczewski⁷, (1)Center for Autism Spectrum Disorders, Children's National Hospital, College Park, MD, (2)Center for Autism, Children's National Hospital, Washington, DC, (3)Department of Psychology, Virginia Tech, Blacksburg, VA, (4)Center for Autism Spectrum Disorders, Children's National Hospital, Washington, DC, (5)Children's National Hospital, Washington, DC, (6)Center for Autism Spectrum Disorders, Children's National Health System, Washington, DC, (7)Center for Autism, Center for Autism Spectrum Disorders, Children's National, Washington, D.C., DC

Background: Adolescence is characterized by active and ongoing identity development as individuals make meaning of their lived experiences in the context of their social environment (Jones et al., 2015). Extant studies of autistic identity development highlight that more positive feelings about autistic identity lead to better mental health outcomes for adolescents (Davies et al., 2024; Cooper et al., 2023). Increasingly more studies acknowledge autism as an aspect of identity (Botha & Gillespie-Lynch, 2022), yet relatively few have examined how autistic adolescents feel about their autism diagnoses, and whether they consider autism to be a facet of who they are.

Objectives: The aim of this study was to explore autistic adolescents' thoughts, feelings, and attitudes about their autism diagnosis.

Methods: Sixty autistic teens (Mage = 16.65, SD = 1.18, range = 14.77-18.57; IQ range: 83-141) living in the Washington, D.C metropolitan area participated in semi-structured interviews prior to their participation in an executive functioning intervention. Participants were primarily White (76.7%) and male (70%) and had an average full-scale IQ of 109.78 (SD = 13.58, range = 83-141). All participants were diagnosed with autism according to parent-report, the Social Communication Questionnaire (Rutter, Bailey, & Lord, 2003), and/or met criteria for autism per an expert clinician using DSM-5 criteria (American Psychological Association, 2013) or an ADOS-2 (Lord et al., 2012). Interviews asked the teens to describe their current diagnoses, feelings towards those diagnoses, and whether they disclose their diagnoses to friends or feel comfortable talking about them in social settings. Reflexive thematic analysis (Braun and Clarke, 2006) was used to code the interview responses and generate preliminary themes.

Results: Many teens self-reported having at least one co-occurring diagnosis in addition to autism. ADHD (65%) and anxiety (27%) were the most commonly reported additional diagnoses. Preliminary thematic analysis revealed six emergent themes: 1) The label of 'autism' doesn't feel like me, 2) My diagnosis helps with self-understanding, 3) Connection to neurodivergent community/friends, 4) Weighing and wrestling with how I feel about aspects of my diagnoses, 5) Doubt and/or denial of my autism diagnosis, and 6) Autism is just a part of who I am.

Conclusions: Our findings highlight the heterogeneity among autistic adolescents' thoughts and attitudes about their autistic identities. Some teens describe struggling with the label of autism (many preferring to rely on alternative terms such as Asperger's) and several participants doubted or denied their diagnoses altogether. Others found that their diagnoses helped them understand themselves better or were part of their emerging self-concept. Most teens were engaged in a continual, iterative process of weighing and wrestling with their feelings to make meaning of their autism diagnoses, often comparing the impact of their autism to other co-occurring diagnoses in their day-to-day experiences. Importantly, this study includes autistic adolescents without intellectual disability. Future studies should explore attitudes towards autism diagnosis and identity within an autistic sample with greater diversity in race/ethnicity and IQ.

427.087 Trajectories of Psychological Distress and Life Satisfaction in Parents of Children with Autism from Early Childhood to Late Adolescence

W. Liu¹, P. A. Thompson², K. M. Gray² and R. P. Hastings³, (1)Department of Special Education, Central China Normal University, Wuhan, Hubei, China, (2)School of Social Policy and Society, University of Birmingham, Birmingham, West Midlands, United Kingdom, (3)School of Social Policy and Society, University of Warwick, Birmingham, West Midlands, United Kingdom

Background: The existing evidence on trajectories of wellbeing in parents of children with autism (Barker et al., 2011; Benson, 2016; May & Williams, 2022) is scarce and mixed. Additionally, there are very few studies focusing on both mental health difficulties and mental wellbeing when examining trajectories of wellbeing in parents of children with autism. Moreover, although child behaviors have been demonstrated as important predictors of parental wellbeing, very few studies have considered both between- and within-person effects (Barker et al., 2011).

Objectives: We aimed to examine trajectories of psychological distress and life satisfaction in parents of children with autism between early childhood and late adolescence. Additionally, both between- and within-person effects of child externalizing and internalizing problems, and child prosocial behavior on the trajectories of parental psychological distress and life satisfaction were examined.

Methods: Participants were parents of 636 children with autism (77% male; 89% white; 51% families living in deprived circumstances) drawn from the UK Millennium Cohort Study. Seven waves of data, collected when cohort children aged approximately 9 months, 3, 5, 7, 11, 14, and 17 years, were analyzed. The Kessler 6 (Kessler et al., 2002) was used to measure parental psychological distress. Participants were asked to rate their life satisfaction on a scale of 1 to 10. The Strengths and Difficulties Questionnaire (Goodman, 1997) was used to measure child externalizing and internalizing problems, and prosocial behavior. Data were analyzed using multilevel growth modeling.

Results: Parental psychological distress increased linearly from child ages 3-17 years ($B = .16, SE = .02, p < .001$), whereas parental life satisfaction showed a cubic rate of change, initially decreasing from 3-5 years ($B = -.36, SE = .06, p < .001$), then improving between 5-11 ($B = .11, SE = .01, p < .001$), and returning to decline from 11-14 years ($B = -.01, SE = .00, p < .001$). Regarding the between-person effect of child behaviors, higher average child externalizing and internalizing problems over time were associated with higher initial parental psychological distress at child age 3 years ($B = .25, SE = .05, p < .001$; $B = .32, SE = .05, p < .001$). Higher average child internalizing problems over time were associated with lower initial parental life satisfaction ($B = -.07, SE = .03, p = .044$). At the within-person level, within-child changes in externalizing and internalizing problems were positively associated with within-parent changes in psychological distress ($B = .09, SE = .03, p = .001$; $B = .10, SE = .02, p < .001$); within-child changes in prosocial behavior were positively associated with within-parent changes in life satisfaction ($B = .05, SE = .03, p = .039$).

Conclusions: Across early childhood to late adolescence, psychological distress and life satisfaction in parents of children with autism show differing shapes of change, despite sharing an overall reduced trajectory. Trajectories of psychological distress and life satisfaction in parents of children with autism have distinct sets of child behavior predictors, specifically differing in within- and between-person effects.

427.088 Autism Services for Latinx Children and Their Families: Professionals' Perspectives

L. R. Gomez¹ and A. D. Duenas², (1)University of Florida, Gainesville, FL, (2)Counseling, Educational Psychology, and Special Education, SDSU, East Lansing, PA

Background: Latinx children with autism and their families face significant disparities in accessing autism services, received fewer intervention services compared to non-Latinx White children, and are less satisfied with the services they receive. There are cultural differences, language barriers, and systemic inequities that contribute to these disparities, creating challenges for both families and professionals. There is limited research focusing on professionals' experiences working with culturally and linguistically diverse families, particularly Latinx families receiving autism services. This study aims to explore professionals' perspectives, challenges and needs when working with Latinx children with autism and their families, as well as to review their practices using the Cultural Competence Framework (Cross et al., 1989).

Objectives: The objectives of this study are to (1) examine professionals' experiences working with Latinx children with autism and their families, (2) identify professionals' challenges and needs in delivering culturally responsive services, and (3) explore the process of developing cultural competence among professionals using the Cultural Competence Framework.

Methods: This qualitative study involved interviews with 13 professionals, including speech-language pathologists, early intervention specialists, Board-Certified Behavior Analysts, etc., across two U.S. states. Participants were recruited through early intervention agencies that serve Latinx populations. Interviews were conducted via Zoom, focusing on professionals' practices, challenges, and perceived needs to provide successful services to Latinx families. Data were analyzed using thematic analysis to identify common themes, guided by inductive coding methods and triangulation to ensure reliability and validity. Two coders coded all interviews individually and met frequently to discuss discrepancies and reach consensus.

Results: Four key themes emerged from the data: (1) Navigating Latinx Families' Cultural Beliefs and Values, where professionals reported awareness (or lack of thereof) of cultural differences, and challenges related to these cultural differences such as familismo and mistrust in autism diagnoses and services; (2) Addressing Cultural Mismatches, highlighted the difficulties of providing culturally congruent services, especially due to language barriers and mismatched cultural expectations; (3) Addressing Professional Development and Resource Shortages, revealed a need for more robust training and culturally tailored resources for professionals; and (4) Fluctuations in Cultural Competence, illustrating the continuous developmental process professionals undergo in moving from cultural incapacity to proficiency, with a focus on self-awareness and ongoing professional development.

Conclusions: These findings highlight the importance of culturally responsive training and resources for professionals working with Latinx children with autism. Professionals face several challenges in aligning services with Latinx families' cultural expectations and addressing systemic barriers. The Cultural Competence Framework provides a valuable lens for understanding, analyzing and improving services delivery for Latinx populations, offering pathways for enhancing professional development and bridging cultural gaps in autism care.

427.089 Navigating Work Environments, Education Systems, and Discourses of Disability in Schools: A Reflexive Thematic Analysis of Autistic Educators' Lived Experiences and Perspectives

R. Guo¹, Y. Shen², J. Hinson-Williams³, S. C. LaPointe⁴, R. McKinnon⁴ and K. Bottema-Beutel⁵, (1)Teaching, Curriculum, and Society, Boston College, Boston, MA, (2)Teaching, Curriculum, and Society, Boston College, Chestnut Hill, MA, (3)University of North Carolina-Chapel Hill, TEACCH Autism Program, Carrboro, NC, (4)Lynch School of Education and Human Development, Boston College, Boston, MA, (5)Lynch School of Education and Human Development, Boston College, Chestnut Hill, MA

Background:

Prior research on autistic people's experiences in schools has primarily focused on autistic students' perspectives (Danker et al., 2016; Humphrey & Lewis, 2008). However, researchers have recently begun examining autistic educators' work experiences (StEvans, 2024; Wood & Happé, 2023). Including the perspectives of autistic teachers can bring valuable insights into supporting their well-being and quality of life, which is aligned with the goals of neurodiversity movements (Pellicano & den Houting, 2022).

Objectives:

This reflexive thematic analysis (RTA; Braun & Clarke, 2022) explores autistic educators' lived experiences in their workplaces. Throughout an interactive and recursive process, we (re)construct (Agar, 2021) participants' shared stories of navigating the assumptions and expectations of co-workers and leaders, their contributions to and struggles within inclusive education, perceptions of disability discourses, and positive experiences in their workplace.

Methods:

We conducted semi-structured interviews with eight autistic educators currently working in U.S. schools. We analyzed transcripts as a team of researchers with various experiences working in schools. We systematically engaged with our data, kept a clear memoing record, and met frequently to construct our themes and collectively present a coherent and multilayered narrative. We generated themes through six rounds of data analysis by adapting Braun and Clarke's (2022) RTA approach: initial data familiarization and sense-making; open individual coding; team thematic mapping with flexibly defined codes and initial themes; coding and sorting in pairs of researchers to capture candidate themes with clear central ideas; theme revision and refinement; and theme defining and naming.

Results:

We generated four themes that cut across our participants' work experiences (see Table 1 for example quotes and codes exemplifying each theme). First, their stories illustrated declining respect towards the teaching profession, revealing a systemic-level crisis of teacher agency that likely impacts all teachers, but may more significantly impact autistic teachers. Second, autistic educators' unique contributions to inclusive education were often barricaded by manifestations of neuronormative power relations, such as neurotypical practitioners' dismissal of autistic teachers' neurodiversity-informed support for disabled students. Third, there were pervasive consequences of disability discourses that were detrimental to autistic teachers as well as to students. For example, ableist discussions of students' disabilities discouraged autistic teachers from disclosing their own disability. Fourth, their descriptions of positive work experiences revealed traces of hope, but participants also suggested that higher-level changes occurred due to interest convergence with non-autistic teachers, not necessarily as efforts to improve autistic teachers' work conditions.

Conclusions:

Our participants are passionate educators who made valuable contributions to their schools. The four intertwined themes indicate the complexity of their experiences. Rooted in systems, power relations, and discourses of disability, problems underlying participants' challenges amplified each other. However, participants' positive experiences demonstrated that solutions to those problems exist and that changes can potentially happen. Future researchers, school practitioners, and policymakers should listen to autistic educators to empathize with their experiences and perspectives. All school professionals should reflect on practices and policies to synergically resist ableism and promote positive institutional and systemic changes for a more just work and learning environment.

427.090 Understanding Latinx Autism Community Perspectives on the Puzzle Piece and Infinity Symbol

C. Montiel-Nava¹, J. Abouchard Anaya², A. C. Ramirez¹, V. L. Villarreal³ and C. Navarro³, (1)Department of Psychological Science, University of Texas Rio Grande Valley, Edinburg, TX, (2)University of Texas Rio Grande Valley, Edinburg, TX, (3)Department of Psychological Science, University of Texas Rio Grande Valley, Edinburg, TX

Background: Puzzle pieces have symbolized the Autism community for decades . Recently, however, there has been a growing debate against its use. Autistic self-advocates suggest that a puzzle piece represents an incomplete self (Gernsbacher et al., 2018), heightening stigma against the community. Despite the puzzle piece's global recognition, self-advocates suggest the use of a golden infinity symbol instead. According to self-advocates, the golden infinity symbol represents acceptance and inclusivity, aligning with the neurodiversity movement's values. The rainbow infinity symbol represents neurodiversity as a whole, marking the importance of all neurological conditions. In the context of autism, community-based participatory research is crucial as it fosters collaboration between researchers and communities, ensuring that studies are culturally relevant, address the specific needs of underrepresented groups, and lead to more accessible and impactful interventions for autistic individuals and their families.

Objectives: To examine the Latino Autism community interpretation of the puzzle and infinity symbol as representation of the autism community in a Mexican-US border town.

Methods: Four focus groups (3 with parents of autistic children and 1 with autistic self-advocates) were conducted by two bilingual trained facilitators following a script informed on previous literature. These comprised 25 parents of children on the spectrum and 8 autistic adults, and happened between March and May 2023. Audio recordings were transcribed for later analysis using thematic analysis. Three independent coders reviewed the transcripts, identifying different themes and subthemes. After comparing findings, they reached a consensus on the common subjects. Data was abstracted from a larger project focusing on predictors of language development in autistic children.

Results: The qualitative analyses of the self-advocates' responses noted that the puzzle piece, although not joint to anything else, still represents a functional person. Whereas the use of the infinity symbol acknowledges the neurodiversity community as a whole, and it shows awareness on the researchers behalf. Parents had no negative connotation of the puzzle symbol, and regarded that seeing it heightened their sense of belonging.

Additionally, they noted that it represents a community.

Conclusions:

Overall, the community's interpretation of both symbols is positive, and they encourage the use of both to foster a sense of belonging and inclusivity. This study highlights that the notoriety of the puzzle piece is acknowledged and should not be entirely discarded from outreach efforts, particularly when engaging with Latinx communities. In the Rio Grande Valley, a region located in the U.S.- Mexico border which has been historically underserved with limited access to services and education, outreach efforts rely heavily on the implication of belonging and trust. Given that about 42% of people in the RGV are considered illiterate, symbols can transcend language barriers. Additionally, visual communication accounts for 80% of the information processed by the brain (Thomasino, 2019). Therefore, it is imperative to understand the community's interpretation of symbols, given their cultural characteristics (Domiszewska, 2023), to foster a sense of trust. As the golden infinity symbol gains more traction, it may be important to revisit the community's interpretation of both symbols.

427.091 Understanding the Neurodivergent Superordinate Identity: Identity Endorsement and Language Preference

S. M. Bury¹, R. L. Flower², P. Dwyer³, E. Richardson⁴, D. Phillips⁴ and J. R. Spoor⁵, (1)Olga Tennison Autism Research Centre, La Trobe University, Melbourne, VIC, Australia, (2)Department of Psychology, Counselling, & Therapy, La Trobe University, Australia, Bendigo, VIC, Australia, (3)Olga Tennison Autism Research Centre, La Trobe University - OTARC, Melbourne, VIC, Australia, (4)La Trobe University, Bundoora, VIC, Australia, (5)Department of Management & Marketing, La Trobe University, Melbourne, VIC, Australia

Background:

With the rise of the neurodiversity movement, "neurodivergent" or "neurodiverse" has emerged as a broad, superordinate identity that potentially includes various minority groups. While social identity theory suggests that superordinate identities can unite individuals under a shared banner, the neurodivergent identity presents some unique challenges. First, the neurodiversity movement originated from autism advocacy—a political movement led by a single minority group. Second, there remains no accepted, clear definition of which minority groups or characteristics "neurodivergent" encompasses. Current literature lacks clarity on how individuals identify with this identity and what terminology they prefer to describe it.

Objectives:

To explore how four commonly included neurodivergent minority groups identify with the neurodivergent superordinate identity, and the terminology they prefer and find offensive.

Methods:

Participants were 772 Neurodivergent adults ($M_{age} = 34.88$, $SD = 10.51$; Woman = 370, Man = 354, Non-binary/genderfluid = 39) from the United Kingdom ($n = 398$) and United States ($n = 367$) recruited from Prolific. Participants reported a sole formal diagnosis of Autism ($n = 193$), ADHD ($n = 206$) and Dyslexia ($n = 180$), or formal diagnoses of both Autism + ADHD ($n = 193$). Participants responded to demographic questions and trait measures of Autism (English et al., 2021), ADHD (Kessler et al., 2005), and Dyslexia (Snowling et al., 2012). A social identity measure (Leach et al., 2007) was first worded to assess endorsement of a diagnostic identity, and then neurodivergent identity. Participants then responded on a 7-point Likert scale assessing preferences for (1=Strongly dislike; 7=Strongly like) or offensiveness of (1=Least offensive; 7=Most offensive) six terms identified in a pilot study of neurodivergent individuals as key terms used in the community. Participants also rated how frequently they use any of the neurodiversity terms (1=Never; 5=Always).

Results:

Overall one-way ANOVA showed that groups differed on individual diagnostic traits as would be expected (see Table 1). Dyslexic participants were less likely to endorse a diagnostic identity. Dyslexic participants were significantly less likely to endorse a neurodivergent identity than all other groups, and the Autism + ADHD group were significantly more likely to endorse a neurodivergent identity. 'Neurodivergent' had the highest rated mean preference score, significantly higher than all other labels. 'Neurodiverse' was rated second and significantly different to all other labels, and 'neurominority' was statistically the least preferred label. Offensiveness scores reflect the preference findings (i.e., neurodivergent = least offensive). The Autism + ADHD group reported using the neurodiversity terms the most frequently, and the dyslexia group the least, with no significant differences between the Autism and the ADHD groups.

Conclusions:

Together these findings suggest that not all who fall under the 'neurodivergent' superordinate identity endorse that identity to the same degree. This is especially true for dyslexic participants who endorsed the neurodivergent identity below the midpoint of the measure. Neurodivergent was the most popular and least offensive label, with neurominority the least popular and most offensive. Groups tended to have a similar pattern of preference for labels, but dyslexic people were least likely to use them.

427.092 Unheard Voices: A Systematic Review of Studies Using Self-Report to Gather the Perspectives of Autistic Adults with Intellectual Disability

V. Gibbs, R. Y. Cai, A. M. Love, C. Edwards and M. Al Ansari, *Aspect Research Centre for Autism Practice, Autism Spectrum Australia, Sydney, NSW, Australia*

Background: Autistic individuals, particularly those with intellectual disability, have been historically underrepresented in autism research. Traditional studies have often relied on informant reports from parents, teachers, or clinicians, which may not fully capture autistic people's lived experiences. Autistic individuals with intellectual disability remain underrepresented in research due to inaccessible methods and recruitment challenges, limiting the understanding of their lived experiences. Innovative approaches, such as photovoice and Talking Mats®, have been used in intellectual disability research to adapt to participants' communication strengths. Autism researchers are now beginning to explore similar inclusive methods, however, a comprehensive review analysis of this body of research remains absent. Understanding the scope of existing research and the methodologies employed is crucial for informing and directing future studies that aim to address the significant gaps in the inclusion of autistic adults with co-occurring intellectual disability. A systematic review can also provide researchers with a repository of various methods, enabling them to select and apply appropriate techniques, thereby increasing the usage and recognition of these methods as rigorous and valid approaches. **Objectives:** This systematic review aims to critically examine existing research that employs self-report methods in studies focused on Autistic adults with intellectual disability. It will evaluate the scope of this research, the self-report measures used, and the extent of community involvement.

Methods: A systematic literature review was conducted in accordance with PRISMA guidelines. We searched PsycINFO, Scopus, MEDLINE, ERIC, CINAHL, and Web of Science for studies published between January 2013 and July 2023. A narrative synthesis was undertaken to evaluate study characteristics, the use of self-report measures, and the involvement of autistic individuals and their communities in the research process.

Results: We screened 4,451 abstracts and 277 full-text articles. Fourteen studies met the inclusion criteria. The majority of studies primarily concentrated on evaluating interventions, with limited emphasis on investigating the broader lived experiences of Autistic adults with intellectual disability. Although 24 self-report measures were identified, only two were validated with a sample of individuals with intellectual disability, and less than half of the remaining measures used adaptations (e.g., visual aids or simplified language). Alarming, community involvement was almost entirely absent, with no studies incorporating co-production with autistic individuals.

Conclusions: This review reveals a critical and urgent need for autism research that authentically includes and represents the self-reported perspectives of autistic adults with intellectual disability. It is imperative that future research prioritizes the development and rigorous validation of accessible self-report tools, expands its focus beyond intervention outcomes, and commits to meaningful involvement of autistic individuals throughout the research process. Addressing these gaps is not only essential for building an equitable body of knowledge but also crucial for ensuring that the voices of autistic individuals with intellectual disability are heard and understood in research.

427.093 University Belonging on Canadian Post-Secondary Campuses: The Autism Centred - University Belonging Model

H. Santilli¹, **H. M. Brown**¹, **C. Bendevis**², **E. Coombs**³, **R. Del Colle**⁴, **C. Devlin**⁵, **P. Dwyer**⁶, **M. Janse van Rensburg**⁷, **M. Pabia**¹, **N. Pogue**⁸, **L. Ripley**⁹, **J. Ryan**⁹, **I. Weigel-Mohamed**⁴, **H. Ma**¹, **A. Wang**⁴, **T. Connolly**⁷, **B. Di Rezze**¹⁰, **D. B. Nicholas**¹¹ and **S. Thompson-Hodgetts**¹², (1)Educational Psychology, University of Alberta, Edmonton, AB, Canada, (2)First Nations Technical Institute, Elphin, ON, Canada, (3)Counselling Psychology, University of Alberta, Calgary, AB, Canada, (4)University of Alberta, Edmonton, AB, Canada, (5)Ryerson University, London, ON, Canada, (6)Olga Tennison Autism Research Centre, La Trobe University - OTARC, Melbourne, VIC, Australia, (7)Carleton University, Ottawa, ON, Canada, (8)Vancouver Island University, Nanaimo, BC, Canada, (9)Rehabilitation Medicine, University of Alberta, Edmonton, AB, Canada, (10)McMaster University, Hamilton, ON, Canada, (11)University of Calgary, Edmonton, AB, Canada, (12)Occupational Therapy, University of Alberta, Edmonton, AB, Canada

Background: Higher education is more than academic achievement; it fosters social community, encourages identity exploration, and prepares students for future careers. However, many Autistic students face significant barriers that limit their full participation in university life, including social exclusion, inflexible teaching methods, and a lack of sensory-safe spaces.¹ These obstacles often lead to isolation, anxiety, and depression, affecting up to 70% of Autistic adults.² Research shows that Autistic students who feel a sense of belonging experience increased academic success, lower stress, and develop social and coping skills.^{3,4} Using theoretical models that capture students' experiences and challenges can help identify factors influencing belonging and guide the development of targeted inclusion strategies.⁵ Unfortunately, no models that can enhance Autistic student belonging in university exist, making the University Belonging Model (UBM)⁶ a valuable starting point for redefining/adapting frameworks to better reflect Autistic student experiences.

Objectives: To identify factors that promote belonging for Autistic post-secondary students.

Methods: Our participatory research approach integrated and valued the perspectives of 8 Autistic Community Partners throughout the research process. We analyzed 25 participant responses from our long-answer online survey, which asked participants to recount experiences of belonging (or lack thereof) on campus. Participants were 18 years or older, had a formal autism diagnosis or self-identified as Autistic, and had attended a Canadian university for at least six months. An interactionist approach to disability informed the analysis.⁷ We first separated participants' responses into thought units (i.e., meaningful chunks of text). Then, we used framework analysis⁸ to code the thought units deductively according to the 3 UBM pillars (explained below).⁹ After this, we applied inductive coding within each pillar to uncover nuanced insights into Autistic students' university belonging.⁹ Using interpretive description¹⁰, we ensured our analysis captured the complexity of participants' experiences while remaining grounded in theory.

Results: The first UBM pillar, University Support and Acceptance, emphasizes the importance of accommodating sensory needs, offering accessible support and growth opportunities, and fostering institutional efforts to destigmatize disability. The second pillar, Faculty and Staff Relations, identified how instructional adaptation, the confidentiality of diagnoses, and the presence of neurodivergent staff members contributed to students feeling understood and supported. Our new pillar, Peer Relations, underscored the impact of social perceptions and the need to mask aspects of identity while demonstrating the value of building friendships in fostering a sense of belonging. Unlike the UBM, we found little evidence of University Affiliation—pride and connection to the institution—in the participant's descriptions of their experiences of belonging.

Conclusions: This research highlights that existing models of university belonging may not fully capture the experiences of Autistic students. The innovative Autism-Centred University Belonging Model (AC-UBM) offers critical insights into the factors influencing Autistic postsecondary students' sense of belonging. The AC-UBM provides a helpful framework for improving belonging by addressing peer relationships, sensory needs, and faculty support. Strategies targeting these areas can significantly improve the experiences and well-being of Autistic post-secondary students.

427.094 Using Community Perspectives to Promote Career Success for Autistic Employees

I. Moura¹, **S. Wright**² and **J. Nicholson**³, (1)Lurie Institute for Disability Policy, Brandeis University, Waltham, MA, (2)University of Colorado Denver, Denver, CO, (3)Institute for Behavioral Health, Brandeis University, Waltham, MA

Background: Autistic adults experience greater joblessness and underemployment than either the general population or people with other disabilities. Improving employment outcomes involves retention, promotion, and career progression in addition to hiring. Increasing employment success for autistic adults requires understanding their needs and priorities, as well as those of their family members, coworkers, employers, and direct support agencies and staff.

Objectives: We aim to use perspectives of stakeholders who contribute to employment outcomes for autistic adults to identify factors related to job retention and career advancement. We focus on the following research questions: (1) How do different stakeholders define successful employment for autistic adults? (2) What do different stakeholders perceive as the barriers and facilitators to successful employment experienced by autistic adults? (3) What do different stakeholders suggest to improve employment outcomes for autistic adults?

Methods: We conducted exploratory interviews with 101 participants focused on identifying barriers to and facilitators of employment success for autistic employees, and the kinds of resources that could support their job satisfaction and performance. Table 1 shows the identities and roles held by participants. Interview transcripts were coded by team members using an iterative process, drawing on previous literature and on themes that emerged in the data. Validation checks were performed to ensure consistency of coding. The team met regularly to develop a shared understanding of codes and themes, and to reach agreement on additional patterns and relationships as they emerged.

Results: We identified multiple themes related to barriers to and facilitators of employment success for autistic individuals, including specific practices; the critical role of employer attitudes; and context and circumstance as mediators. Our analysis revealed that while there is broad agreement on many of the barriers to and facilitators of employment success for autistic individuals, different stakeholders had perspectives that at times diverged from one another. For example, autistic people more often expressed concerns about stereotyping due to reliance on attitudes about autistic people's "special" skills (e.g., technical aptitude or ability to perform repetitive tasks) to facilitate employment. Interviewees also noted that the same practice can be either a barrier or a facilitator depending on the situation. Participants across groups highlighted the need for policy change at both the corporate and government level to facilitate employment of autistic individuals. They stressed the importance of interventions that can improve non-autistic managers' and co-workers' ability to support and work with autistic colleagues, and the role of increasing awareness and acceptance among people who make hiring, retention, and promotion decisions.

Conclusions: Our findings suggest a number of important lessons for research and employment-related interventions and services. First, engaging directly with autistic adults is critical for addressing barriers to employment. Our results also point to the importance of customization and flexibility, and of ensuring that assistance does not preclude self-determination. Finally, our findings emphasize the role of thinking expansively about who needs assistance in order to address the needs of employers and managers and seek solutions to systemic inaccessibility and ableism in the workplace.

427.095 Utilizing Caregiver Perspectives and Experiences to Better Understand the Nuances of the Antecedents, Behaviors, and Consequences of Emotion Dysregulation in Young Autistic Children

A. R. Borow¹, S. Deese² and S. R. Edmunds¹, (1)Psychology, University of South Carolina, Columbia, SC, (2)University of South Carolina, Columbia, SC

Background: Frustration and emotion dysregulation are found to be more common in young autistic children compared to typical development (Edmunds et al., 2024). Identifying the nuances of emotion dysregulation/regulation and supporting emotion regulation in young autistic children might help reduce future mental health disorders (Waxmonsky et al., 2021). Research demonstrates, both like and unlike non-autistic children, common preceding events (antecedents) of autistic emotionally dysregulated behaviors include transitions, ending preferred activities and exposure to anxiety-provoking stimuli (Cale et al., 2009).

Objectives: We captured the behaviors that indicate emotion dysregulation, and their associated antecedents and consequences (what happens after a behavior) through caregiver interviews to support autistic children during moments of emotion dysregulation and understand differences in emotion dysregulation between autistic and non-autistic children.

Methods: This study included 28 caregivers of autistic children between the ages of 2-5 years ($M = 3y;7m$). Caregivers completed a semi-structured interview via Zoom to report about their child's behaviors associated with emotion dysregulation, and corresponding antecedents and consequences. Using Rapid Qualitative Analysis (Hamilton & Finley, 2019), two research assistants summarized transcripts into a coding matrix, independently and deductively extracted themes, iteratively discussed themes until reaching consensus, and extracted thematic frequencies for content analysis (Hsieh & Shannon, 2005).

Results: Caregivers reported Antecedent themes, such as child being tired (29% of caregivers reported) or hungry (14%), being overwhelmed (14%), overstimulated (14%), transitions and routine changes (43%), not getting their way (32%) or what they want (39%). Caregivers reported a variety of behaviors such as child yelling (71%), crying (64%), throwing self on floor (50%), and throwing/handling objects roughly (32%), banging head against surface (29%), hitting or pushing others (29%), child engaging in full body posturing and stiffness or "going limp" (14%), as well as other behaviors associated with autism characteristics such as spinning (4%) and rocking (4%). Caregivers reported consequences, such as redirection or distractions (68%), physical touch or affection (46%), engagement in deep pressure (14%), child engaging with their comfort items (36%), caregivers "talking it out" with their child (29%), child getting what they wanted (29%), and taking time and space from a situation (25%). Some caregivers also reported engaging in strategies to try and keep the child safe (7%), such as including use of a gentle hold and moving objects out of the way. Caregivers also reported child exhaustion (7%), and lasting effects from moments of dysregulation (7%).

Conclusions: Results indicate consistency with antecedents commonly reported in dysregulation for children with autism based on prior literature. While there are many behaviors and consequence themes associated with characteristics of autism, many themes described could be typical in non-autistic children. Results of this study point to potential emotion regulation strategies parents are using "in real life" that may or may not be part of existing interventions, and therefore could be evaluated for effectiveness. Next steps of this project include comparing reported themes with a non-autistic sample. Results of this study might help develop intervention goals or packages that embrace specific emotion regulation goals for young autistic children.

427.096 Video-Based Autism Education for College Students: Bridging the Gap of Autism Knowledge with Parents of Autistic Children

X. Zhang¹, **H. W. Lam²** and **W. C. So³**, (1)Educational Psychology, The Chinese University of Hong Kong, Hong Kong, Hong Kong, China, (2)Educational Psychology, The Chinese University of Hong Kong, Hong Kong, Hong Kong, (3)Educational Psychology, The Chinese University of Hong Kong, Hong Kong, NA, Hong Kong (China)

Background: Public stigma is the negative perception of individuals who are different (Corrigan & Watson, 2002). Yu and colleagues (2020) have shown that 38% of the public in China endorse stigma, compared to 14% of the USA (Yu et al., 2020). Such culture would make inclusion difficult for autistic individuals including those studying in the colleges. One of the reasons for endorsing stigma toward autism is the lack of knowledge about autism (Underhill et al., 2022; McLeod et al., 2019). A larger proportion of people in China have poorer knowledge about autism, including its causes, symptoms, and long-term consequences, than in many other parts of the world, although Chinese parents have better knowledge than the general public (Harrison et al., 2023; Wei et al., 2022; Yu et al., 2020). Thus, educating the public, specifically the college community, would enhance knowledge about autism, reduce the stigma, and create a more inclusive and supportive environment for autistic students.

Objectives: We first investigated the autism knowledge and stigma toward autism among Chinese college students and compared theirs to those of Chinese parents of autistic children (Study 1). We then examined the effectiveness of video-based training in enhancing college students' autism knowledge and reducing stigma (Study 2). We hypothesized that Chinese college students would have poorer autism knowledge and more stigma than parents (H1), but training would improve their understanding and reduce stigma (H2).

Methods: In Study 1, 101 college students (79 females; mean age = 21.78 years; SD = 2.10) and 104 parents (88 females; mean age = 41.16 years; SD = 5.46) of autistic children were recruited online. The Chinese version of Autism Stigma and Knowledge Questionnaire (ASK-Q; Harrison et al., 2017) was administered. In Study 2, college students from Study 1 received a 35-minute video-based training. The ASK-Q was administered to the students four times: one month before (Time 1), the day before (Time 2), immediately after (Time 3), and one month after training (Time 4).

Results: In Study 1, the students' ASK-Q subscale scores indicated that they had adequate knowledge of autism and did not endorse autism. Yet, their scores on the subscales of etiology, treatment, and stigma were significantly lower than those of the parents (see Table 1). In Study 2, immediately after the video-based training intervention, there was a significant increase in college students' ASK-Q scores in the domains of etiology and treatment, and stigma. Figure 1 displays the changes of students' ASK-Q scores over time. After training, their scores on the subscales of etiology and stigma (Time 3) were comparable to those of Chinese parents. However, one month later (Time 4), their scores on the stigma domain were significantly lower than parents' (see Table 1).

Conclusions: The study revealed that while Chinese college students had adequate knowledge of autism, they scored lower than parents on specific aspects, indicating a need for educational training. A video-based training significantly improved students' understanding and reduced stigma, but some effects diminished over time, underscoring the importance of ongoing education.

**427.097** Voices from the Field: Non-Specialist Workers' Experiences of Delivering a Parent-Mediated Autism Intervention in the Community in Urban India

A. Chopra¹, **S. S. Dash²**, **M. Abhilashi³**, **S. Pal⁴**, **R. Roy⁵**, **K. Leadbitter⁶**, **V. Patel⁷**, **J. Green⁸** and **G. Divan⁹**, (1)La Trobe University, New Delhi, Delhi, Australia, (2)Sangath, New Delhi, Delhi, India, (3)Sangath, Delhi, Delhi, India, (4)Child Development Group, Sangath, Delhi, Delhi, India, (5)COMPASS, Sangath India, New Delhi, Delhi, India, (6)University of Manchester, Manchester, UNITED KINGDOM, (7)Harvard Medical School, Boston, MA, (8)University of Manchester, Manchester, United Kingdom, (9)Child Development Group, Sangath India, New Delhi, India

Background: The care gap for autism in low-and middle-income countries is high, resulting in limited access to appropriate services. This gap could be addressed through task-sharing, i.e., redistributing healthcare tasks to trained non-specialist workers (NSWs). In India, a systematic approach was adopted to adapt and expand the Preschool Autism Communication Trial (PACT) – a specialist-delivered intervention developed in the United Kingdom – into Parent-mediated Autism Social communication Intervention for non-Specialists (PASS) Plus, with a focus on training a cadre of Accredited Social Health Activists (ASHAs) – female NSWs under India's National Health Mission. After the classroom training, ASHAs undertook an internship, which involved delivering PASS Plus to practice case families, followed by a competency assessment. The Communication Centred Parent-Mediated Treatment for Autism Spectrum Disorders in South Asia (COMPASS) trial was designed as a definitive evaluation of this model, examining the effectiveness and cost-effectiveness of PASS Plus against treatment as usual.

Objectives: To understand the ASHAs' experiences of PASS Plus training and supervision methodology, and their perspectives on feasibility of scaling this model for young children with autism.

Methods: Sample included nine ASHAs who completed PASS Plus training and internship (see Table 1). Seven of these ASHAs achieved competency and delivered PASS Plus in COMPASS trial, out of which one resigned before trial completion. The other two did not achieve competency. Using an exploratory qualitative design, semi-structured interviews were conducted between December 2023 and March 2024 by researchers with Masters in Psychology who had no prior engagement with ASHAs. Transcribed interviews were analyzed on MAXQDA 2020 (VERBI Software 2019) by two researchers collaboratively using inductive approach to reflexive thematic analysis.

Results: Mean age of the ASHAs was 46 years with an average of 11 years of experience in their role. Their highest qualification was post-graduation. ASHAs who achieved competency delivered 62 PASS Plus sessions on an average.

Nine key themes were extracted from the interviews (see Figure 1). Most ASHAs reported that while they were unfamiliar with autism initially, PASS Plus training, supervision and delivery enhanced their knowledge and enabled them to identify and challenge internally held stigmatizing attitudes and misconceptions about disability. ASHAs' familiarity with the community facilitated increased trust towards them, making them a dependable resource for families seeking guidance about their children with autism. It was also noted that while ASHAs can be trained to deliver the intervention at scale, their ability to do so would vary based on their individual skills and motivations.

"If they (ASHAs) decide... they want to help such children... want to do something for these children... they can do it." – (P6)

Conclusions: ASHAs without prior knowledge of autism were trained on PASS Plus and delivered the intervention in the COMPASS trial with high fidelity, highlighting the feasibility of scaling-up the intervention. However, sustainable implementation through existing health and care systems will require addressing stigma around autism and systemic challenges around workload and incentives.

427.098 Voices in Transition: Exploring Stakeholder Roles in ASD Student Transition Planning

E. Nsiah¹, L. M. Rubenstein², Q. Xiong³, L. A. Ruble⁴, A. M. Love⁵ and N. Morehouse¹, (1)Ball State University, Muncie, IN, (2)Educational Psychology, Ball State University, Muncie, IN, (3)Department of Counseling Psychology, Social Psychology, and Counseling, Ball State University, Muncie, IN, (4)Department of Special Education, Ball State University, Muncie, IN, (5)Aspect Research Centre for Autism Practice, Autism Spectrum Australia, Sydney, NSW, Australia

Background: In the U.S., approximately 50,000 adolescents with Autism Spectrum Disorder (ASD) transition out of high school each year (Smith et al., 2023), making this period critical for enhancing adaptive community functioning. Despite federal laws supporting the transition from school to adult services, autistic adults rank second to lowest in independent living among 11 other disabilities (Sandford et al., 2011). Only 14% hold paid jobs, while around half (54%) engage in unpaid activities, and over a quarter (27%) have no work or day activities at all (Roux et al., 2017). In response to these alarming results, stakeholders are increasingly focused on the transition planning process designed to equip students with the skills and resources needed to navigate post-school life successfully (Patton & Kim, 2016). Despite these efforts, interventions aimed at improving postsecondary outcomes have shown mixed results. For example, the Collaborative Model for Promoting Competence and Success (COMPASS), a personalized goal-setting and intervention planning intervention combined with a coaching-based implementation strategy, resulted in significantly higher IEP goal attainment for transition-age youth, but improvements in postsecondary outcomes were not observed (Ruble et al., 2018).

Objectives: The goals of this study are to examine the perspectives, roles, responsibilities and barriers to collaboration among stakeholders, including autistic students, caregivers, teachers, and pre-employment specialists (Pre-ETS). This understanding was used to revise COMPASS Across Settings (CAST) to improve the collaboration among stakeholders and improve the postsecondary goal attainment outcomes of autistic students.

Methods: Four focus groups were conducted with teachers (n=10), caregivers (n=4), and Pre-ETS (n=9) to (a) explore their experience collaborating, (b) understand the feasibility of implementing CAST, and (c) identify potential barriers. The focus group discussions were transcribed, and key themes were identified to guide the development of an initial draft of findings.

Results: Findings revealed that stakeholders play vital roles in facilitating smooth transitions, such as providing resources to all team members and offering extensive longitudinal, contextual knowledge of students. However, challenges such as communication issues, lack of self-advocacy, and limited shared empathy emerged as barriers to effective stakeholder contributions.

Conclusions: The results suggest that teachers bring invaluable professional knowledge and possess a deep understanding of the educational requirements necessary for creating effective transition plans for students. Meanwhile, caregivers contribute contextualized longitudinal knowledge about the students and ongoing support. Pre-ETS offer insights into community and employment options, while teachers bring their specialized knowledge of individualized instruction, accommodations, and the transition IEP. All stakeholders agreed that involving students in the transition planning fosters greater collaboration among the team and promotes a holistic understanding of the students. Three key obstacles were identified including effective communication, student advocacy, and shared empathy. All stakeholders recognized that these challenges impacted their ability to facilitate a smooth transition for students on the autism spectrum.

427.099 What Does It Mean to be Involved with and to Support the Neurodiversity Movement? Many Things to Many People

A. Pax Arcari Mair¹, J. Gudknecht², A. Gurba³, S. K. Kapp⁴, S. M. Rivera⁵, P. Dwyer⁶ and K. Gillespie-Lynch⁷, (1)University of Edinburgh, Edinburgh, Scotland, United Kingdom, (2)Psychology, University of Portsmouth, Portsmouth, Hampshire, United Kingdom, (3)Psychology and Brain Sciences, AJ Drexel Autism Institute, Philadelphia, PA, (4)School of Psychology, Sport and Health Sciences, University of Portsmouth, Portsmouth, Hampshire, United Kingdom, (5)Department of Psychology, University of California, Davis, Davis, CA, (6)Olga Tennison Autism Research Centre, La Trobe University - OTARC, Melbourne, VIC, Australia, (7)Department of Psychology, CUNY Graduate Center, Staten Island, NY

Background: The neurodiversity movement (NDM), which advocates for full societal inclusion of neurominorities, has fostered an ongoing sea change in how autism is conceptualized, supported and researched (Chapman, 2024). In early research, neurodiversity awareness was associated with viewing autism as a valuable minority identity (Kapp et al., 2013). More recently, NDM quantitative support/alignment has been associated with reduced stigma among non-autistic people and heightened self-esteem among autistic people (Ferenc et al., 2023; Kim et al., 2023). However, little remains known about what NDM support actually means to people. Closed-ended measures of NDM support/alignment may conflate authentic NDM support and support for neurodiversity-lite, which co-opts ideas from the NDM without addressing the systemic inequalities the NDM challenges (Dwyer et al., 2024).

Objectives:

1. Examine how people describe their involvement with the NDM;
2. Determine if NDM involvement and/or conflicts in involvement vary based on relationships to autism;
3. Explore associations between ratings of NDM support and categories of NDM involvement.

Methods:

Autism community members were surveyed about perceptions of and involvement with the NDM. Respondents self-identified with non-mutually exclusive relationships to autism: autistic ($n = 275$), researcher ($n = 98$), parent/caregiver ($n = 154$), other family ($n = 72$), and other professionals (e.g. clinicians, educators) ($n = 122$). Two masked coders used content analysis to classify 491 open-ended responses to, "Can you say more about your involvement with the neurodiversity movement?". NDM support/identification was self-rated on a 5-item Likert scale adapted from Nario-Redmond et al. (2013). Chi-square analyses are significant at $\alpha = .001$.

Results:

Participants most often described their NDM involvement in terms of level/amount of involvement, visibility, role, and intent (Table 1). When participants described NDM involvement in terms of roles, these often aligned with identities (e.g., professionals more often described involvement through teaching and interventions). Participants also noted conflicts in involvement e.g., in positionality.

Autistic participants more often described being involved with the NDM online while professionals more often described offline involvement.

Autistic participants were more likely to be involved through identity-based groups (e.g., being neurodivergent, having family) and to be involved "when I can" and less likely to be uninvolved. Parents were more likely to not be involved. Autistic people were more likely to be involved through advocacy and less often involved through clinical work. Professionals were more often involved through clinical work, including ABA, and to say they were trying to change ABA.

Among autistic and non-autistic participants, closed-ended NDM support was positively associated with the overarching codes of community, visibility, level/amount, role, and intent of involvement, and negatively associated with conflicts in involvement, as well as many sub-codes.

Conclusions: NDM involvement is much more multidimensional than closed-ended scales convey. Consistent with the history of the NDM (Kapp, 2020), autistic people remain more likely to be involved online and the opposite for professionals. Differences across mediums may magnify miscommunications that foster neurodiversity-lite. However, autistic and non-autistic supporters of the NDM shared common goals and conflicts in involvement. Future work should examine conflicts in relation to intersectionality and lateral ableism.

427.100 What Kind of Virtual Care Is Useful for School-Age Autistic Children? a Qualitative Study of Caregiver Perspectives

A. S. K. Wong^{1,2}, P. Owusu³, A. Tint⁴, J. Lee⁵, V. Courchesne⁶, S. H. Ameis⁷, K. Tilleczek⁸, J. A. Brian⁹, M. Penner¹⁰, A. Kushki¹¹, E. Anagnostou¹², J. Lai¹³, M. Spoelstra¹⁴, O. Golan¹⁵, J. A. Weiss¹⁶ and M. C. Lai¹⁷, (1)Azrieli Adult Neurodevelopmental Centre, Centre for Addiction and Mental Health (CAMH), Toronto, ON, Canada, (2)Margaret and Wallace McCain Centre for Child, Youth & Family Mental Health, Centre for Addiction and Mental Health (CAMH), Toronto, ON, Canada, (3)Centre for Addiction and Mental Health, Toronto, ON, Canada, (4)University of Calgary, Calgary, AB, Canada, (5)University of Toronto, Toronto, ON, Canada, (6)University of Montreal, Montréal, QC, Canada, (7)Child and Youth Mental Health, The Centre for Addiction and Mental Health, Toronto, ON, Canada, (8)York University, Toronto, ON, Canada, (9)Holland Bloorview Kids Rehab Hospital, Toronto, ON, Canada, (10)Autism Research Centre, Bloorview Research Institute, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (11)Bloorview Research Institute, Autism Research Centre, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (12)Bloorview Research Institute, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (13)Autism Alliance of Canada, North York, ON, Canada, (14)Autism Ontario, Toronto, ON, Canada, (15)Department of Psychology, Bar-Ilan University, Department of Psychology, Ramat-Gan, ISRAEL, (16)Psychology, York University, Toronto, ON, Canada, (17)Campbell Family Mental Health Research Institute, Centre for Addiction and Mental Health, Toronto, ON, Canada

Background:

Despite the increasing popularity of virtual health care for autistic children especially since the pandemic, there remain significant knowledge gaps regarding the barriers, facilitators, and best practices for virtual care for autistic children. An important step to fill the gaps is to understand the recent experiences of virtual care with autistic children, including benefits and challenges compared with in-person care. There have been few qualitative studies that incorporate the voices of caregivers of autistic children regarding virtual care.

Objectives:

As part of a larger mixed-methods and multi-perspective study on the experiences of virtual mental health care for autistic school-age children, this qualitative study aims to understand the needs of autistic children from the perspectives of their caregivers regarding virtual care.

Methods:

A total of 20 caregivers of autistic children (aged 5-12 years) living in Canada who had experienced virtual mental health care participated in in-depth individual interviews. Interview questions centered on caregiver perspectives and experiences with their autistic children's virtual care, and how these experiences compared to the experiences with in-person care. Facilitators and barriers to virtual care tailored to autistic children were specifically inquired. Interview data were transcribed verbatim. Data analysis, guided by an inductive thematic analysis approach, was assisted by NVivo. The team read the transcripts to identify emerging ideas and discussed and identified codes. These codes were refined iteratively to inform the identification of themes.

Results:

Initial analyses from 13 interviews identified two primary candidate themes: "A delicate balance of familiarity" and "(Not) worth the effort". First, it was found that if elements of the virtual care sessions were familiar to the autistic children (e.g., with familiar peers and clinicians, and structured lesson plans), and clinicians were familiar with the children (e.g., being able to tailor the sessions to match with the children's needs and preferences), it was more likely that the children would benefit from virtual care. Meanwhile, however, too much familiarity might yield negative impacts as caregivers also identified the importance of novelty and creativity in virtual care for successful engagement of their autistic children. Secondly, while several advantages of virtual care were identified (e.g., convenience, no need for commute), the majority of caregivers did not feel that the benefits outweighed the significant efforts (e.g., ensuring readiness of tools, helping their children continue the care by sitting next to them during the whole session) required to help their children engage in virtual care. In fact, many caregivers shared negative feelings towards virtual services, such as feeling overwhelmed, frustrated, and useless, and most caregivers expressed that virtual care were less preferred as compared to in-person services. Data analysis is ongoing with the remaining interviews, and full results will be presented at the conference.

Conclusions:

While virtual care is likely not a panacea, it is important to understand the elements for effective care provision. Different aspects of virtual care should have an optimal balance in familiarity and novelty to enhance engagement, and caregivers' perceived burden and barriers should be addressed.

427.101 When Design Makes You Sick: Physical, Emotional and Practical User Experiences with Navigating Daily Life Data Visualisations

M. Alzahrani¹, S. Uitdenbogerd², M. Wybrow¹, B. Tag¹ and B. Johnson³, (1)Monash University, Clayton, VIC, Australia, (2)Royal Melbourne Institute of Technology, Melbourne, VIC, Australia, (3)Monash University, Notting Hill, VIC, Australia

Background: The growing presence of data in our daily lives highlights the importance of making information visually accessible and easy to understand. Despite a growing body of research focused on designing accessible visualisations, autistic people have been largely overlooked in the design process, which may impact wellbeing and daily living. Autistic people often describe their cognitive and perceptual experiences, such as sensory responses, visual motion processing, and detail-focused thinking styles, as being distinct from neurotypical approaches. The needs and experiences of Autistic adults in order to create accessible visual design practices and guidelines.

Objectives: Our aim was to design more inclusive and effective data visualisation tools that enhance both comprehension and emotional well-being. This study explored how Autistic people experience and interpret data visualisations, by identifying specific strengths, challenges, needs, and preferences they encounter when interacting with real life examples of visualised data. Our research went beyond improving the clarity of visualisations to consider also the emotional and daily impact that visuals may have on Autistic people.

Methods: We employed a mixed-methods approach, combining surveys, user studies, and semi-structured interviews. The initial survey gathered demographic data, Autism Spectrum Quotient (AQ short) scores, and an overview of participants' experiences with data visualisations. Following this, participants took part in user studies featuring both static and interactive web-based visualisations, which measured the accuracy and efficiency of task performance. Semi-structured interviews were then conducted to gain deeper insights into participants' experiences, and the data were analysed using reflexive thematic analysis (Braun and Clarke, 2019). Reflexive thematic analysis was undertaken by a non-autistic researcher, with codes and themes confirmed by consensus with an autistic researcher.

Results: A total of 65 participants initially responded to the survey, with 33 participants (16 diagnosed autistic, 1 identifying as autistic, and 16 non-autistic) completing the user study and interview stages. Participants represented diverse levels of independence, education, and autism traits, ensuring that a broad range of experiences was captured.

Our reflexive thematic analysis identified seven themes: usability and accessibility, physical and emotional user experiences, strategies for managing responses, problems with accessible adaptations, strategies for understanding and interpreting data, impacts on daily living, and user needs and suggestions. Emotional and physical responses to data visualisations were prominent, often resulting in visceral reactions. Strategies for managing these responses varied, with participants adjusting screen settings or avoiding certain visualisations altogether, though not all strategies were effective. Participants expressed how these challenges impacted daily living, work, and learning, leading to missed opportunities in some cases. Participants expressed how these challenges impacted daily living, work, and learning, leading to missed opportunities in some cases. Participants provided valuable improvements for creating accessible visualisations, highlighting the importance of simplicity, reducing movement, and customisability.

Conclusions: How data and information is visually presented in daily life significantly impacts education, work and daily living for Autistic adults, in ways that do not impact non-autistic adults. Our findings provide the groundwork for extending guidelines for creating accessible data visualisations that benefit not only the Autistic community, but the broader population.

427.102 Who Am I: The Balance between Masking and Identity

T. M. Burns¹ and **M. Botha²**, (1)University of Stirling, Stirling, United Kingdom, (2)Department of Psychology, Durham University, Stirling, United Kingdom

Background: Autistic people experience worse mental health outcomes than non-autistic people. Masking (concealing autistic traits) is found to relate to poor mental health. Research shows autistic people indicate relationships between masking and difficulties creating or maintaining a sense of identity. Personal identity is rarely studied within autism research. This study aims to bridge this gap by exploring the connection between identity formation difficulties (both social and personal), and its impact on poor mental health in autistic people. It examines levels of identity conflict and distress in autistic and non-autistic people and whether identity distress mediates and identity conflict moderates the relationship between masking and psychological distress.

Objectives: This study looked at the potentially disruptive nature of masking on identity development in the autistic community and the implications of such disruption on mental health outcomes.

Methods: Data were collected for autistic ($n = 139$) and non-autistic people ($n = 133$) using an online survey (JISC).

Results: Autistic people were found to experience higher levels of identity distress ($M = 23.41$, $SD = 6.25$) than non-autistic people ($M = 17.05$, $SD = 5.96$), $F(1, 255) = 75.92$, $p < .001$, $\eta_p^2 = 0.40$, identity conflict ($M = 10.45$, $SD = 2.69$ vs. $M = 6.98$, $SD = 3.40$), $F(1, 261) = 90.11$, $p < .001$, $\eta_p^2 = 0.27$, and psychological distress ($M = 23.41$, $SD = 6.85$ vs. $M = 17.05$, $SD = 5.96$), $F(1, 260) = 88.87$, $p < .001$, $\eta_p^2 = 0.36$. Identity distress represents a full mediation of the relationship between masking and psychological distress in the autistic cohort (mean bootstrapped indirect effect = 0.18, 95% CI = 0.08, 0.28), $k^2 = 1.79$, but a partial mediation in the non-autistic cohort (mean bootstrapped indirect effect = 0.30, 95% CI = 0.21, 0.39), $k^2 = 0.50$. Identity conflict did not moderate any relationships within the model for either cohort. However, it did have a significant direct relationship with each variable.

Conclusions: These findings suggest that autistic people may experience worse mental health outcomes due to difficulties with cohesive identity formation. Additional research into the role of autism in identity development may identify other areas in which identity difficulties negatively impact autistic people, such as long-term planning and suicidality.

**427.103 Young Adults' Sibling Relationship Quality, Links with Autism Diagnosis, Autistic Identity, and Autistic Traits**

A. Jensen¹ and **M. Bennett²**, (1)Brigham Young University, Provo, UT, (2)School of Family Life, Brigham Young University, Provo, UT

Background:

Sibling relationships are important across the lifespan, especially for those with autism spectrum disorder (ASD; Hendricks & Wehman, 2009). Past research, however, suggests that when one sibling has ASD, relationship quality tends to be lower (Hastings & Petalas, 2014; Orsmond et al., 2009). These studies have one major limitation; they largely rely on the perspectives of non-autistic siblings. How do autistic individuals feel about their sibling relationships? Additionally, past studies have also largely focused on cases where the autistic sibling has been clinically diagnosed with ASD. The growing neurodiversity movement suggests that an overreliance on clinical diagnoses misses the real experiences of those who identify as autistic or even have a higher level of autistic traits (Kapp et al., 2013). Do those who have been clinically diagnosed with ASD report different sibling relationship experiences than those who have not been diagnosed but identify as autistic or display higher levels of autistic traits?

Objectives:

The objective of the current study is to examine the perspectives of young adults on their sibling relationships. Specifically, we examined the perspectives of non-autistic young adults, those diagnosed with ASD, those who identify as autistic, and those who are high in autistic traits.

Methods:

Participants for this study were collected via Prolific (www.prolific.co). Participants were young adults, ages 18-29 (M age = 24.61, $SD = 2.90$; 50.42% female; 63.07% White), who resided in the United States and had at least one living sibling. Participants provided demographic information about themselves (including ASD diagnoses and autistic identity) and their closest aged siblings, their sibling relationship quality using the Emerging Adults Relationship with Siblings Scale (Jensen et al., 2023), and their autistic traits using the Autism Quotient (Baron-Cohen et al., 2021).

Results:

Using ANCOVA, we examined group differences of sibling closeness and conflict between non-autistic participants ($N=720$), participants diagnosed with ASD ($N=97$), participants who self-identified as autistic but were not diagnosed with ASD ($N=80$), and participants high in autistic traits based on the Autism Quotient but did not identify as autistic and had not been diagnosed with ASD (Baron-Cohen et al., 2001; $N=67$). Non-autistic participants reported greater sibling closeness and lower sibling conflict than all other groups. All other groups were not significantly different from one another.

Conclusions:

Young adults with ASD, or who identify as autistic, or who have higher levels of autistic traits, report lower relationship quality than non-autistic young adults. The relational experiences of different autism groups may be driven by autistic traits rather than by clinical diagnoses or identities. Discussion will focus on perceptions of sibling relationships of individuals with ASD and challenges they may face in those relationships compared to non-autistic individuals.

427.106 Socioeconomic Status and Families' Cultural Characteristics Influence the Time of Suspicion for Autism: Results from a Structured Study.

E. Grossi¹ and **E. Castagna²**, (1)Autism Research Unit, Villa Santa Maria SCS, Tavernerio, Como, Italy, (2)Autism Research Unit, VILLA SANTA MARIA SCS, Tavernerio, Italy

Background:

Research suggests that families' education and economic status together with cultural perceptions of autism, can affect parents' recognition of the first signs of autism in their children and influence their decision to seek medical help for ASD suspicion. No specific studies in this regard have been conducted in Italy.

Objectives:

The focus of this pilot study is the association between age at first medical contact for diagnostic suspicion and parental characteristics in Lombardy Region, the most populous and rich Region in Italy.

Methods:

Forty-nine ASD cases referred to our Institute for Rehabilitation from 2022 to 2024 coming from Lombardy municipalities were included in the study. The age at first medical contact for parental concern, determined from parents' reports, was the prediction target. Child gender and age at presentation in our Centre, mother, and father age at childbirth, their education achievement level, their occupation level, and their place of birth (North, Centre, South Italy, Foreign country) were used for input data.

The existence of a poor linear correlation between features and targets prompted us to use a machine-learning system approach. The evolutionary algorithm TWIST was used to subdivide the dataset into training and testing sets as well as to select features yielding the maximum amount of information. After this pre-processing, 11 out of 18 input variables were selected and different machine learning systems were used to develop a predictive model based on a training-testing crossover procedure able to distinguish subjects lying in the two classes of age at first medical contact (<36 months vs >36 months). A fourth- generation artificial neural network called Auto-CM coupled with a minimum spanning tree filter developed a semantic connectivity map of the 20 variables on study (figure1).

Results:

The study group was composed of 33 males and 16 females (mean age at presentation 7.5 yrs; range 2-15 yrs) diagnosed with autism according to DSM V criteria. The age at first medical contact for parental concern ranged between 6 months and 8 years (mean 38 months). TWIST systems selected 11 variables (Child age at observation, parents' education and occupational level, parents place of birth). A machine learning model using these variables predicted class age at first contact with an overall accuracy of 88.65% (sensitivity 93.5% - specificity 83.7%) with a ROC/AUC = 0.85. Higher socio-economic status and north parental origin were associated to a later age at first contact.

Conclusions:

The educational professional and cultural background of parents play a substantial role in influencing the decision to seek medical help for ASD suspicion in a complex way. A machine learning model built on study variables predicted class of age at first contact with high accuracy.

**427.107 Qualitative Analysis of Sleep Disorders in Parents of Children and Adolescents with Autism.**

E. Grossi¹ and E. Castagna², (1)Autism Research Unit, Villa Santa Maria SCS, Tavernerio, Como, Italy, (2)Autism Research Unit, VILLA SANTA MARIA SCS, Tavernerio, Italy

Background:

Several studies have reported disturbed sleep patterns (e.g. frequent nocturnal awakenings, morning wakefulness, and overall shorter sleep times) in children with autism spectrum disorders (ASD). Since almost all these sleep disturbances are reported by parents, it is logical to assume that the parents' sleep patterns are also disturbed, resulting in poorer sleep quality and quality of life. No study so far has included a validated self-assessment measure of sleep quality in parents of children with ASD.

Objectives:

The purpose of this exploratory study is to examine sleep quality and sleep-wake patterns in parents of children with ASD in comparison with parents of typically developing children matched for age and gender.

Methods:

Parents of 29 children and adolescents with autism (21 males; 8 females; age range: 4-17; mean age 10.9 years) were involved in the study. Twenty-three out of 29 subjects with autism had level 3 severity according to DSM V. Principal caregivers who took part in the study were 13 fathers and 16 mothers (age range 30-52 years). They were asked to fill out the Pittsburgh Sleep Quality Index questionnaire -validated Italian version- consisting of 19 questions and 7 dominions (subjective evaluation, latency, duration, efficacy, disturbances, hypnotic use, daily dysfunction).

The control group was represented by parents (9 males and 14 females- age range 29-58 years) of 23 typically developing (TD) kids (13 males; 10 females; age range 3-15 years mean age 9.8 years).

To graphically show the most important connections among the variables a fourth-generation artificial neural network called Auto-CM coupled with a minimum spanning tree filter developed a semantic connectivity map of the variables in the study (Figure).

Results:

The map developed by the Auto-CM system clearly shows a separation between the two groups' sleep qualities. The node of parents of the ASD group was directly connected with short sleep duration, linked to scarce sleep efficacy and in sequence high sleep latency, subjective evaluation of sleep poor high sleep disturbances, and dysfunction during the day (figure). The low scores of seven dominions were connected to parents of the Control group starting with normal sleep duration.

Conclusions:

Our study confirms that parents of children with ASD have poorer sleep quality and more disturbed sleep patterns than parents of TD children.

**427.108 Training Law Enforcement about Autism: Increased Knowledge and Confidence Responding to Calls**

L. Gardner¹, L. Powell¹ and J. M. Campbell², (1)Johns Hopkins All Children's Hospital, St. Petersburg, FL, (2)Psychology, Western Carolina University, Cullowhee, NC

Background: In the United States (US), research supports the general population's knowledge and beliefs about autism is limited (Golson et al., 2022), and those with little knowledge are often unaware of their own ignorance (McMahon et al, 2020). The importance of autism knowledge within certain professions is recognized, but does not necessarily result in professional training. Gardner et al. (2019) found the majority of Law Enforcement Officers (LEOs) have no formal training about autism, despite working in a state that requires such training. It is currently estimated in the US that 1 in 36 children have a diagnosis of autism (Maenner et al., 2023), and 1 in 45 adults have autism (Dietz et al., 2020). As such, it is not surprising that LEOs report interacting with autistic individuals in their professional role. These interactions include responding to calls for elopement, unusual behaviors, suspected abuse/neglect, or disruptive behavior (Gardner et al., 2019). In addition, LEOs respond to calls for victimization including assaults, bullying, and other mistreatment (Pfeffer, 2016). Rava et al. (2017) found that by age 21, approximately 20% of autistic individuals reported having been stopped and questioned by LEOs, and nearly 5% had been arrested.

Objectives: The aim of the study is to assess the impact of a training for LEOs on their perceived knowledge of autism and their confidence in responding to autism related calls. Training content included an interactive presentation and virtual reality.

Methods: Four-hundred and one ($N = 401$) sworn LEOs attended ten separate training sessions. LEOs were 82.0% male with a mean age of 41.07 years ($SD = 10.04$) and 13.61 years of law enforcement experience ($SD = 9.57$). Most LEOs ($n = 279$; 69.6%) reported no prior autism training. Each participant completed a pre- and post-training questionnaire assessing perceived knowledge of autism and confidence in responding to calls.

Results: LEOs reported increases in their knowledge of autism from pretest ($M = 2.59$; $SD = 0.8$) to posttest ($M = 4.03$; $SD = 0.7$; $t(343) = 29.20$, $p < .001$). Similarly, LEOs reported increases in their confidence in responding to calls from pretest ($M = 18.57$; $SD = 5.2$) to posttest ($M = 27.48$; $SD = 3.9$; $t(377) = 32.30$, $p < .001$). Likewise, 91.3% of LEOs ($n = 396$; 98 of the sample) reported the training would positively impact their professional interactions with autistic individuals. LEOs without prior autism training and without a prior relationship with an autistic individual reported greater increases in knowledge and confidence; gender, age, and years of experience did not predict knowledge or confidence increases.

Conclusions: Combined in-vivo and virtual reality training was associated with increased knowledge and confidence in responding to calls for LEOs. LEOs without prior autism training and those without a relationship with an autistic individual reported greater changes in knowledge and confidence. Future research should investigate the long-term impacts of autism training on LEO behavior and call outcomes from the perspective of both LEOs and autistic civilians.

427.109 Law Enforcement Officers' Anti-Stigmatizing Autism Beliefs: Predictors and Response to Training

J. M. Campbell¹, L. Powell² and L. Gardner², (1)Psychology, Western Carolina University, Cullowhee, NC, (2)Johns Hopkins All Children's Hospital, St. Petersburg, FL

Background: In the U.S., it is currently estimated that 1 in 36 children are autistic (Maenner et al., 2023), and 1 in 45 adults have autism (Dietz et al., 2020). With these prevalence rates, it is not surprising that law enforcement officers (LEOs) report interacting with autistic individuals in their professional role. For example, Rava et al. (2017) found that by age 21, approximately 20% of autistic individuals reported having been stopped and questioned by LEOs, and nearly 5% had been arrested. LEOs report limited knowledge about autism, which is associated with improved knowledge as a result of training (e.g., Gardner & Campbell, 2020). Similarly, LEOs report improved confidence in responding to autism-related calls (e.g., Gardner & Campbell, 2024). To our knowledge, no study has investigated stigmatizing attitudes reported by LEOs and if such attitudes are responsive to training.

Objectives: The aims of the study are to: (a) evaluate changes in anti-stigma autism attitudes associated with a training experience for LEOs, and (b) identify predictors of LEO's anti-stigma autism attitudes.

Methods: Two-hundred and nine ($N = 209$) sworn LEOs attended five separate training sessions about autism. The training consisted of a four-hour workshop presentation which includes a virtual reality component (Gardner & Campbell, 2024). LEOs were 75.6% male with a mean age of 40.86 years ($SD = 10.7$) and 13.86 years of law enforcement experience ($SD = 10.7$). Most LEOs (64.1%) reported no prior autism training and 33.3% reported having a personal relationship with an autistic individual. Before and after the training session, each participant completed the Autism Anti-Stigma (AAS) measure, a 10-item scale measuring anti-stigmatizing attitudes towards autistic individuals, with higher scores indicated more favorable attitudes about autism (VanDaalen et al., 2024).

Results: LEOs reported increases in their anti-stigma attitudes from pretest ($M = 38.43$; $SD = 5.5$) to posttest ($M = 39.50$; $SD = 7.3$; $t(179) = 2.21$, $p < .01$). Linear regression analysis with gender, age, prior training, personal relationship, and years of experience predicting AAS pretest scores, resulted in a significant model, $F(5, 171) = 5.36$, $p < .001$. Only gender emerged as a significant predictor ($\beta = .31$; $p < .001$), with female LEOs endorsing higher anti-stigma attitudes ($M = 41.88$; $SD = 4.5$) when compared to male LEOs ($M = 37.5$; $SD = 5.3$). The set of variables also significantly predicted AAA posttest scores, $F(5, 167) = 2.61$, $p < .01$, with gender emerging as the sole significant predictor ($\beta = .24$; $p < .01$). The variables did not predict change in anti-stigma attitudes, $F(5, 160) = 0.25$, $p = .94$.

Conclusions: Combined in-vivo and virtual reality training was associated with increased anti-stigma autism beliefs. Female LEOs reported higher anti-stigma attitudes before and after the training when compared to male LEOs. Future investigations should explore relationships between LEOs' anti-stigma attitudes about autism and responses to calls involving autistic individuals. [Word count = 475].

427.110 Teachers' Self-Efficacy in Teaching/Supporting Autistic Pupils in Mainstream Schools in England: Impact of Knowledge of Autism, Prior Training and Experience

B. Besdere¹, K. Burgoyne², K. Leadbitter³ and G. Squires², (1)Education, The University of Manchester, Manchester, United Kingdom, (2)University of Manchester, Manchester, Manchester, United Kingdom, (3)University of Manchester, Manchester, UNITED KINGDOM

Background: Many autistic pupils think that schools would be better places when their teachers understand them (APPGA, 2017). Teachers' knowledge and understanding of autism and self-efficacy are related to more inclusive practices (Woodcock et al., 2022) and decreased risk of teacher burnout (Ruble et al., 2011). Professional development (PD) may play a promising role in improving teachers' understanding and self-efficacy. Understanding teachers' current level of knowledge and self-efficacy level, along with variables affecting them, is important to provide better support to teachers and to improve autistic students' school experiences.

Objectives: This study investigates a) general education (mainstream) teachers' knowledge of autism and their self-efficacy levels in teaching and supporting autistic students along with group differences based on teaching role, school level, PD experiences, and exposure to autism training in initial teacher education (ITE), and b) variables associated with teacher self-efficacy, including autism knowledge, age, prior training experience (e.g. ITE and PD), teaching roles, school level, and years of experience teaching autistic pupils.

Methods: A cross-sectional survey was conducted between March and May 2024 in England with mainstream teachers through an online survey on Qualtrics. The Knowledge of Autism Questionnaire-UK (KAQ-UK; Langhorne et al., 2024) and Teachers' Self-Efficacy for Autism Scale (TSEAS; Love et al., 2019) were used to measure teachers' autism knowledge and self-efficacy, respectively. Of the 524 consenting participants, 511 mainstream teachers completed the KAQ-UK, while 492 participants completed the TSEAS.

Results: Special Educational Needs Coordinators (SENCOs), who are specialist teachers coordinating support for students with SEND in mainstream schools, demonstrated significantly higher knowledge of autism ($n=178$, $m=27.7$, $p<0.001$) and self-efficacy ($n=170$, $m=40$, $p<0.001$) compared to other teachers ($n=333$, KAQ-UK $m=24.2$; $n=322$, TSEAS $m=38$). Teachers with no PD experience scored significantly lower than teachers with PD experience on The KAQ-UK ($p<0.05$), and self-efficacy levels generally increase as the number of PD increases. Teachers who received autism content in ITE had significantly lower knowledge of autism than those who did not receive autism training in ITE ($p<0.05$) but the effect size was small, and there were no significant group differences in self-efficacy ($p>0.05$). Self-efficacy correlated positively with knowledge of autism ($r=0.227$), years of experience in teaching autistic pupils ($r=0.163$), and number of PD attended ($r=0.309$). Regression analysis indicated that age, years of experience teaching autistic pupils, and knowledge of autism are significant predictors of teachers' self-efficacy. Some PD types, while not statistically significant, were close to significance, suggesting their potential value.

Conclusions: The higher knowledge of autism and self-efficacy scores among SENCOs and the significance of teaching experience as predictors of self-efficacy suggest that specialist training and direct experience with autistic students are crucial factors in teacher development. The fact that ITE training and the number of PD attended did not predict self-efficacy may suggest that the design features of PD and their alignment to teachers' professional backgrounds and needs may be more critical than quantity.

427.111 Mechanisms and Effectiveness of Autism-Specific Teacher Professional Development Programs on Teacher or Student

Outcomes: A Systematic Review

B. Besdere¹, K. Burgoyne², K. Leadbitter³ and G. Squires², (1)Education, The University of Manchester, Manchester, United Kingdom, (2)University of Manchester, Manchester, Manchester, United Kingdom, (3)University of Manchester, Manchester, UNITED KINGDOM

Background: Inclusive education requires teachers who can support each pupil regardless of their diverse needs. Autistic students' unmet needs and statements of teachers' professional support needs are still being reported. However, the best way of providing professional development (PD) is still not under consensus, and there is a clear need for an evidence-based PD framework.

Objectives: To examine the research evaluating autism-specific PD programs 'delivered to in-service mainstream teachers and analyse the mechanisms of these PD attempts with their impact on teacher and student outcomes.

Methods: A systematic search of the literature was conducted in August 2023 using the databases Scopus, Web of Science, PsycINFO and ProQuest (ERIC, Education Database, Dissertations & Theses) and Ebsco (British Education Index). A testable PD framework (IGTP framework or balanced design PD framework) was used in this systematic review of randomised and controlled studies as an organiser framework.

Results: The primary researcher screened titles and abstracts of 2346 studies against the inclusion/exclusion criteria. After full-text screening of 156 studies, 5 studies met the inclusion/exclusion criteria. Results showed that only one study had included mechanisms from all four goals (Insight, Goal, Technique, Practice) of the balanced design PD framework, and it had a greater impact on the cognitive, language, social and behavioural outcomes of students in the experimental group compared to the comparison group. However, studies coded with fewer mechanisms also reported a positive impact on the measured outcomes. Overlapped measured outcome was teacher self-efficacy.

Conclusions: Limited randomised controlled studies made differentiating between more and less effective mechanisms impossible. However, there are overlapped mechanisms between the proposed balanced design PD and the two studies' PD intervention, which reported positive outcomes. High-quality PDs are needed to support teachers in teaching/supporting autistic pupils. Therefore, more randomised controlled studies are needed to examine causalities between mechanisms and PD programs' impact and test the balanced design PD framework.

427.112 Predictors of Parental Stress in Mothers and Fathers of Autistic Children

S. Firat¹, L. Sneed², A. Herguner³, B. Pfingston⁴ and S. Herguner⁵, (1)Private Practice, Samsun, Turkey, (2)Research Institute, Catalight, Walnut Creek, CA, (3)Ankara, Ankara, Turkey, (4)Research Institute, Catalight, Walnut Creek, CA, (5)Sarıkonak Apt Çukurambar, Sabri Hergüner, Ankara, Turkey

Background: Robust findings demonstrate that parents of autistic children experience high levels of parenting stress that are associated with negative outcomes for families (1). One of the important factors affecting parental stress in parents of autistic children is gender of the parent (2, 3). Some studies indicate that the factors affecting parental stress in mothers and fathers may differ from each other (4).

Objectives: In this study, we aimed to investigate whether there is a difference between the factors predicting parental stress in mothers and fathers of autistic children.

Methods: Mothers (n=140) and fathers (n=97) of autistic children between the ages of 2-11 years participated in this study. Participants were asked to fill out Parent Stress Scale (PSS), Depression Anxiety Stress Scale-21 (DASS-21), Autism Quotient - 10 (AQ-10: to assess parental autistic traits), Social Responsiveness Scale (SRS: to determine the level of autistic symptoms of children), and Aberrant Behavior Checklist (ABC: to determine behavioral problems of children).

Results: The results revealed that mothers perceived significantly higher levels of depression ($p=0.000$), stress ($p=0.000$), anxiety ($p=0.000$), and parental stress ($p=0.000$) than fathers. Mothers' SRS scores were significantly higher than fathers, indicating higher autistic symptoms in their children ($p=0.01$). There was no significant difference between mothers and fathers in terms of AQ-10 and ABC scores. The factors predicting parental stress in mothers were the severity of autistic symptoms of the child ($B=0.051$; $p=0.019$), behavioral problems of the child ($B=0.053$; $p=0.044$), and autistic traits of the mother ($B=0.647$; $p=0.03$), while the factor predicting parental stress in fathers was the level of depression of the fathers ($B=0.368$; $p=0.000$) (Table 1).

Conclusions: A clearer understanding of the divergent pattern of determinants of parenting stress across genders and using this to develop tailored support programs would have a clear practical benefit.

427.113 Turkish Validity and Reliability of Parental Stress Scale in Parents of Autistic Children

S. Fırat^a, L. Sneed^a, A. Herguner^b, B. Pfingston^a and S. Herguner^a, (1)Private Practice, Samsun, Turkey, (2)Research Institute, Catalight, Walnut Creek, CA, (3)Ankara, Ankara, Turkey, (4)Research Institute, Catalight, Walnut Cree, CA, (5)Sarikonak Apt Çukurambar, Sabri Hergüner, Ankara, Turkey

Background: Parental stress refers to the emotional strain that emerges from the demands linked to the parenting role. Research has shown that parents of autistic children tend to experience higher levels of stress compared to parents of typically developing children or even those with other disabilities (1). This issue is particularly significant because elevated parental stress is associated with decreased effectiveness in parent-mediated interventions (2). Psychological stress and burnout in parents of autistic children have been linked to increased levels of depression, anxiety, and a decline in family cohesion, which may, in turn, reduce their caregiving capacity (3). Therefore, developing reliable, accessible, and easy-to-administer measures of parental stress is crucial for expanding our understanding and improving interventions.

Objectives: The aim of this study was to assess the psychometric properties of Parental Stress Scale - Turkish Version (PSS-TV), as completed by mothers and fathers of autistic children aged 2 to 11 years.

Methods: The participants in this study were parents of autistic children, aged between 2 and 11 years, including 140 mothers and 97 fathers. The validity of the scale was examined using exploratory factor analysis. Reliability was assessed through Cronbach's alpha, item-total correlation, test-retest analysis and by examining the difference between the top and bottom 27% of the scale's scores.

Results: In the first exploratory factor analysis, two items (items 6 and 12) in the 15-item scale were removed from the scale because they loaded on two factors at the same time and the factor loadings between them were less than 0.10. In the EFA conducted after the two items were removed from the scale revealed three dimensions underlying parental stress: Burdensome (Factor 1, $\alpha=.80$), rewarding (Factor 2, $\alpha=.79$), and consuming. (Factor 3, $\alpha=.51$) (Table 1). The PSS-TV demonstrated good internal consistency ($\alpha=.81$), while the test-retest reliability was moderate ($ICC=.675$). There is a significant difference between the top and bottom 27% of the scale scores ($m1:45,01$ $m2: 26,32$ $p=0.000$). The scale showed the expected correlations with DASS-21- Stress subscale ($r=0.56$).

Conclusions: In conclusion, our findings support the reliability and validity of the PSS-TV, suggesting it to be a valuable tool for measuring parental stress in a Turkish context. Furthermore, our results emphasize the importance of addressing parental stress and associated needs during assessments and when planning interventions for families with autistic children

427.114 Barriers and Facilitators to Primary Healthcare Encounters As Reported By Autistic Adults: A Qualitative Study

L. I. Duker (Stein)^a, W. Giffin^a, E. Taylor^a and A. P. Davidson^a, (1)Chan Division of Occupational Science and Occupational Therapy, University of Southern California, Los Angeles, CA, (2)University of Southern California, Los Angeles, CA, (3)Mrs. T. H. Chan Division of Occupational Science and Occupational Therapy, Chan Division of Occupational Science at the University of Southern California, Los Angeles, CA, (4)Health and Rehabilitation Sciences, Temple University, Philadelphia, PA

Background: Primary care is designed to co-manage health concerns, contribute to preventive care, and provide medical care coordination. Receiving primary care may be especially vital for autistic people, many of whom disproportionately experience psychiatric and physical health conditions. However, autistic adults often face barriers to receiving primary care, and first-hand accounts of these challenges are limited.

Objectives: Therefore, the purpose of this study was to describe barriers and facilitators to primary care encounters as reported by autistic adults.

Methods: Interviews were conducted with 34 autistic adults in Los Angeles and Philadelphia, lasted an average of 26 minutes, were transcribed verbatim, and analyzed using thematic analysis. This dataset is part of a larger study that interviewed autistic adults, caregivers, and primary care providers (PCPs).

Results: Participants had a mean age of 32 years and were primarily White and non-Hispanic; 22% of participants self-identified as an under-served race/ethnicity. Five overarching themes describing challenges and potential strategies to improve care emerged from the interviews: (1) finding a primary care provider, (2) the physical environment, (3) communication, (4) autism-specific knowledge, and (5) support for primary care encounters, *while simultaneously highlighting* the importance of tailoring care for autistic adults to improve primary care experiences. Results, specifically in the communication and autism-specific knowledge themes, were consistent with the neurodiversity model of autism, as participants highlighted stigma and mutual communication as key healthcare barriers.

Conclusions: Findings provide a nuanced understanding of autistic adult participants' primary care experiences, highlighting their perception of barriers and facilitators to these healthcare encounters. These results offer valuable insights for improving the accessibility and quality of care for autistic people, many of which are practical, low/no cost, and easy to implement. Strategies also emphasized the diversity of experiences and preferences for autistic patients, highlighting the importance of tailoring accommodations in the primary care setting.

427.115 Afirm for Paraeducators: Increasing Knowledge of Evidence-Based Practices for Paraeducators

A. Sam¹ and **J. R. Steinbrenner²**, (1)Frank Porter Graham Child Development Institute, Carrboro, NC, (2)Health Sciences, University of North Carolina at Chapel Hill, Chapel Hill, NC

Background: While federal law requires training and professional development for paraeducators, the detailed review of state requirements by Massafra et al., (2020) revealed that 43 states do not require initial training and 40 states do not have provisions for ongoing professional development. Overall, paraeducators report lack of time and appropriateness of training offered as barriers to professional development (Morin et al., 2022) despite paraeducators becoming increasingly responsible for instruction of autistic children in US schools. These findings highlight the significant gap in professional development for paraeducators and their supervising teachers. With the purpose of introducing core evidence-based practices to paras, a core set of modules were designed using innovative instructional design technology. This resulted in six interactive modules (introduction to autism, reinforcement, prompting, time delay, visual cues, and supporting peer interactions) that are short, self-paced, and flexible (i.e., to allow for the variety of para and teacher schedules) and reflect the most innovative design methodology currently available. These modules are free and publicly available.

Objectives: This study aims to explore the knowledge gain when paraeducators use the AFIRM for Para modules and the social validity of the modules.

Methods: Users completed a pre-test and post-test and an evaluation of the modules. Each test had ten questions and was scored on a 100-point scale. The evaluation focused on the quality, relevance, and usefulness of the modules and was based on a Likert-type scale four-point rating scale, with four being the highest rating.

Results: A total of 68,635 users have accessed the AFIRM for Paraeducator modules with the majority being paraeducators (29,253). Users have completed a total 141,312 modules with introduction to autism being the most accessed modules (n = 38,635) and supporting peer interactions the least accessed modules (n = 7,008). Users had the highest mean scores at pretest for introduction to autism (n=38,635, mean = 77.84, SD 16.41) and lowest mean scores at pretest for time delay (n=9,604, mean = 45.88, SD 19.5). To determine knowledge gain, a paired sample t-test was conducted on the pretest and post-test taken by users. Significant change from pre-test to post-test occurred for all practices at the p<.001 level. Standardized mean differences (ES) were computed for each practice using Cohen's d formula. The mean ES was 0.46 (CI 0.46-0.47) with ESs among individual practices from 0.66 (CI 0.637-0.674) for prompting to 0.46 (CI 0.45-0.47) for introduction to autism. All modules were rated as high quality (mean = 3.57, SD 0.56), relevant (mean = 3.57, SD 0.62), and useful (mean = 3.55, SD 0.62).

Conclusions: The AFIRM for Para modules provide a mechanism for paraeducators to access professional development on evidence-based practices for autistic students, and could serve as a cost-effective tool to provide initial training for professionals supporting autistic children. Users (including paraeducators) find these modules socially valid. Additional work is needed to examine how paraeducators will then use this knowledge in classrooms working with autistic students.

428.116 Little Correlation between Parent and Teacher Ratings of Executive and Adaptive Functioning, Whether for Children with or without Autism Spectrum Disorder

M. T. Chen, Department of Educational Psychology and Counseling, National Taiwan Normal University in Taiwan, Taipei City, State, Taiwan

Background: There have been studies exploring the consistency between parent's and teacher's assessments of numerous domains of functioning for children with autism spectrum disorder (ASD). However, little research has examined the potential discrepancy of such parent-teacher consistency between typically developed children and those with autism spectrum disorder.

Objectives: The current study aims to investigate if a parent's ratings on adaptive function and executive function can predict the same ratings by teachers, and if the predictability varies and depends on whether the children are typically developed or have been diagnosed with ASD.

Methods: We recruited children aged between 6-12 years old and FSIQ > 80. For children in the TD group, the exclusion criteria were having been diagnosed with any chronic diseases or mental diseases. Children in the ASD group must have been diagnosed with ASD by a psychiatrist or a clinical psychologist. The exclusion criteria for children in the ASD group were having been diagnosed with intellectual disability, seizures, or Tourette's syndrome. Finally, there were 19 children in the TD group (mean age = 9.34 years; SD = 1.32) and 24 children in the ASD group (mean age = 9.62 years; SD = 0.93) in the current study. All participants were boys. The researchers used BRIEF-2 (Behavior Rating Inventory of Executive Function, Second Edition) to assess executive function and Vineland-3 to assess adaptive behaviors.

Results: To test the background level first, there was no difference between TD group and autism group in child's chronological age, mother's age, mother's educational level, father's age, and father's education level. Next, we examined if the parent's ratings can predict teacher's rating and if the group (TD v.s. Autism) would moderate the effect. The results showed that, among the 4 main scores (Global Executive Composite [GEC], behavior regulation index [BRI], emotion regulation index [ERI], and cognitive regulation index [CRI]), only parent's CRI predicted teacher's CRI and there was no group main effect or the interaction effect between group and parent's ratings in predicting teacher's rating. It means the effect of parent's ratings' predicting teacher's ratings didn't vary because of their groups. For adaptive function, parent's ratings effectively predicted teacher's ratings on the adaptive behavior composite, daily living skills, and socialization, but not communication. However, for the two maladaptive behaviors indices, parent's ratings didn't predict teacher's ratings. Moreover, for all indices, there was no group effect or the interaction effect between group and parent's ratings.

Conclusions: In the assessment of adaptive behavior and executive function, it seems the consistency between parent's and teacher's ratings does not vary based on whether the child is diagnosed with autism or is a typically developing child. However, this is not entirely because of the assessment being invariant and working to the same degree for both groups, but often because – as we found – parent and teacher ratings are correlated for neither group. We therefore suggest extending the research to more cognitive-behavioral domains and raters of more social roles in the future.

428.118 Modulation of Social Attentional Differences By Gaze Direction in Infants and Toddlers with and without ASD: A Longitudinal Study

C. D. Yoon¹, K. J. Dommer², A. Ajwani³, J. Skytta⁴, M. Kim⁵, M. Aubertine⁶, H. Willis⁷, M. Reninger⁸, K. Hegerberg⁹, S. Corrigan¹, E. Olson⁷, K. Michener⁸, D. Christakis⁸, S. J. Webb⁹ and F. Shic², (1)University of Wisconsin-Madison, Madison, WI, (2)Center for Child Health, Behavior and Development, Seattle Children's Research Institute, Seattle, WA, (3)Seattle Children's Hospital, Seattle, WA, (4)Seattle Children's Hospital and Research Institute, Seattle, WA, (5)University of Virginia, Charlottesville, VA, (6)Child Health, Behavior & Development, Seattle Children's Research Institute, University of Washington, Seattle, WA, (7)University of Washington, Seattle, WA, (8)University of Washington School of Medicine, Seattle, WA, (9)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA

Background:

Social attention is a dynamic construct that evolves throughout infancy and toddlerhood, with developmental trajectories that are often nonlinear. The variability in ASD presentation—where some children exhibit clear signs of social attention difficulties early on, while others show significant differences later—complicates the identification of specific developmental milestones that reliably predict ASD across all children. Therefore, understanding how social attention unfolds over time and in different social contexts is essential for identifying early markers of ASD that align with individual developmental patterns.

Objectives:

This study aims to explore: (a) how diagnosis (i.e., group; ASD, neurotypical [NT], and ATP [not ASD nor NT]) and age influence social attention outcomes, as measured by %Head (looking at the head) and %Activity (looking at the activity); and (b) how the gaze direction of adults engaged in an activity (towards the activity or in mutual gaze) affects these outcomes and whether this varies by groups and age.

Methods:

A total of 218 infants/toddlers (ASD: $n = 40$; NT: $n = 137$; ATP: $n = 41$) were seen across four timepoints (7.45, 13.81, 28.41, and 39.23 months). At each visit, children watched 20-second-long videos of two women engaged in child-appropriate activities while their eyes were being tracked. A generalized linear mixed model with a beta-distributed outcome and post-hoc pairwise comparisons were conducted to address the aims.

Results:

The analysis showed that the effect of age on %Head was non-linear and significant ($p < .001$). Group differences were particularly pronounced under certain gaze conditions and at specific ages. In the 'towards the activity' condition, the ASD group showed lower odds of %Head compared to the ATP ($p = .014$) and NT groups ($p = .023$) at the earliest timepoint (7.45 months). In the 'mutual gaze' condition, the ASD group also had lower odds of %Head than both groups at later timepoints (at 28.41 months [$p = .004$, $.040$, respectively] and at 39.23 months [$p = .007$, $.0009$, respectively]). Similarly, the effect of age on %Activity was non-linear and significant ($p < .001$), with group differences emerging over time ($p = .037$). The interaction between group and age was significant ($p = .024$), indicating that %Activity changes with age differed across groups. Notably, by 39.23 months of age, the ASD group had lower odds of %Activity in the 'towards the activity' condition compared to the NT group ($p = .035$).

Conclusions:

Findings highlight the variability in social attention development among young children with and without ASD, supporting the notion that ASD encompasses diverse developmental pathways. Infants and toddlers with ASD may follow distinct trajectories in attending to social stimuli, with patterns varying by age and context. Social attention difficulties in ASD appear early and persist, though their nature evolves over time. While these results point to potential early markers of ASD, the developmental patterns remain non-uniform, emphasizing the complexity and heterogeneity of social attention challenges in ASD.

428.120 Oculomotor Characteristics across the Paediatric Autism-ADHD Spectra

E. J. Forbes¹, J. Tiego², J. Langmead³, K. E. Unruh⁴, M. W. Mosconi⁵, A. Finlay⁶, K. Kallady⁶, M. Moses³, K. Cappel¹, R. Knott⁶, T. Chau⁷, V. P. Mohanakumar Sindhu⁸, A. Bellato⁹, M. Groom⁹, R. Kerestes³, M. A. Bellgrove² and B. Johnson³, (1)School of Psychological Sciences, Monash University, Melbourne, VIC, Australia, (2)Turner Institute for Brain and Mental Health, Monash University, Clayton, VIC, Australia, (3)Monash University, Notting Hill, VIC, Australia, (4)Kansas Center for Autism Research and Training (K-CART), University of Kansas Life Span Institute, Lawrence, KS, (5)Clinical Child Psychology Program, Schiefelbusch Institute for Life Span Studies, University of Kansas, Lawrence, KS, (6)Monash University, Clayton, VIC, Australia, (7)Department of Paediatrics, Monash University, Clayton, VIC, Australia, (8)The University of Nottingham, Nottingham, United Kingdom of Great Britain and Northern Ireland, (9)Faculty of Medicine and Health Sciences, University of Nottingham, Nottingham, United Kingdom

Background: Oculomotor characteristics, such as accuracy, timing, and sensorimotor processing, are sensitive intermediate phenotypes for neurodevelopmental conditions, such as autism and ADHD. Oculomotor characteristics have been studied separately in autism and ADHD, however few studies have investigated oculomotor processes among those with co-occurring autism+ADHD, despite the high prevalence of clinical overlap between these conditions.

Objectives: This study aimed to identify oculomotor characteristics across the autism-ADHD spectra, across visually guided saccade (VGS), anti-saccade (AS), sinusoidal pursuit and step-ramp pursuit tasks to thoroughly interrogate bottom-up and top-down processing systems.

Methods: Four hundred and five (405; 226 males) Australian children aged 4.04 years to 18.75 years with ADHD ($n = 64$), autism ($n = 66$), ADHD+autism ($n = 146$), or who were neurotypical ($n = 129$) were compared on oculomotor variables from four different oculomotor tasks as part of the Monash Autism and ADHD Genetics and Neurodevelopment (MAGNET) Project: visually guided saccade, anti-saccade, sinusoidal pursuit and step-ramp pursuit tasks. Post-hoc exploratory confirmatory analyses were conducted using separate datasets acquired from Nottingham University ($n = 17$ autism, $n = 22$ ADHD, $n = 32$ autism+ADHD, $n = 30$ neurotypical) and University of Kansas ($n = 29$ autism, $n = 41$ neurotypical).

Results: Linear mixed effect models controlling for sex, age and family revealed children with autism+ADHD exhibited increased variability in saccadic final eye position accuracy compared to neurotypical children from the MAGNET cohort. Meanwhile, autistic children demonstrated a greater number of catch up saccades during sinusoidal pursuit compared to neurotypical children. No significant anti-saccade effects were observed. Overall, findings were not confirmed in post-hoc analyses of Nottingham and Kansas cohorts.

Conclusions: Findings suggest that the accuracy of visually guided saccades and pursuit eye movements, both probing bottom-up processing networks, are emerging biomarkers of autism+ADHD and autism, respectively.

428.121 Performance in Cold and Hot Executive Functions in High-Functioning Autistic Children and Adolescents from the Dominican Republic and Cuba

A. Rosoli Murillo¹, L. Badenes Rivera² and A. Ferrer³, (1)Projects, Organizacion Estados Iberoamericanos, Santo Domingo, Dominican Republic, (2)Universidad de Valencia, Valencia, Valencia, Spain, (3)Department of Developmental and Educational Psychology, ERI Lectura. University of Valencia, Valencia, Spain

Background: For decades, research on executive functions in autistic people has focused on behavioral aspects related to cold executive functions. However, since the beginning of the century, the distinction between a cold-cognitive system and a hot-emotional one has allowed us to analyze how both cognitive and emotional experiences occur and thus respond to the relationship between mental life and the adaptive functioning of people. Despite its relevance, research on hot executive functions in autistic individuals remains limited, particularly during late childhood and adolescence. Understanding the relationship between cold and hot executive functions in children aged 8 to 18 years is essential for comprehending cognitive processes that are critical to social relationships, educational development, and preparation for adulthood.

Objectives: To explore whether an association exists between the performance of cold executive functions—such as cognitive flexibility, inhibition, and working memory—and hot executive functions, specifically theory of mind and decision-making under risk, in high-functioning autistic children and adolescents aged 8 to 18 years.

Methods: A cross-sectional study was conducted between September 2016 and March 2019 in the Dominican Republic and Cuba. A convenience sample included 30 male children and adolescents with a mean age of 12.45 years (15 diagnosed with high-functioning autism spectrum disorder [ASD] and 15 with typical development). Inclusion criteria were: a) age between 8 and 18 years, b) a prior ASD diagnosis, and c) an intellectual quotient of 80 or above measured through the Wechsler Intelligence Scale for Children. Exclusion criteria included the presence of comorbid clinical conditions, ongoing pharmacological treatment, significant deficits or absence of oral language production, and lack of formal education. Identical criteria, except for the ASD diagnosis, were applied to select participants with typical development. Ethical approval was granted by the CONABIOS (Consejo Nacional de Bioética en Salud), Dominican Republic.

Cold executive functions were assessed using measures of flexibility, inhibition, and working memory, while hot executive functions were evaluated through theory of mind and decision-making under risk tasks.

Results: The performance of children and adolescents with ASD on cognitive flexibility and working memory tasks was independent of their performance on hot executive function tasks. However, a statistically significant relationship emerged between inhibition, measured by the Stroop test, and decision-making under risk, evaluated using the Cake Gambling Task (CGT). Specifically, significant positive correlations were observed between inhibition and performance on the Adequate Strategy ($r = .65$, $p = .009$) and the Risk Index or Global CGT ($r = .64$, $p = .010$), indicating that participants who performed better on the Stroop test also employed more effective strategies and demonstrated better-calibrated risk-taking behavior.

Conclusions: The results suggest that cognitive flexibility and working memory are independent of hot executive function performance in high-functioning autistic children and adolescents. However, in this sample, the ability to inhibit prepotent responses was significantly associated with the use of appropriate strategies in risk-related decision-making scenarios. These findings indicate that inhibition is not linked to theory of mind but is instead connected to emotional processes involved in making decisions under risk.

428.122 Phenotypes of Social Attention across Infant Risk Groups for Autism Spectrum Disorder

G. Johnson¹, K. J. Dommer², J. Skytta³, M. Kim⁴, M. Aubertine⁵, H. Willis⁶, M. Reninger⁷, K. Hegerberg⁸, S. Corrigan³, E. Olson⁷, K. Michener², D. Christakis⁸, S. J. Webb⁹, F. Shic² and A. Ajwani², (1)University of Washington School of Medicine, MT WWAMI, Bozeman, MT, (2)Center for Child Health, Behavior and Development, Seattle Children's Research Institute, Seattle, WA, (3)Seattle Children's Hospital and Research Institute, Seattle, WA, (4)University of Virginia, Charlottesville, VA, (5)Seattle Children's Hospital, Seattle, WA, (6)Child Health, Behavior & Development, Seattle Children's Research Institute, University of Washington, Seattle, WA, (7)University of Washington, Seattle, WA, (8)University of Washington School of Medicine, Seattle, WA, (9)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA

Background: Autism Spectrum Disorder (ASD) may develop around a complex interplay between environmental and genetic risk factors, reflecting a highly individualized process. Eye tracking provides a means of quantifying attention as an early marker for ASD. It has been shown that at 6 months, neurotypical (NT) infants pay selective attention to mouths during speech (potentially scaffolding early language acquisition), and shift attention towards eyes near 1 year of age as language proficiency matures. ASD children gaze less at people's mouths during videos featuring directed speech than neurotypical children at 6 months, suggesting potential early differences in audiovisual synchrony (AVS) sensitivity.

However, little is known about how birth events, such as low birthweight or gestational age, may relate to early AVS attention profiles.

Objectives: To determine whether or not atypical birth events as well as familial history of ASD, both associated with higher rates of ASD, would both be associated with diminished AVS sensitivity in infancy.

Methods: In a longitudinal study of early development (6 to 42 months), valid eye-tracking data was acquired from 3 recruitment groups of infants (low birth weight (LBW, n=72); siblings of children with ASD (SIB, n=30); or low likelihood for atypical development (LL, n=120)). The LBW group was further divided into heavier (LBW-H, n=37, weight at birth 1.7-2.4kg) and lighter (LBW-L, n=35, 0.5-1.7kg). This abstract is an exploratory examination of differences in attention to areas of AVS from matched social (speaking faces) and non-social (houses with windows flashing in synchrony to synthesized sine-wave speech) stimuli at the first timepoint (average age 7.5m, gestational age corrected), as calculated from spline-based beta modeling of group-based developmental trajectories. An exploratory analysis considered group-differences in children with ASD outcomes.

Results: The LBW-H group exhibited greater attention to social AVS (speaker mouths) than all other groups (vs. SIB $p=.002$, LBW-L $p<.001$, LL $p=.004$). The only other recruitment-group difference was that the LBW-L group looked less at mouths than LL ($p=.007$). No differences were evident in the non-social AVS (flashing windows) condition, excepting a suggestive lower AVS sensitivity in LBW-L versus SIB ($p=.093$). In the subset of children with ASD outcomes, LBW-H infants showed higher AVS social looking than SIBs ($p=.02$). When grouped by later outcomes (e.g. ASD), there were no significant differences evident in social or non-social AVS looking at 7.5m.

Conclusions: Contrary to expectations, the LBW-H group showed elevated rates of social AVS looking compared to other groups. Because LBW children had lower gestational ages than non-LBW children, it is possible that gestational age correction incompletely accounted for longer visual experience shaping AVS sensitivity. However, very light (and also even younger) LBW-L children showed evidence of broad diminished AVS sensitivity, suggesting potential dose-dependency in the severity of perinatal birth events and AVS responsivity. Sustained differences between LBW-H and SIBs with ASD outcomes suggest that that different biological pathways towards ASD (exhibited by our distinct risk groups), including non-genetic pathways, may confer varying levels of penetrance and expressivity of elementary social information processing mechanisms at 7.5 months.

428.123 Predictive Coding and Autism Spectrum Disorder: Unraveling the Interplay of Systemizing and Empathizing Mechanisms

D. Chettri¹, D. Kumar² and L. Saraswat³, (1)HUMANITIES AND SOCIAL SCIENCE, IIT Kanpur, KANPUR, UTTAR PRADESH, India, (2)Department of Cognitive Science, Indian Institute of Technology, Kanpur, Kanpur, Uttar Pradesh, India, (3)Department of Humanities and Social Sciences, Indian Institute of Technology, Kanpur, Kanpur, Uttar Pradesh, India

Background: This study explores the intricate relationship between autism spectrum disorder (ASD) and the predictive coding framework, aiming to illuminate the underlying mechanisms contributing to the diverse symptomatology observed in individuals with ASD. Rooted in Systemizing and Empathizing mechanisms, the research investigated how the interplay of high Systemizing quotient (SQ) and low Empathizing quotient (EQ) contributes to the manifestation of ASD symptoms. The investigations focus on how these two mechanisms affect the ability to use different cues (social and non-social) in making decisions.

Objectives: To verify whether the ASD process and response to errors (or violations of their predictions) is a primary dysfunction that, when viewed in the context of the functioning of the Systemizing and Empathizing mechanism, provides a meaningful explanation for different symptoms of ASD. This research scrutinised how individuals with varying Systemizing and Empathizing traits differ in learning cue contingencies in probabilistic reward tasks.

Methods: The study was conducted on 33 students of IIT Kanpur (Male = 20, Female = 13) with a mean age of 21 ($\sigma = 2.54$). The sample size was calculated using G POWER software (Faul, Erdfelder, Lang, & Buchner, 2007; Happe & Booth, 2008). The power of 0.8 with the effect size ($d = 0.4$) from the previous study was used to calculate the sample size with $\alpha = 0.05$.

We conducted Linear mixed-effects analysis for transition probability of staying even after a loss as a function of SQ and EQ, cue type (context) and Volatility as fixed effects and participant as a random effect. The model that best fitted the data was the full interaction model between the three fixed effects ($p \text{ lose stay} \sim \text{SQ} * \text{EQ} * \text{condition} * \text{volatility} + (1|\text{PID})$, data=df, REML=FALSE).

Results: We have taken EQ, volatility and condition as the main effects and participants as random effects in our model. The models were compared, and we obtained a chi-square value of 40.335 ($p < 0.001$) with AIC = -7711.9 and BIC = -7591.1. The model shows the interaction effect of SQ, EQ, condition and volatility.

Conclusions: LME analysis findings indicate that individuals with high SQ and low EQ exhibit efficient non-social cue utilisation when the cue-target relationship is stable but struggle to disengage from them during the volatile phase, aligning with documented intolerance to change in ASD. The study delves into cue contingency learning patterns, revealing that individuals with high EQ and SQ prefer to stay with social cues in non-volatile conditions. Conversely, those with low EQ and high SQ favour non-social cues, especially in volatile situations. The study also suggests that different prediction tasks engage the Systemizing and Empathizing mechanisms differentially, offering a more nuanced perspective on the cognitive processes involved in prediction and its link with the two mechanisms.

428.124 Preserved but Un-Sustained Responses to Bids for Dyadic Engagement in School-Age Children with Autism

C. A. Wall¹, C. M. Hudac², K. J. Dommer³, B. Li⁴, A. Atyabi⁵, C. Foster⁶, E. Barney⁷, Y. A. Ahn⁷, M. Kim⁸, M. M. Mahony⁹, R. A. Bernier¹⁰, P. E. Ventola¹¹ and F. Shic³, (1)Department of Psychology, Duke University Medical Center, Columbia, SC, (2)Department of Psychology; Carolina Autism and Neurodevelopment (CAN) Research Center, University of South Carolina, Columbia, SC, (3)Center for Child Health, Behavior and Development, Seattle Children's Research Institute, Seattle, WA, (4)Computer Science and Engineering, University of Washington, Seattle, WA, (5)Seattle Children's Research Institute University of Washington, Seattle, WA, (6)Binghamton University, Binghamton, NY, (7)University of Miami, Psychology, Seattle, WA, (8)University of Virginia, Charlottesville, VA, (9)Bernier Lab, Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (10)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (11)Yale Child Study Center, Yale University School of Medicine, New Haven, CT

Background:

Social attention, including attention to conversational speaker and flow, is essential for positive social interactions. Dynamic eye-tracking paradigms are an engaging way to capture social attention in autism, yet there is a need to build upon years of autism research to develop novel paradigms that capture developmentally appropriate, socially rich aspects of social attention, especially given ongoing updates to the prevalence, demographic characteristics, and phenotypic heterogeneity of autistic individuals.

Objectives:

This study introduces a novel eye-tracking task designed to assess social attention during complex conversational interactions among school-aged children. We focused on three primary outcomes: overall face-looking, responses to dyadic bids, and post-dyadic bid attention modulation.

Methods:

A sample of 161 school-aged children (78 autistic, 83 neurotypical) was administered a novel eye-tracking task that consisted of six video clips depicting three adult actors seated at a table engaging in conversation with one another. Periodically, one of the actors would look directly into the camera and break the fourth wall to speak to the viewer. Following the dyadic bid, the bidder would look back to another actor and their conversation would resume. The primary variable of interest was the percentage of time looking at the actors' faces.

Results:

Autistic children displayed significantly lower overall attention to faces compared to their neurotypical peers ($p < .0001$). Contrary to expectations, both groups demonstrated preserved responses to dyadic bids, with no significant differences in attention towards the bid speaker. However, a significant divergence was observed following the dyadic bid: neurotypical children showed more attention to other conversational agents' faces than autistic children ($p = 0.017$).

Conclusions:

These findings highlight key differences and similarities in how autistic and neurotypical children engage with social cues, particularly in dynamic and interactive contexts. The preserved response to dyadic bids in autism, alongside the absence of post-bid attentional shifts, suggests nuanced and context-dependent social attention mechanisms that should be considered in future research and intervention strategies. This study challenges our previous assumptions about the role of eye tracking in autism research. First, eye-tracking paradigms can leverage both temporal- and region-based regions of interest to more accurately reflect the complex and often nuanced dynamics at play during sophisticated social interactions. This is particularly relevant as eye-tracking continues to be deployed across the lifespan as either an index of autism or a marker of treatment response. Second, whereas much existing eye-tracking work highlights autistic differences in social attention, these findings show how eye-tracking can elucidate nuanced patterns of social attention across groups. We demonstrate that, in school-age children, autistic children are equally sensitive to the social salience of the dyadic bid. Our findings suggest that, while autistic children may need additional support to develop skills necessary to navigate the complex social world, they do engage in socially appropriate shifts in attention in the context of naturalistic depictions of social interactions.

428.125 Quantifying Divergent Visual Engagement Trajectories in Autism: A Bayesian Network Approach to Social Learning Pathways

C. Gibeily¹, S. Shultz² and W. Jones³, (1)Emory University, Atlanta, GA, (2)Marcus Autism Center, Emory University School of Medicine and Children's Healthcare of Atlanta, Atlanta, GA, (3)Marcus Autism Center, Atlanta, GA

Background:

Eye-tracking-based measurement of social visual engagement—how children engage with and look at the social environment—has been identified as a key endophenotype in autism spectrum disorder (ASD). Social visual engagement and learning are tightly linked: directing attention to certain stimuli while excluding others provides opportunities for learning that influence future allocation of attention. While studies show that autistic children attend to social information differently than children without autism, studies have not yet examined how these different learning experiences shape future action, leading to increasingly divergent pathways of learning.

Objectives:

We aimed to develop a novel approach for quantifying how a toddler's current looking behaviors (what they look at now) depend on past experiences (what they looked at previously) by calculating the conditional dependencies between different viewing targets. High conditional dependence between two visual targets indicates that a toddler's past viewing experience resulted in learning that modified their current looking behaviors. By contrast, low conditional dependence between visual targets suggests that a toddler's past viewing experience did not lead to learning that impacted where they looked next.

Methods:

Eye-tracking data were collected from typically developing toddlers ($n=75$) and toddlers with ASD ($n=81$) while watching videos featuring toddlers interacting. Eye, mouth, body, object and background regions of interest (ROIs) were coded. Visual targets at each frame were defined in three ways: by ROIs, hotspots (i.e. areas fixated by most viewers), and fixation coordinates. These three datatypes were used to fit Bayesian networks for each group to assess the structural similarity in visual engagement trajectories (i.e. conditional dependence between visual targets) across different datatypes and by group. For each datatype, frames were selected where the population-wise median salience value (quantifying the density of fixations per frame) was $\geq 75^{\text{th}}$ percentile of median salience and downsampled to ensure the number of variables was <100 . Hotspots were created by thresholding ROIs with a salience value $\geq 95^{\text{th}}$ percentile, returning a Boolean variable asserting whether a participant fixated in that hotspot or not. For each datatype, Bayesian network structures were learned using the hill climb algorithm with the Bayesian information criterion as the scoring method.

Results:

ASD viewers spent a higher proportion of viewing time on background and body ROIs (kstest2: $p_{\text{background}} = 0.004$, $p_3 < 0.001$, $p_7 = 0.03$, $p_{10} = 0.013$), fixating on the bodies of the two toddlers in the video, Riley and Sam (R and S, respectively), while TD participants spent a higher relative proportion fixating on the eyes of R and S ($p_1 < 0.001$, $p_5 < 0.001$, respectively).

Networks constructed for TD and ASD groups using the three datatypes were significantly correlated within and between groups, showing higher intra-group correlation (Fig 1G), offering convergent evidence of the network fit and highlighting different viewing pathways between groups.

Conclusions:

Our findings, demonstrating high convergence between three different approaches for Bayesian modeling of visual learning pathways, provide proof-of-concept for quantifying structural similarity in visual engagement trajectories, paving the way for the development of eye-tracking-based measures of real-time social learning in autism.

428.127 Robust Retrieval Practice and Post-Retrieval Feedback Effects Extend to Include Autistic Learners

B. E. Cairney¹, H. D. Lucas² and E. Haebig³, (1)Psychiatry, Yale Child Study Center, New Haven, CT, (2)Psychology, Louisiana State University, Baton Rouge, LA, (3)Communication Sciences and Disorders, Louisiana State University, Baton Rouge, LA

Background: Retrieval practice—testing oneself on recently learned information—enhances learning across a wide range of topics and modalities, and is generally most effective when the learner is provided feedback about their performance. Despite robust evidence that retrieval practice is an effective strategy across many clinical populations who cope with memory difficulties, it has not been studied in autism. Autism can affect learning in different and often nuanced ways, and autistic learners are at higher risk of learning disorders and intellectual disability. It is therefore crucial to identify effective learning strategies for autistic individuals, and retrieval practice is a promising approach worth examining.

Objectives: We measured the effects of retrieval practice and post-retrieval feedback on associative learning among autistic learners, who are at higher risk of learning disorders and intellectual disability but were previously overlooked in the testing effect literature.

Methods: Across two experiments, autistic (Aut) and non-autistic (NonAut) learners completed a word pair associative learning task. In Experiment 1, 40 Aut (17 women, 11 men, 10 non-binary, 2 unreported; age 18–35, $M = 27.3$, $SD = 5.22$) and 40 NonAut (22 women, 18 men; age 19–35, $M = 26.9$, $SD = 4.60$) participants listened to audio clips of unrelated cue-target pairs during an initial study block (e.g., *typing flower*). A cued recall test followed, in which feedback was provided for half of the trials, and the experiment concluded with a final cued recall test. In Experiment 2, retrieval practice took the form of a four-alternative forced choice recognition test, and study and test trials were all presented in written text; experimental procedures were otherwise similar to Experiment 1. Experiment 2 was complete by 80 Aut (33 women, 38 men, 7, non-binary, 2 unreported; age 18–35, $M = 22.2$, $SD = 4.60$) and 80 NonAut (44 women, 34 men, 2 non-binary; age 19–35, $M = 26.8$, $SD = 4.58$) adults.

Results: In Experiment 1, final cued recall performance revealed that participants in both groups demonstrated better memory when feedback was provided after the initial retrieval attempt. For all participants in Experiment 2, recall for retrieval practice trials, with and without feedback, was higher compared to restudy trials, and this difference was statistically significant only between the retrieval practice with feedback condition relative to the restudy condition. These results (1) provide assurance that improved recall performance observed in Experiment 1 was due to post-retrieval feedback and not over-exposure to feedback trials and (2) demonstrate that retrieval practice and post-retrieval feedback facilitated learning relative to restudying material for autistic and non-autistic learners alike.

Conclusions: This study is the first to our knowledge to measure retrieval practice and post retrieval feedback effects in an autistic cohort. Our results suggest that the well-documented effects of retrieval practice, in concert with feedback following retrieval attempts, extend to support learning among individuals with autism. Future studies should examine the effects of retrieval practice and post-retrieval feedback among autistic learners to identify in which contexts these strategies are most effective.

428.128 Short-Term Relational Memory in Visuospatial and Multimodal Integration Tasks in Autistic and Non-Autistic Children
B. von Woedtke¹, D. M. Bowler², S. B. Gaigg³, V. Roessner⁴, N. Vetter⁵, T. Volk⁶, N. Beyer¹ and M. Ring¹, (1)Child and Adolescent Psychiatry, Technische Universität Dresden, Dresden, Germany, (2)Autism Research Group, City St George's, University of London, London, UNITED KINGDOM, (3)Autism Research Group, City St George's, University of London, London, UNITED KINGDOM, (4)Child and Adolescent Psychiatry, Technische Universität Dresden, Dresden, Germany, (5)Psychology, Medical School, Berlin, Berlin, Germany, (6)Technische Universität Dresden, Dresden, Germany

Background:

Autistic people without intellectual disabilities display memory characteristics including difficulties with episodic memory (Desaunay et al., 2020), temporal order (Poirier et al., 2016) and item-context associations (Bowler et al., in press). All these characteristics have in common a difficulty with *relational binding* (Ring et al., 2017) thought to be mediated by fronto-hippocampal processes (Gaigg et al., 2015). Most of the work in this area has focussed on long-term memory (LTM) processes, with relatively few studies of short-term memory (STM) binding. Among such studies, Ring et al (2020) found diminished visuospatial and multimodal spans in autistic adults using a task developed by Quinette et al. (2006, illustrated below).

Objectives:

To extend Ring et al's finding of diminished visuospatial and multimodal span in autistic adults to autistic and non-autistic children.

Methods:

31 (29m, 2f) autistic children ADI/ADOS diagnosed to ICD-10 criteria and 31 (30m, 1f) non-autistic children matched on developmental level took a *Visuospatial Span Task* requiring recall of serial order of spatial locations of crosses on a computer screen, and a multimodal *Integration Task* (Quinette et al, 2006, illustrated) testing binding of letters and screen locations via colour. We also collected parent ratings using the BRIEF. Example of two test trials of the version of Quinette et al's (2006) Integration Task used here. Participants had to memorize the letter in the location with the cross of that same colour and form letter-location associations. After a 1s interval a lowercase black letter was presented and participants had to indicate by keypress if the location of the letter corresponded to the letter-location association they previously formed (bottom) or not (top).

Results:

Because age correlated with Visuospatial span ($r_{ASD} = 0.462, p < .001$; $r_{TD} = 0.313, p < .001$) and Multimodal span ($r_{ASD} = 0.431, p < .001$; $r_{TD} = 0.582, p < .001$) in both groups, it was included as a covariate in group comparisons. Autistic children had significantly lower Visuospatial Span and Multimodal span than the non-autistic children (Visuospatial Span ($M_{ASD} = 0.13, SD_{ASD} = 0.17$; $M_{TD} = 0.22, SD_{TD} = 0.12, F(1,59) = 12.09, p < .001, h^2_p = 0.17$); Multimodal Span ($M_{ASD} = 0.29, SD_{ASD} = 0.18$; $M_{TD} = 0.35, SD_{TD} = 0.18, F(1,59) = 6.56, p < .02, h^2_p = 0.11$)), but although the BRIEF scores were significantly lower in the autistic children ($M_{ASD} = 71.60, SD_{ASD} = 10.12$; $M_{TD} = 46.10, SD_{TD} = 10.69$), $t(57) = 9.41, p < .001$, Cohen's $d = 2.45$, 95% CI [1.77, 3.13], these did not correlate with performance on either of the span tasks for either group (Max. $r = -.23$; Min $p = .23$).

Conclusions:

Our results replicate those of Ring et al (2020) with autistic adults and suggest that the processes measured here are present from childhood. The failure to find correlations with the executive function measure on either task in contrasts with Ring et al's (2020) finding of significant correlations for their autistic adults using the Color Trails task, and may reflect differences between direct and parent-report measures of EF.

428.129 Similarities and Differences in Neurodiverse Youth with and without Autism Spectrum Disorder

L. Swiggard¹, M. Abapolnikova², T. White³ and N. Sadeghi¹, (1)Section on Social and Cognitive Developmental Neuroscience, National Institute of Mental Health, Bethesda, MD, (2)American University, Washington, DC, (3)National Institute of Mental Health, NIH, Bethesda, MD

Background: Autism Spectrum Disorder (ASD) is thought to exist on a spectrum from mild to severe with autistic traits extending into the general population. While social cognitive impairments are a hallmark feature of ASD, they are also characteristic of many neurodevelopmental and psychiatric disorders. In addition, comorbid conditions, such as anxiety, aggression, attention problems, gender dysphoria, and sleep problems have higher rates in youth with ASD. However, it's unclear how youth with social cognitive deficits without ASD compare to youth with social cognitive deficits with ASD across behavioral and cognitive domains.

Objectives: Our objective is to compare behavioral and cognitive profiles in youth with social cognitive deficits, but with and without ASD. We also aim to compare this group to typically developing youth.

Methods: The Adolescent Brain Cognitive Development (ABCD) Study is a longitudinal population-based study of 11,868 children across the US. We included data from baseline assessment (9-10 years-of-age) through the 4th year follow-up (13-14 years-of-age). We split participants into one of four groups. Group 1 had high SRS scores, and no ASD diagnosis ($n = 835$). Group 2 had high SRS scores and an ASD diagnosis ($n = 166$). Group 3 had low SRS scores, and an ASD diagnosis ($n = 56$). Group 4 was our control group, having low SRS scores and no ASD diagnosis ($n = 10,106$). We measured autistic traits using the Short Social Responsiveness Scale (S-SRS). Autism diagnoses were obtained via either parent report or the Kiddie Schedule for Affective Disorders and Schizophrenia (K-SADS). Behavioral problems were measured using the internalizing and externalizing problem scores on the Child Behavior Checklist (CBCL). Additional comorbidities such as Attention Deficit Hyperactivity Disorder (ADHD), Obsessive Compulsive Disorder (OCD), Generalized Anxiety Disorder (GAD) and Major Depressive Disorder (MDD) were measured using the K-SADS. Cognitive performance was measured using the NIH Toolbox. Finally, we measured prosocial behavior using the prosocial behavior subscale of the Strengths and Difficulties Questionnaire (SDQ). We also analyzed Gender Dysphoria by using the youth gender survey. For analyses, we used linear mixed effects models to compare the four groups on internalizing, externalizing, symptom scores, controlling for age, sex, race/ethnicity, and parental education level. We also assessed differences in comorbid and cognitive performance between the four groups.

Results: Group 1 had higher internalizing and externalizing problems than Groups 2, 3, and 4 ($\beta_s = -4.00, -9.90$, and -12.00 for internalizing $-2.12, -13.65$, and -12.17 for externalizing, respectively, all $p < 0.05$). Group 1 had a larger reduction in symptoms over time than Groups 3 and 4 ($\beta_s = 0.48$ and 0.44 for internalizing and 0.90 and 0.51 for externalizing, respectively, all $p < 0.05$), but no difference from Group 2.

Conclusions: Participants high on autistic traits/social impairments without ASD may differ from both the neurotypical and the ASD population and may have different developmental trajectories.

428.130 Social Attention and Social Knowledge in Autistic and Non-Autistic Children

L. A. Langille¹, A. F. Boatswain-Jacques², A. Gazith¹, E. Stubbert¹ and J. Burack², (1)McGill University, Montreal, QC, (2)Educational & Counselling Psychology, McGill University, Montreal, QC, Canada

Background: and Objectives:

The study of attention among youth with autism spectrum disorder (ASD) has shifted towards a focus on the styles and strengths of attention, and away from the traditional deficit-focused view of attention (Burack et al., 2016). In this study, we address the particular suggestion that diminished attention both to static faces and to socially relevant stimuli may indicate differences in attention to socially-laden stimuli (Klin et al., 2010; Guillon et al., 2014; McPartland et al., 2010). Thus, we explore the relationship between attention to socially relevant stimuli on a dynamic, three-dimensional attention task and social knowledge among autistic and non-autistic youth.

Methods:

To measure the attention styles and biases, 31 autistic (*Age* = 11.8 years) and 49 non-autistic (*Age* = 10.7 years) participants were presented with a three-dimensional version of the biological motion task (BM; Johansson, 1973). In this task, the participants examined a moving image of a walking human figure to determine the walking direction. The task becomes harder when distractor dots are added to the surround. Furthermore, to measure social competence, the participants' caregivers completed the Multidimensional Social Competence Scale (MSCS; Yager & Iarocci, 2013). We examined the MSCS items pertaining to social knowledge (e.g., participant understands what constitutes a friend, and has reasonable expectations of friends).

Results:

One-way ANOVA results indicated that the non-autistic participants received higher caregiver ratings on social knowledge, $F(1, 93) = 42.1, p < .001$, but no group differences were found for biological motion, $F(1, 78) = 1.83, p = .180$. The results of a moderation analysis suggested that the scores on the biological motion test were predicted by scores on social knowledge ($B = 5.98, p = .029$), but that the interaction effect of group on social knowledge and biological motion was not significant ($B = -3.78, p = .318$). A significant correlation between BM scores and social knowledge ($r = .340, p = .017$) was found in the non-autistic group, but not in the autistic group ($r = .248, p = .233$).

Conclusions:

As depicted in our results, we found that, for both groups, social knowledge predicts performance on a social attention task. Additionally, we found that the autistic and non-autistic groups differed in caregiver-reported social knowledge, but not in their performance on a social attention task. We did not find group differences regarding the relationship between social knowledge and performance on a social-attention task. Differences in attention to social stimuli between autistic and non-autistic individuals have been reported in previous research (Klin et al., 2002). We suggest that, though these attentional group differences are salient, autism may not affect the relationship between social knowledge and performance on a social attention task. In other words, while social knowledge and social attention task performance seem to be related, this relationship appears to be independent of autism. Differences in sample size may explain some of the group differences. Further research is required to determine the nature of the relationship between social knowledge and social attention in children with autism.

428.131 Subtyping Autism in Early Childhood Based on Autism Symptoms, Executive Functioning, Language, and Cognitive Skills
S. Jeong¹, J. Kim², S. J. Hong³ and S. H. Kim¹, (1)School of Psychology, Korea University, Seoul, Seoul, Korea, Republic of (South), (2)Korea Institute of Science and Technology, Seoul, Seoul, Korea, Republic of (South), (3)Center for Neuroscience Imaging Research, Institute for Basic Science, Suwon, Gyeonggi-do, Korea, Republic of (South)

Background: Autism Spectrum Disorder (ASD) is characterized by significant phenotypic heterogeneity, making it essential to identify meaningful subtypes to tailor interventions and gain insights into developmental and etiological pathways. Previous research has predominantly focused on symptom severity and has primarily included school-age children, adolescents, and adults (Cholemkery et al., 2016; Kloppe et al., 2017). Although some studies have explored subgroups reflecting functional domains, few have incorporated the characteristics of executive function (EF) and expressive language into subtyping. Since language delays, EF deficits, and cognitive variability are common and significant predictors of developmental outcomes in ASD (Demetriou et al., 2018; Howlin, 2003), incorporating these domains into subtyping is crucial.

Objectives: This study aims to (1) identify distinct clusters within young autistic kindergarteners based on core autism symptoms, lab-based EF, real-world EF (parent-reported), expressive language, and NVIQ, and (2) compare these clusters on demographic and clinical characteristics, including age, gender, adaptive functioning, and behavioral problems.

Methods: The sample included 94 autistic children from South Korea (mean age=69.35 months, 72 males), who were cognitively-able (mean NVIQ=102.13, SD=15.29) and verbal (i.e., flexible phrases or complex sentence). Autism symptoms were assessed with the ADOS-2 calibrated severity scores (Hus et al., 2014). Expressive language was evaluated using the calibrated metric of the ADOS-2 Overall Level of Non-Echoed Spoken Language item (Mazurek et al., 2019). Lab-based EF (inhibitory control, working memory, and attention shifting) was assessed via EF Touch (Willoughby et al., 2010), a tablet-based task, while real-world EF was measured using parent-reported measure, the BRIEF-2. NVIQ was measured using K-WPPSI-IV, adaptive functioning via K-Vineland-II, and behavioral problems via K-CBCL. All scores were standardized. NbClust() on R was conducted to determine the optimal number of clusters, followed by k-means clustering. Group differences were examined using ANOVAs, Kruskal-Wallis tests, and χ^2 tests, with corrections for multiple comparisons.

Results: (1) Four distinct subgroups emerged, characterized by different profiles of autism symptoms, EF, language, and NVIQ: Cluster 1 "Impaired Generalized EF, High Language & IQ," Cluster 2 "Low Lab-based EF Skills, Low Language & IQ," Cluster 3 "High Overall EF, Low ASD Symptoms, High Language & IQ," and Cluster 4 "Moderate EF Impairments, Low IQ & High ASD Symptoms" (BSS/TSS = 48.6%). (2) Subgroup comparisons revealed significant differences in adaptive behavior and behavioral problems. Cluster 1 had significantly higher behavioral problems than the other three clusters ($F(3,90) = 11.97, p < 0.001, \eta^2 = 0.29$), while Cluster 3 had significantly higher adaptive behavior scores compared to Clusters 1 and 2 ($H(3) = 33.8, p < 0.001, \eta^2 = 0.33$). No differences among the clusters emerged for age and gender.

Conclusions: Identifying these subtypes enhances our understanding of the developmental trajectories of autistic children and provides a deeper insight into potential developmental pathways and the design of more effective, tailored interventions.

428.132 The Combined Impact of Autism Traits and Target-Distractor Similarity on Visual Search Guidance
C. A. Halpern and J. Geng, Psychology, University of California, Davis, Davis, CA

Background: Individuals with autism often demonstrate a detail-oriented perceptual style, which is linked to core symptoms of the disorder (Behrmann et al., 2006; Alink & Charest, 2020) and extends to autism traits in neurotypical populations (Chouinard et al., 2013). This detail-oriented processing is associated with enhanced visual search performance in autism (Gilga et al., 2015; O’Riordan et al., 2001). However, many studies on visual search in autism have used feature-conjunction tasks, (Kaldy et al., 2016), which involve structurally similar distractors that require more direct, detailed evaluation of items in the search display (Wolfe, 2021). Therefore, these studies may not capture the complexities of real-world search, where target-distractor similarity varies.

Objectives: To examine how autism traits interact with expected and current target-distractor-similarity to influence visual search performance.

Methods: Eighty participants ($M_{age}=19.58$, $SD_{age}=1.43$; 19 male) completed a visual search task, with eye tracking. Participants were assigned to one of two groups: the similar-distractor context group (SCG) primarily saw *similar-distractor trials* and the distinct-distractor context group (DCG) primarily saw *distinct-distractor trials* (Figure 1). Each group completed 150 test trials — 130 trials with their group-assigned target-distractor similarity (similar or distinct) and 20 trials with the opposite similarity. Autism traits were measured using the Autism Spectrum Quotient (AQ; Baron-Cohen et al., 2001). A linear mixed-effects model was used to analyze the relationship between AQ score, distractor-similarity context, and trial target-distractor similarity on attentional guidance (time to first target fixation).

Results: The analysis revealed a significant main effect of trial distractor-similarity ($b=404.061$, $p<0.001$). Participants took longer to fixate the target on *similar-distractor trials* than *distinct-distractor trials*. Although there was no significant main effect of AQ score, participants with higher AQ scores showed smaller increases in attentional guidance on *similar-distractor* versus *distinct-distractor trials* ($b=-8.317$, $p=0.014$), indicating reduced sensitivity to distractor similarity with higher autism traits. A significant three-way interaction ($b=13.701$, $p=0.007$; Figure 2) indicated differential effects of AQ score across groups. In the DCG, as AQ scores increased, the difference in guidance times between *distinct-distractor* and *similar-distractor trials* decreased, suggesting reduced sensitivity to target-distractor similarity. In the SCG, higher AQ scores led to greater increases in guidance time on *similar-distractor trials* compared to *distinct-distractor trials*, suggesting that higher AQ scores were associated with more careful assessment of detailed information in the search array when targets and distractors were highly similar.

Conclusions: These findings challenge the idea that autism traits are broadly related to a visual search advantage. While participants with higher AQ scores guided attention faster to targets on *similar-distractor trials*, likely due to their enhanced detail perception, this advantage was absent when distractors were distinct from the target. Critically, participants with higher AQ scores were only faster on *similar-distractor trials* when in a context where attention to detail was not emphasized, such as repeatedly searching for a target among distinct distractors. When they regularly encountered similar distractors, participants with higher AQ scores slowed their guidance to the target, possibly overemphasizing detailed processing at the expense of broadly evaluating the display to guide eye movements.

428.133 The Impact of Sex and Symptom Severity on Academic Outcomes in Autism

S. Larmer¹, K. E. Hannah², Y. Huang², K. McRae² and R. A. Stevenson², (1)Western University of Ontario, London, ON, Canada, (2)University of Western Ontario, London, ON, Canada

Background:

Autism is often associated with differences in academics, but the current literature is dominated by autistic boys, lacking sufficient representation of girls. The known factors that differ in how autism presents in girls and boys may directly impact academic outcomes. For example, increased camouflaging in autistic girls, both in terms of the social elements of autism as well as of restricted and repetitive behaviors, may lead to different academic experiences and outcomes for autistic girls and boys. Given the relationship between academics and numerous life outcomes, understanding how sex and autistic features interact to impact academics is critical to supporting the needs of autistic children.

Objectives:

Our goal was to explore whether sex and autism symptom severity interact to predict various academic outcomes.

Methods:

We extracted data from the Child Mind Institute’s large scale data collection biobank, the Healthy Brain Network, including 652 autistic participants (120 females, age 5-21) that completed measures related to autism symptoms and academics. The Repetitive Behaviors Scale, Social Responsiveness Scale, and Social Communication Questionnaire were used to explore autism symptom severity. The Wechsler Individual Achievement Test and the Test of Word Reading Efficiency were used to evaluate academic outcomes (see Figure 1 for subscales). We conducted linear regressions with sex, symptom severity, and a sex*severity interaction to predict each academic outcome measure, with a focus on identifying interactions between sex and symptom severity.

Results:

Overall, greater autism symptom severity was significantly ($\alpha=0.05$) linked to worse academic outcomes. Importantly, regressions revealed multiple areas where the relationship between symptom severity and academic outcomes differed between girls and boys. Results revealed that sex and repetitive behaviors significantly interacted to predict multiple reading measures (Phonemic Decoding Efficiency, Total Word Reading Efficiency, Word Reading, and Pseudoword Decoding), with repetitive behaviors more negatively correlated with reading measures in girls than in boys. Also, sex and social responsiveness significantly interacted to predict reading measures with social responsiveness more negatively correlated with some reading measures in girls (Phonemic Decoding Efficiency, Sight Word Efficiency, and Total Word Reading Efficiency), but more negatively correlated in boys with Word Reading and Spelling. Finally, sex and social communication significantly interacted, with social communication in boys more negatively correlated with Math Problem Solving (see Figure 2).

Conclusions:

In autism, symptom severity predicted several academic outcomes differently in girls than in boys. It seems girls are more negatively impacted in reading by more severe repetitive behavior symptoms. Furthermore, girls seem to be more negatively impacted by more severe social responsiveness symptoms in measures of reading efficiency. It is possible that reading is the academic domain most affected by symptom severity in autistic girls. Regarding autistic boys it seems there is greater breadth in the academic domains that are impacted by more severe symptoms, with select reading skills negatively impacted by social responsiveness symptoms and math skills by social communication symptoms. Understanding what factors differentially contribute to academic success in autistic girls and boys permits focusing on the bases of academic challenges.

428.134 The Influence of Eye Refraction on Gaze Patterns in Facial Affective Recognition Among Children with Autism Spectrum Disorder

L. Kong¹, A. Li², M. Liu³, X. Pan⁴, Y. Zhao⁵, Z. Zhang⁶, Y. Guo⁷, W. Zhang⁷ and **C. Wang⁸**, (1)Nankai University, Tianjin, Tianjin, China, (2)Nankai University, tianjin, tianjin, China, (3)1.Tianjin Medical University, Tianjin, China ;2.Tianjin Eye Hospital, Tianjin, China; 3.Nankai University affiliated Eye Hospital, Tianjin, China; 4.Tianjin Key Lab of Ophthalmology and Visual Science, Tianjin, China, tianjin, tianjin, China, (4)Autism Research Center, Nankai University, Tianjin, China, tianjin, tianjin, China, (5)1. Department of Social Psychology, School of Sociology, Nankai University, 38 Tongyan Road, Tianjin, China 2. Autism Research Center, Nankai University, Tianjin, China, tianjin, tianjin, China, (6)Department of Pathology, School of Medicine, Nankai University, Tianjin, 300071, China, tianjin, tianjin, China, (7)1. Tianjin Eye Hospital, Tianjin, China ; 2.Tianjin Key Lab of Ophthalmology and Visual Science, Tianjin, China, tianjin, tianjin, China, (8)Department of Social Psychology, School of Sociology; Autism Research Center, Nankai University, Tianjin, Tianjin, China

Background:

Previous research has shown that children diagnosed with Autism Spectrum Disorder (ASD) often have deficits in recognizing facial expressions and tend to avoid eye contact, which significantly affects their ability to perceive and interpret social cues. Eye refraction is a key factor in assessing ocular function and may influence gaze behavior during social interactions. However, empirical evidence is needed to examine the impact of eye refraction on facial expression recognition in children with ASD.

Objectives:

This study aimed to explore differences in gaze patterns between children with ASD and typically developing (TD) children, considering their refractive states, during the recognition of seven distinct human facial expressions.

Methods:

Children with ASD and typical refractive status ($N=40$, $M_{age} = 5.15$, $SD = 1.03$, 87.5% male) and those with atypical refractive status ($N=34$, $M_{age} = 5.39$, $SD = 1.24$, 76.47% male), as well as age-matched TD children with typical refractive status ($N=40$, $M_{age} = 4.62$, $SD = 0.87$, 52.5% male) and those with atypical status ($N=34$, $M_{age} = 4.42$, $SD = 1.09$, 57.58% male), were recruited from Tianjin, China. The participants underwent eye-tracking experiments involving images depicting seven facial expressions: anger, disgust, fear, sadness, surprise, happiness, and calmness. Additionally, their refractive status was assessed. Total fixation duration (TFD) and fixation count (FC) on specific areas of interest (AOIs), such as the face, eyes, and mouth, were analyzed and compared across the groups.

Results:

The results indicated a significant decrease in both FC and TFD for children with ASD compared to TD children, particularly in the face and eye regions, when viewing the seven facial expressions (Interaction effect of TFD: $F(2, 18) = 17.423$, $p < 0.001$; Interaction effect of FC: $F(1.92, 276.126) = 12.490$, $p < 0.001$). Additionally, both ASD and TD children with typical refractive status demonstrated more frequent fixations on the eye region compared to those with atypical refractive status ($p < 0.01$), especially for expressions of disgust and happiness (disgust pictures: $F(1, 144) = 5.034$, $p < 0.05$; happiness pictures: $F(1, 144) = 2.528$, $p < 0.05$). Children with ASD and typical refractive status exhibited significantly longer TFD in the face region when viewing pictures of happiness than those with atypical refractive status ($p < 0.05$), while no significant difference in TFD was observed between the two TD groups ($p = 0.325$).

Conclusions:

This study demonstrated that the refractive status of children with ASD may contribute to their reduced ability to perceive and interpret social cues, particularly in relation to eye contact and facial expressions, compared to TD children. Improving eye refraction in children with ASD may enhance their performance in facial expression recognition and social interactions.

**428.135** Unpacking Engagement in the Neurodiversity Movement: A Latent Class Analysis of Involvement, Strengths-Based Perceptions, and Self-Advocacy

J. Gudknecht¹, A. Pax Arcari Mair², K. Gillespie-Lynch³, A. Gurba⁴, S. M. Rivera⁵, S. K. Kapp⁶ and P. Dwyer⁷, (1)Psychology, University of Portsmouth, Portsmouth, Hampshire, United Kingdom, (2)University of Edinburgh, Edinburgh, Scotland, United Kingdom, (3)Department of Psychology, CUNY Graduate Center, Staten Island, NY, (4)Psychology and Brain Sciences, AJ Drexel Autism Institute, Philadelphia, PA, (5)Department of Psychology, University of California, Davis, Davis, CA, (6)School of Psychology, Sport and Health Sciences, University of Portsmouth, Portsmouth, Hampshire, United Kingdom, (7)Olga Tennison Autism Research Centre, La Trobe University - OTARC, Melbourne, VIC, Australia

Background:

Little research has focused on collective advocacy of neurodivergent people through the neurodiversity movement (NDM). The NDM not only promotes strengths-based approaches to neurodivergence but embodies a broader expression of self-determination for neurodivergent people's common future. Despite academic interest in neuro-affirming principles and associations between NDM support and other factors (like stigma) toward autistic people (Kim & Gillespie-Lynch, 2023; Gillespie-Lynch et al., 2017), little is known about what NDM involvement actually means to people, including non-autistic neurodivergent people and neurotypical people.

Objectives:

- 1) To examine underlying latent classes of involvement in the NDM and the role of neurodivergent people in shaping collective, strengths-based advocacy
- 2) To analyze how perceptions of neurodiversity and the NDM influence movement participation

Methods:

Autism community members completed a survey about perceptions of and involvement with the NDM. Content analysis classified 491 open-ended responses to "Can

you say more about your involvement with the neurodiversity movement?". Latent class analysis (LCA), which helps identify hidden groups, revealed underlying NDM involvement profiles. Separately in autistic ($n_{aut}=275$) and nonautistic participants, we examined whether class membership was predicted by relationships to autism (i.e., autism researchers, caregivers), non-autism conditions (i.e., anxiety, depression, ADHD), self-rated NDM support/identification, and previously-coded open-responses to views on neurodiversity/the NDM.

Results:

LCA fit indices endorsed a four-class solution with the following classes (see Figure 1): Personal Supporters (9%), Public Supporters (45%), Passive Involvement (20%), and Uninvolved (26%). Covariate analyses showed that both autistic ($OR_{aut}=8.468, p=.033$) and non-autistic ($OR_{nonaut}=4.466, p=.043$) ADHDees were more likely to be Personal Supporters than Passively Involved; non-autistic ADHDees were more likely to be Public Supporters than Passively Involved ($OR_{nonaut}=4.002, p=.006$). In contrast, non-autistic depressed people were more likely to be Passively Involved than Public Supporters ($OR_{nonaut}=3.032, p=.031$). Higher NDM support/identification was associated with lower odds of being Uninvolved compared to Public Supporters ($OR_{aut}=0.355, p=.006$; $OR_{nonaut}=0.782, p<.001$).

Further analysis showed insights into how perceptions of the NDM shaped involvement. Autistic people who defined neurodiversity as including everyone were less likely to be Uninvolved than Public Supporters ($OR_{aut}=0.816, p<.001$). Non-autistic people who viewed the NDM as "trying to change society" were less likely to be Uninvolved than Public Supporters ($OR_{nonaut}=0.139, p<.001$), Personal Supporters ($OR_{nonaut}=0.193, p=.023$), and Passive Involvement ($OR_{nonaut}=0.252, p=0.17$).

Conclusions:

This study highlighted the varied ways that people engage with the NDM. A large portion of the sample reported public, visible support. Results showed that autistic

people and ADHDees play a key role in asserting self-agency through their Personal and Public Support. Understanding motivations and barriers to involvement, such as mental health conditions, is a critical step to ensuring more inclusive engagement. Findings indicated perceptions of the NDM as including everyone and focused on changing society led to higher support profiles. Future advocacy should use these insights to create tailored, strengths-based initiatives that encourage broader NDM participation.

428.136 Unraveling the Dimensionality of Social Attention through Psychometric Optimization of an Eye-Tracking Battery: Results from the Autism Biomarkers Consortium for Clinical Trials (ABC-CT)

A. Naples¹, F. Shic², G. Hellemann³, G. Dawson⁴, A. R. Levin⁵, N. Kleinbans⁶, R. A. Bernier⁷, S. Jeste⁸, S. Faja⁹, K. Chawarska¹⁰, C. Sugar¹¹, S. J. Webb¹, D. Senturk³, J. Dziura¹² and J. McPartland¹³, (1)Yale Child Study Center, Yale University School of Medicine, New Haven, CT, (2)Center for Child Health, Behavior and Development, Seattle Children's Research Institute, Seattle, WA, (3)UCLA, Los Angeles, CA, (4)Department of Psychiatry and Behavioral Sciences, Duke University, Durham, NC, (5)Neurology, Boston Children's Hospital / Harvard Medical School, Brookline, MA, (6)University of Washington, Seattle, WA, (7)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (8)Children's Hospital Los Angeles, Los Angeles, CA, (9)Boston Children's Hospital, Boston, MA, (10)Child Study Center, Yale University School of Medicine, New Haven, CT, (11)University of California, Los Angeles, Los Angeles, CA, (12)Yale University, New Haven, CT, (13)Yale Child Study Center, Yale Child Study Center, New Haven, CT

Background:

Social attention is a core domain of research in autism, with eye-tracking serving as a primary research method to quantify time spent looking at social information. However, there is no consensus operationalization of “social information,” and different studies use stimuli with highly variable visual properties to address this question. While these studies are informative for a given participant sample and set of stimuli, it remains unclear how to translate experimental results into generalizable and practical measures. Item response theory (IRT) is a psychometric framework that guides the development of effective measurement tools by precisely measuring how specifically a given item on a test measures a quantitative trait, such as social attention, and how well any set of items discriminates between different levels of a trait. Here we conceptualize individual eye-tracking stimuli as test items to, for the first time, employ IRT to eye-tracking data in autism research.

Objectives:

We employ IRT to: (1) Determine if social attention is a unidimensional construct amenable to measurement; (2) Identify an optimal set of stimuli for effectively measuring social attention while removing redundant or poorly performing stimuli (3) Determine what aspects of stimuli optimally measure different strata of social attention.

Methods:

Data were collected as part of the Autism Biomarkers Consortium for Clinical Trials (ABC-CT); a multisite, naturalistic study of 280 autistic and 118 neurotypical 6-11 year-old children. Eye-tracking data were collected from 70 distinct eye-tracking stimuli varying in static/dynamic nature, duration, image composition, and sound. Social attention was quantified, at the level of stimuli, as the propensity for a participant to look to social information (faces, eyes) greater than chance. IRT analyses of stimuli employed a 2-parameter logistic model.

Results:

Social attention, measured by this heterogeneous battery, is unidimensional, i.e., variation in social looking can be conceptualized as a measurable latent trait. Distinct stimulus properties more effectively measure variability at different levels of social attention. For people with reduced social attention, dynamic videos with speech are more effective. Conversely, for people with high levels of social attention, these stimuli are less effective measures for measuring social interest. Streamlining the battery using only high-performing items allowed removal of 70% of the items, reducing experimental burden from 30 to approximately 7 minutes while increasing measurement performance.

Conclusions:

The results of this research are immediately applicable to more accurately measure social interest in autism and optimizing experimental designs to be maximally informative.

428.137 A Cross-Sectional Investigation of Dynamic Attention Among Autistic and Non-Autistic Children and Adolescents

A. Gazith¹, E. Stubbett², A. F. Boatswain-Jacques³, G. Rey³, **L. A. Langille¹**, A. Bertone³ and J. Burack², (1)Educational & Counselling Psychology, McGill University, Montreal, QC, (2)Educational & Counselling Psychology, McGill University, Montreal, QC, Canada, (3)McGill University, Montreal, QC, Canada, (4)McGill University, Montreal, QC

Background: With the advent of the neurodiversity movement, common deficit narratives about visual attention and social functioning by autistic individuals have been recast in terms of alternative styles and ways of processing, some of which may reflect unique strengths (e.g., Ames & Fletcher-Watson, 2010; Burack et al., 2016). Moreover, to gain a better understanding of the attentional styles of autistic individuals, ecologically valid paradigms should be adapted to capture the dynamic and complex social and non-social stimuli in the real-world environment (Birmingham et al., 2012).

Objectives: The focus of the present study was to compare the performance of autistic and non-autistic children and adolescents on three-dimensional (3D) dynamic versions of the biological motion (social; Johansson, 1973) and multiple object tracking (non-social; Pylyshyn & Storm, 1988) visual attention tasks.

Methods: The participants included 27 children and adolescents diagnosed with autism ($M_{CA} = 11.19$, $M_{MA} = 9.90$) matched on MA to 27 non-autistic children and adolescents ($M_{CA} = 8.81$, $M_{MA} = 9.53$) between the chronological ages (CA) of 6-17 years. The autistic and non-autistic participants were further divided into two mental age (MA) groups (lower MA: 4-10 years; higher MA: 11-18 years) to clarify the developmental patterns in performance on the attention tasks.

Results: The main findings indicate no differences in performance on the biological motion task between the autistic and non-autistic groups nor between the MA groups. Additionally, on the multiple object tracking task, no differences in performance were found between the autistic and non-autistic groups, but the higher MA group performed better than the lower MA group for the autistic and non-autistic participants.

Conclusions: These findings suggest developmental similarities between MA-matched autistic and non-autistic children and adolescents in their performance on more ecologically relevant adaptations of commonly used dynamic attention tasks.

428.138 Working Memory and Language Development in Autistic Preschoolers: A Bidirectional Exploration

A. Sehgal¹, G. Schnur² and S. Faja³, (1)Developmental Medicine-Laboratories of Cognitive Neuroscience, Boston Children's Hospital, Brookline, MA, (2)Laboratories of Cognitive Neuroscience, Boston Children's Hospital, Brookline, MA, (3)Boston Children's Hospital Laboratories of Cognitive Neuroscience, Brookline, MA

Background: Executive function (EF) has been suggested as an effective predictor of language acquisition. EF refers to top-down cognitive processes that are crucial for regulation of thoughts and actions. Past research has shown that autistic individuals demonstrate delays in executive functioning (Howard et al., 2023). Few longitudinal studies have been conducted to establish a bidirectional relationship between EF and language development in preschool children. Veraksa and colleagues (2018) demonstrated a relationship between the individual components of executive function (working memory, inhibition, and cognitive flexibility) and spoken language skills in older preschool aged children. They found significant associations between individual EF components and language development in preschool children. Their analysis showed that the level of language development is significantly associated with scores on working memory tasks. Working memory is an EF subdomain that involves manipulating information in memory to solve more complex problems. Autistic children often have difficulty with working memory and language development appears closely related to concurrent working memory ability. Yet, the longitudinal relation between working memory and language development still needs further investigation.

Objectives: To explore the bidirectional relationship between working memory and language development over time in autistic preschoolers.

Methods: Longitudinal data have been collected from a sample of 29 autistic children (28.6% female, Time 1 Age M = 31 months, SD = 3.22). Children were assessed at baseline and three years later including developmental testing and an EF battery. Language development was measured using the verbal developmental quotient from the Mullen Scales of Early Learning (Mullen, 1995). The working memory battery consisted of three behavioral activities: Boxes (Diamond et al., 1997), Self-Ordered Pointing (Petrides & Milner, 1982), and Hide and Seek (Garon et al., 2014). Working memory composite scores were computed at each timepoint from z-scores. Linear regressions were run to investigate the relationship between working memory skills and language development in young autistic children.

Results: Preliminary analyses show that initial language level predicted working memory two years later, $\beta = .384, p = .04$. However, when examining whether working memory at the participant's first assessment predicted language level two years later only a trend effect was detected, $\beta = .384, p = .06$.

Conclusions: Findings suggest that language scores at age two predict future working memory skills in preschool-aged children. This is consistent with the existing literature showing a close relationship between EF and language development. Previous research indicates that EF is a predictor of later language acquisition, but with our current sample that included many children with at least single words, the role of language in the subsequent development of working memory is clearer. A nonsignificant relation between initial working memory and later language could be due to our small sample size as the study is ongoing. As we collect additional longitudinal data, we will be able to fully test the bidirectional relationship between working memory and the different facets of language development. These findings are essential for understanding how children's early skills impact later development and can inform future interventions for autistic children.

428.139 Attention and Executive Delays in Early Childhood: A Meta-Analysis of Neurodevelopmental Conditions

K. A. Boulton¹, D. Lee², C. Sun³, N. L. Phillips⁴, M. Munro⁴, F. F. Kumfor⁴, E. A. Demetriou⁵ and A. J. Guastella¹, (1)Brain and Mind Centre, Children's Hospital Westmead Clinical School, Faculty of Medicine and Health, University of Sydney, Sydney, NSW, Australia, (2)Brain and Mind Centre, University of Sydney, Sydney, NSW, Australia, (3)Faculty of Medicine and Health, University of Sydney, Sydney, NSW, Australia, (4)University of Sydney, Camperdown, NSW, Australia, (5)Eleni Demetriou, Camperdown, NSW, Australia

Background: In the first years of life, children develop core cognitive capacities that are crucial for lifelong skills. Attention and executive function (EF) are believed to be particularly important, as they underpin adaptive and goal-directed behaviour. Delays in attention and EF have been associated with atypical brain development and various neurodevelopmental conditions, including autism, ADHD and intellectual disabilities. This has led to suggestions that attention and EF delays may be core transdiagnostic features of neurodevelopmental conditions. However, it remains unclear whether these delays can be identified in the first years of life.

Objectives: The first objective of this systematic review and meta-analysis was to determine, using a transdiagnostic approach, whether and when children with (or at risk of) neurodevelopmental conditions demonstrate delays in attention and EF in the first 5 years of life, compared to neurotypical (or low risk) peers. A second objective was to examine the different factors (age group, sex distribution, specific diagnosis, type of measure) that may moderate attention and EF delays. Finally, we aimed to explore whether the early attention and EF impairments in children with neurodevelopmental conditions are related to divergences in their structural and/or functional brain development.

Methods: MEDLINE, EMBASE, and PsycINFO databases were searched to June 30, 2023, and studies comparing attention or executive function between children with (or at risk for) neurodevelopmental conditions and neurotypical (or low risk) peers, 0 to 5 years old, were included. Of the 4338 studies identified, 111 studies with 12292 participants were included in the meta-analysis. The qualitative analysis of brain development included 5 studies. Primary outcomes were the standardised mean difference (Hedges' g) in attention and executive function between groups. Meta-regressions examined moderating effects of age, biological sex, diagnosis, and measure type.

Results: Our quantitative analysis showed that children with neurodevelopmental conditions showed small delays in attention ($n=49$ studies, $k=251$ outcomes, $g=0.36$, 95% CI 0.23-0.48, $p<0.001$) and moderate delays in executive function ($n=64$ studies, $k=368$ outcomes, $g=0.64$, 95% CI 0.53-0.76, $p<0.001$). Attention and executive function delays could not be identified in the first year, small to moderate delays were found in toddlerhood and moderate delays were observed by preschool. Delays identified were largely transdiagnostic, although there was some evidence of diagnosis-specific delays for attention and moderation by measure type (informant rating vs performance-based vs physiological). Our qualitative analysis describes how delays were underpinned by a divergence of brain development in medial prefrontal regions.

Conclusions: This study shows that attention and EF delays in individuals with neurodevelopmental conditions emerge prior to the age of 5, such that delays that are difficult to detect in infancy, begin to manifest in toddlerhood, and are further pronounced into the preschool years. These findings together contend that transdiagnostic detection and intervention approaches from toddlerhood are feasible and imperative to reduce lifelong impacts for children with neurodevelopmental conditions.

Poster Session

429 - Epidemiology II

May 2nd, 2025, 6:00 PM - 7:00 PM - Hall 4A

429.140 Maternal History of Abuse and Offspring Autism Spectrum Indicators

A. D. Coleman¹, B. Fitzwater², P. Harden³ and C. McColl⁴, (1)Central Michigan University College of Medicine, Mount Pleasant, MI, (2)University of Alabama, Tuscaloosa, AL, (3)University of Alabama at Birmingham Heersink School of Medicine, Birmingham, AL, (4)Wayne State University College of Medicine, Detroit, MI

Background: Autism spectrum disorder (ASD) is a common neurodevelopmental disorder where affected individuals suffer from social isolation, poor mental health, and delayed language development, and is being diagnosed at increasing rates. Several studies have found correlations between ASD and stress experienced by the child's mother during pregnancy or delivery, however there is little information regarding whether stress experienced prior to pregnancy is linked with ASD incidence in children. To our knowledge, only one study with a racially homogenous sample identified such a correlation.

Objectives: This study examined whether maternal experience of abuse throughout life (separated into child abuse of any type, sexual abuse as an adult, or physical abuse as an adult) predicted offspring ASD suspicion or diagnosis prior to age three.

Methods: Medical records (n=214) were reviewed from two pediatric practices in socioeconomically diverse areas of the Midwestern U.S. "Maternal abuse experience" was positive if experiencing abuse was reported in the patient history form, either during prenatal care or at admission to the hospital for delivery. ASD concern (on behalf of the pediatrician) or diagnosis was positive if either was indicated in the child's medical record by the age of three. Analyses were run using binary logistic regression, controlling for potentially confounding factors including (but not exclusive to) maternal age, maternal substance use during pregnancy, child's birth weight, and child comorbid conditions.

Results: Of the 214 charts analyzed, 111 women reported that they never experienced abuse, 54 women reported that they experienced abuse, and 49 women declined to answer. Of the 54 women who reported abuse, 24 reported that they had experienced child abuse of some type. Compared to those who reported no abuse, mothers who experienced abuse of any type were three and a half times more likely to have a child suspected of ASD prior to age three [3.48 (1.60-7.56)]. In addition, mothers who specifically experienced child abuse had a nearly two-fold risk for having a child suspected of or diagnosed with ASD, however this relationship did not reach statistical significance in this smaller sample [1.97 (0.65-6.02)].

Conclusions: Study findings provide insight into the potential pathogenesis of ASD, possibly suggesting epigenetic links at play. By identifying prior maternal abuse as a potential ASD risk factor, pediatricians can be on the lookout for ASD symptoms in their patients at an earlier age, allowing for earlier intervention and better overall outcomes.

**429.141 Maternal Mediterranean-Style Diet during Pregnancy and Child Social Impairment As Measured By the Social Responsiveness Scale: A Prospective US Birth Cohort Study**

X. Qu¹, X. Che¹, H. E. Volk², M. Augustyn³ and X. Wang¹, (1)The Center on the Early Life Origins of Disease, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, (2)Wendy Klag Center for Autism and Developmental Disabilities, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, (3)Developmental and Behavioral Pediatrics, Boston Medical Center, Boston, MA

Background:

While previous studies have reported the role of individual micronutrients in the etiology of autism spectrum disorder (ASD), there is limited and inconsistent evidence for the relationship between maternal diet patterns during pregnancy and social interaction and communication more broadly.

Objectives: To evaluate the association between a Mediterranean-style diet during pregnancy and the severity of social impairment in a racially diverse birth cohort.

Methods: In total, 822 mother-child pairs from the Boston Birth Cohort with relevant data were included in the analysis, including 52 children with an ASD clinical diagnosis. Mediterranean-style Diet Scores (MSDS) during pregnancy were calculated using food frequency questionnaires that were administered within 24 to 72 hours after delivery. The Social Responsiveness Scale (SRS) was used to measure the severity of social impairment in childhood. Restricted cubic splines were plotted to explore a potential non-linear relationship between SRS total scores and MSDS during pregnancy. Linear regressions were applied to quantify the association between MSDS during pregnancy (in tertiles) and child SRS raw scores (total scores and scores of five subdomains).

Results: There was an L-shape association between MSDS during pregnancy and SRS total raw score. Compared to the offspring of women with the lowest MSDS tertile, those with MSDS in the middle (beta (95%CI) = -4.98 (-9.57, -0.38)) and highest tertiles (-5.21 (-9.43, -0.99)) had lower SRS total scores, indicating a decreased level of social impairment. Particularly, maternal MSDS during pregnancy was significantly associated with performance in subdomains of social cognition and social communication.

Conclusions: This study found that greater adherence to a Mediterranean-style diet during pregnancy was associated with children's better social interaction and communication development. The findings emphasize the importance of maternal nutrition during pregnancy in child neurodevelopment and suggest potential targets for early risk assessment and prevention.

**429.142 Maternal Prenatal Depression and SSRI Use and Risk of Child Autism Spectrum Disorder**

L. A. Avalos¹, N. Nathan², N. Oberman², L. A. Croen¹, D. K. Li¹, M. N. Davignon³, E. Kurtovich², C. P. Quesenberry², K. K. Ridout^{2,4}, M. Bhalala⁵ and J. R. Nugent¹, (1)Division of Research, Kaiser Permanente Northern California, Oakland, CA, (2)Division of Research, Kaiser Permanente Northern California, Pleasanton, CA, (3)Pediatric Specialties, Kaiser Roseville Medical Center, Roseville, CA, (4)Department of Psychiatry, The Permanente Medical Group, Santa Rosa, CA, (5)Redwood City Medical Center, Kaiser Permanente Northern California, Redwood City, CA

Background: There remain unanswered questions regarding the neurodevelopmental consequences of prenatal exposure to maternal SSRI use.

Objectives: To evaluate the associations of prenatal depression and SSRI use with autism spectrum disorder (ASD)

Methods: We conducted a population-based retrospective cohort study of pregnant individuals seeking care at Kaiser Permanente Northern California (KPNC) between January 1, 2013 and June 30, 2021. KPNC is an integrated healthcare delivery system with universal prenatal depression screening using the Patient Health Questionnaire (PHQ-9) at multiple time points throughout pregnancy. Prenatal depression severity was defined by maximum PHQ-9 score: none (0-4), mild (5-9), moderate (10-14), and severe (≥ 15); prenatal SSRI medication use (proportion of gestational days covered (PDC)); timing (trimester(s)); effect modification by child sex. ASD was defined by diagnoses recorded in the child's KPNC electronic health record from birth through June 30, 2023. (ICD-9: 299, 299.01; ICD-10 F84, F84.0, 299.8, 299.81, F84.5, F84.8, 299.9, 299.91, F84.9). Cox proportional hazards models including both primary exposures of depression severity and SSRI use were fit overall and by infant sex, adjusting for maternal and paternal sociodemographic characteristics, maternal and paternal mental health comorbidities and treatment, maternal medical comorbidities, adequacy of prenatal care, and prenatal substance use. Sensitivity analyses excluding pregnant individuals with only 1 SSRI prescription were conducted.

Results: The cohort included 276,976 pregnancies born to 217,462 pregnant individuals.

The cohort was on average (SD) 30.7 years (5.1) of age, 27.3% Asian, 6.0% Black, 25.1% Hispanic, and 38.5% White; 10.2% of the pregnancies were insured by Medicaid. Of pregnancies, 37,711 (11.8%) were to individuals with a prenatal depression diagnosis, 12,255 (4.4%) to individuals taking SSRIs. Prenatal depression symptoms were documented as 60,434 (24.2%) mild, 17,281 (6.9%) moderate, and 8,350 (3.3%) severe. There were 11,077 (4.0%) children diagnosed with ASD in the cohort.

Depression symptom severity was associated with ASD after adjustment for potential confounders (versus no depression symptoms; mild HR: 1.16, 95%CI: 1.11-1.22; moderate HR: 1.26, 95%CI: 1.17-1.36; severe HR: 1.20, 95%CI: 1.08-1.32); No significant differences were noted between males and females. An increased risk of ASD was found for prenatal SSRI use >33%-66% of gestational days (HR:1.17, 95%CI: 1.01,1.35) and >66% gestational days (HR:1.17, 95%CI: 1.01,1.35) compared to no use. Prenatal SSRI use in all three trimesters (HR:1.19, 95%CI:1.02-1.37) and 3rd trimester only (HR:1.45, 95%CI:1.12-1.86) compared to no use was associated with an increased risk of ASD. Sensitivity analyses excluding pregnant individuals with one SSRI fill, found similar trimester-specific associations with ASD in males, but not females. Sensitivity analyses support the main findings.

Conclusions: Findings suggest prenatal depression is associated with ASD risk, and that prenatal SSRI use may confer additional risk of ASD when SSRI use is continued for more than a third of pregnancy or initiated in the third trimester. However, the observed associations between SSRI use and ASD risk may be an artifact of exposure misclassification or severity-SSRI use time ordering. Findings can help clinicians and pregnant patients make informed treatment decisions and identify children for targeted early interventions to support healthy development.

429.143 Newborn IgG Antibodies to Maternal Sars-Cov-2 Infection in Pregnancy and Child Neurodevelopmental Outcomes

L. A. Croen¹, Y. Qian¹, L. P. Grosvenor¹, J. L. Ames¹, R. Yolken², S. Alexeeff³, P. Ashwood⁴, J. Van de Water⁴ and D. Kim⁵, (1)Division of Research, Kaiser Permanente Northern California, Oakland, CA, (2)Johns Hopkins University, Baltimore, MD, (3)UC Davis, Sacramento, CA, (4)University of California at Davis, Davis, CA, (5)Stanford University, Palo Alto, CA

Background: Gestational exposure to infection has been linked with neurodevelopmental disorders (ND). Maternal immune activation is the hypothesized mechanism by which prenatal exposure to infection adversely impacts fetal brain development. Levels of SARS-CoV-2 IgG class antibodies generated to viral proteins in the beginning of pregnancy remain detectable at later stages and are transferred across the placenta to the newborn. Thus, the immune profile of the newborn reflects maternal infection, and as such, newborn screening bloodspots are an ideal sample with which to investigate the impact of maternal SARS-CoV-2 infection in pregnancy on child neurodevelopment.

Objectives: To investigate the association between neonatal levels of IgG antibodies to SARS-CoV-2 nucleocapsid and spike proteins and risk of ND among children with gestational SARS-CoV-2 exposure.

Methods: In this longitudinal prospective cohort study, we obtained newborn screening bloodspots from 399 children born at Kaiser Permanente Northern California (KPNC) between April 2020 and September 2021 to mothers who had SARS-CoV-2 infection during pregnancy and had not received the SARS-CoV-2 vaccination. IgG class antibodies to recombinant SARS-CoV-2 nucleocapsid and spike proteins were measured in dried bloodspots using multiplex chemiluminescent immunoassay procedures. All ND diagnoses recorded in children's electronic health records by May 31, 2024 were retrieved and categorized as any ND, autism spectrum disorder (ASD), speech/language delay, or motor delay. We generated separate Cox proportional hazards regression models to estimate hazard ratios (HR) and 95% confidence intervals (CI) for each child outcome associated with the level of IgG antibodies to the SARS-CoV-2 nucleocapsid and spike proteins. Children were followed from 3 months of age until the date of the first ND diagnosis, the date they left the KPNC health system, death, or May 31, 2024, whichever occurred first. Multivariate models included adjustment for maternal age, pre-pregnancy obesity, season of childbirth, trimester of maternal infection, and child sex. Effect modification by child sex and trimester of infection was also evaluated.

Results: Among the 399 children, 69 (17.3%) had a diagnosis of ND (19 ASD, 63 speech/language delay, 11 motor delay). SARS-CoV-2 nucleocapsid IgG antibody level was not associated with risk of ND overall (aHR=1.11, 95% CI [0.93-1.33]), ASD (aHR=1.05 [0.74-1.48]), speech/language delay (aHR=1.19 [0.99-1.43]), or motor delay (aHR=0.81 [0.49-1.32]) in adjusted analyses. However, associations differed significantly by child sex, with increased risk observed only among males (ND: aHR=1.28 [1.02-1.61]; ASD: aHR=1.47 [0.92-2.34]; speech/language delay: aHR=1.37 [1.08-1.73]; motor delay: aHR=1.32 [0.63-2.80]). Risk also differed by trimester of maternal SARS-CoV-2 infection, with over 2-fold increased risks observed with first trimester (ND: aHR=2.21 [1.10-4.45]; speech/language delay: aHR=2.33 [1.09-4.98]) and second trimester (speech/language delay: aHR=2.23 [1.20-4.13]) exposure. Results were similar for associations with the level of IgG antibodies to the SARS-CoV-2 spike proteins.

Conclusions: Higher levels of neonatal antibodies to maternal SARS-CoV-2 infection in pregnancy may indicate increased risk for ND. If replicated, these findings suggest that newborn antibody testing of male infants with prenatal SARS-CoV-2 exposure may provide a novel avenue for early identification of infants at risk for ND and opportunities for early intervention and prevention of adverse child outcomes.

429.144 Parental Age and Autism Spectrum Disorder: The Mediating Role of Parental Education

S. I. Ansari¹, A. Mercier², O. F. Ward², B. Stein², S. O'Kelley² and K. C. Guest¹, (1)Department of Psychology, THE UNIVERSITY OF ALABAMA AT BIRMINGHAM, Birmingham, AL, (2)Department of Psychology, The University of Alabama at Birmingham, Birmingham, AL

Background: Older parental age, which potentially harbors several underlying mechanisms, is commonly associated with various developmental disorders, including autism spectrum disorder (ASD) (Chu et al., 2023; Sandin et al., 2016). Maternal education has been found to mediate the relationship between ASD diagnosis compared to a typical control group (Kelly et al., 2019; Lung et al., 2018; Veldkamp et al., 2021). However, how this mechanism differs among children with ASD and those with other neurodevelopmental disorders (NDDs) remains underexplored. **Objectives:** This study aimed to examine whether parental education mediated the association between maternal and paternal ages and diagnosis (i.e., ASD or a different NDD).

Methods: Participants included individuals who received an interdisciplinary comprehensive ASD assessment between years 2006 through 2020 ($N = 673$, $M_{\text{age}} = 5.67$ years, $SD = 3.42$, ages ranged from 1 year to 18 years old, 77.27% male). Structural equation modeling (SEM) was performed to assess both the direct effects of maternal and paternal ages on ASD diagnosis and the indirect effects of parental education on the association between maternal and paternal ages at birth on ASD diagnosis. The model was estimated using weighted least squares mean and variance adjusted (WLSMV), with autism diagnosis included as a binary variable. Bias-corrected bootstrap analysis was conducted to assess the mediating effects of parental education in the relationship between maternal and paternal ages on ASD diagnosis. Sex, age at ASD evaluation, and birth order were included as covariates in the analysis.

Results: After controlling for sex, participant's age at evaluation, and birth order, mediation analyses revealed that higher maternal age at birth was positively related with increased likelihood of ASD diagnosis ($\beta = 0.21$, $p = .003$). Higher parental education was also positively related with ASD diagnosis ($\beta = 0.17$, $p = .001$). Higher maternal age at birth had an indirect effect through parental education on higher likelihood of ASD diagnosis ($\beta = 0.07$, $p = .004$) over a different NDD diagnosis. Paternal age did not significantly predict ASD diagnosis in the sample.

Conclusions: This study uniquely contributes to previous literature by examining the differences in the relationship between parental age, parental education, and ASD diagnosis using a comparison group consisting of other NDD rather than a typically developing group. This study suggests that higher maternal age and greater parental education are associated with an increased likelihood of an ASD diagnosis (Idring et al., 2014; Kelly et al., 2019) compared to non-ASD diagnoses (such as different NDDs). Additionally, similar to previous studies, parental education, while playing a minimal but significant role, suggests higher education may influence ASD diagnoses (Lung et al., 2018), indicating a potential underlying role of knowledge about ASD, and higher socio-economic status (SES), which likely increases access to services. Unlike previous findings, paternal age did not predict ASD diagnosis in this sample (Sandin et al., 2016). Overall, understanding factors associated with ASD diagnosis are important for targeting parental education related to autism and efforts for early identification.

429.145 Preliminary Study of Differences in Ethnoracial Distributions across Autism and Gender Diversity

A. D. Todd¹, G. L. Wallace², J. J. Michaelson³, A. Jack⁴, G. A. McQuaid⁴, A. L. Fischbach⁵, S. A. Parwani¹, C. S. Parkin⁶ and J. F. Strang⁷, (1)Gender and Autism Program, Children's National Hospital, Washington DC, DC, (2)The George Washington University, Washington, DC, (3)Psychiatry, University of Iowa, Iowa City, IA, (4)George Mason University, Fairfax, VA, (5)Department of Psychology, University of Cincinnati, Cincinnati, OH, (6)Gender and Autism Program, Children's National Hospital, Washington, DC, (7)Gender and Autism Program, Children's National Health System, Washington, DC

Background: Evidence indicates disparities by race and ethnicity in rates of autism diagnosis and in participation in both autism and gender diversity-related research. Given: (1) the proportional over-representation of autism in gender diverse populations and (2) ethnoracial disparities in clinical care access and research participation observed in both autism and gender diversity, we predict: ethnoracial disparities in research representation will be pronounced in autistic gender diverse populations.

Objectives: Employing the standardization sample for the Gender Self-Report (Strang et al., 2023), this study investigates whether the distribution of ethnoracial identities varies across autistic vs. non-autistic cisgender vs. gender diverse subgroups.

Methods: The standardization sample for the Gender Self-Report (GSR; $N = 1654$; Strang et al., 2023) was recruited through 7 independent recruitment efforts across the U.S., with the intention of diversifying representation across autism, gender diversity, and the intersection of autism and gender diversity. For this current study, chi-squared tests were conducted across Black ($n = 115$), Asian ($n = 162$), and Latine/o/a ($n = 144$) subgroups, to test for proportional differences between: (A) non-autistic cisgender vs. non-autistic gender diverse; (B) non-autistic gender diverse vs. autistic gender diverse; and (C) cisgender autistic vs. gender diverse autistic. The priority in these analyses was to avoid Type II, not Type I error, as this study explores potential disparities in representation; for this reason, both uncorrected p values and p values adjusted by False Discovery Rate are presented.

Results: Proportionally, there were fewer Black and Asian gender diverse non-autistic as compared to cisgender non-autistic participants. Such differences were not found for Latine/o/a participants, though the chi-square approached significance before multiple comparison correction (uncorrected $p = .07$). Contrary to our hypothesis, proportional representation of Black, Asian, and Latine/o/a individuals did not differ between gender diverse autistic versus non-autistic groups. Further, ethnoracial proportions between cisgender autistic and gender diverse autistic participants did not differ.

Conclusions: This is the first study to investigate proportional distributions of race and ethnicity in autistic cisgender and autistic gender diverse groups. Although racial disparities in research recruitment were observed in the non-autistic groups (i.e., cisgender vs. gender diverse), no ethnoracial disparities were observed by intersectional autism and gender diversity. Reflections within the autistic community suggest that characteristics of autism may help gender diverse people to more readily express gender diversity; given current findings, this may be observed across ethnic and racial identities.

429.146 Prevalence of Co-Occurring Mental, Neurodevelopmental and Neurological Conditions in Medicaid Beneficiaries with Autism Spectrum Disorder

C. DiGiuseppi¹, Z. Yang², A. Blanchard³, C. Ing² and G. Li³, (1)Colorado School of Public Health, University of Colorado Anschutz Medical Campus, Aurora, CO, (2)Department of Anesthesiology, Columbia University Vagelos College of Physicians and Surgeons, New York, NY, (3)Department of Emergency Medicine, Columbia University Irving Medical Center, New York, NY

Background: Healthcare utilization and costs are significantly higher for individuals with autism spectrum disorder (ASD) compared to the general population, partly because of co-occurring health conditions. As ASD prevalence rises and more youth diagnosed with ASD transition to adulthood, epidemiologic data on co-occurring conditions throughout the lifespan are essential for understanding the healthcare needs of people with ASD.

Objectives: Describe the prevalence of co-occurring mental, neurodevelopmental and neurological conditions among Medicaid beneficiaries with ASD, overall and by demographic characteristics.

Methods: This descriptive epidemiological study analyzed Medicaid claims data, which include individual-level claims for outpatient, inpatient, and long-term care services among people enrolled in Medicaid, the largest health insurance program in the United States (US) and the primary public insurance program for people with ASD. We identified all individuals who had a diagnosis of ASD in 2019 to 2020 based on ICD-10-CM codes on ≥ 1 inpatient claim or ≥ 2 other non-drug claims of any service type. We identified additional mental, neurodevelopmental and neurological diagnoses using the same algorithm for relevant codes. Frequencies were calculated for the total sample and by age, gender and race/ethnicity.

Results: We identified 994,164 Medicaid beneficiaries with ASD. Most (75.4%) were ages ≤ 20 , 20.8% were 21-44, 3.1% 45-64, and 0.7% 65+; 76.9% were male. The largest racial/ethnic group was non-Hispanic White (NHW) (43.6%), followed by Hispanic any race (17.7%) and non-Hispanic Black (NHB) (12.64%); 21.8% were missing race/ethnicity. The most common co-occurring condition was attention-deficit/hyperactivity disorder (ADHD), with a prevalence of 30.5%. Other commonly co-occurring conditions included intellectual disabilities (ID) (20.4%), anxiety (19.3%), bipolar disorder (9.9%), depression (9.0%), epilepsy (8.0%) and cerebral palsy (2.4%). Prevalence varied by age group (Figure 1). ADHD prevalence was highest at 15-24 years (37%), declining with age. Anxiety and bipolar disorders peaked at ages 25-64. Prevalence of ID, depressive disorder, epilepsy and cerebral palsy increased with increasing age. All conditions except ADHD were more common in females. Prevalence also varied by racial/ethnic group (Figure 2). ADHD was the most prevalent condition in all groups except American Indian/Alaskan Native (AI/AN), among whom ID was most prevalent. Anxiety, bipolar and depressive disorders were all less commonly diagnosed in NHB, AI/AN and Hispanic individuals. For most conditions, NHW and multiracial individuals had the highest prevalence and AI/AN and Hispanic individuals the lowest.

Conclusions: Among nearly 1 million publicly-insured individuals with ASD in the US, mental, neurodevelopmental and neurological conditions were common across the lifespan. Differences by age and gender may reflect underdiagnosis of ASD in previous generations and among females, respectively, in the absence of ID or other co-occurring conditions. Racial/ethnic disparities may result in part from less access to mental health services, despite being insured, leading to underdiagnosis of co-occurring conditions. Screening for ADHD in adults with ASD, and for anxiety and depressive disorders in youth and adults with ASD, especially those from disadvantaged populations, may improve health outcomes. The high prevalence of potentially disabling co-occurring conditions across the lifespan has important implications for meeting healthcare needs in individuals with ASD as they age.

429.147 Sex- and Timing-Specific Associations between Prenatal Glucose Intolerance Exposures and Child Neurodevelopmental Outcomes

L. P. Grosvenor¹, J. L. Ames¹, Y. Qian¹, S. Alexeeff², P. Ashwood², D. Kim³, J. Van de Water⁴, L. A. Weiss⁵, E. P. Gunderson¹ and L. A. Croen¹,
 (1)Division of Research, Kaiser Permanente Northern California, Oakland, CA, (2)UC Davis, Sacramento, CA, (3)Stanford University, Palo Alto, CA, (4)UC Davis MIND Institute, Sacramento, CA, (5)Department of Psychiatry and Institute for Human Genetics, University of California San Francisco, San Francisco, CA

Background: Gestational diabetes mellitus (GDM) is associated with increased risk of autism spectrum disorder (ASD) and developmental delay (DD). However, few studies have examined whether associations differ by timing of GDM diagnosis or child sex, and none have examined sub-clinical impaired glucose tolerance as a separate risk factor. Given standard screening and diagnostic practices and availability of treatments, management of GDM and impaired glucose tolerance represents avenues for prevention of adverse child outcomes. A better understanding of the relationship between prenatal glucose intolerance and risk of neurodevelopmental disorders (NDDs) can also provide insight into etiologic mechanisms.

Objectives: To determine associations between prenatal glucose intolerance and risk of child ASD and DD and examine whether associations differ by timing of GDM diagnosis and child sex.

Methods: We ascertained a case-control sample of mother-child pairs from children born at Kaiser Permanente Northern California (KPNC) between January 2011 and December 2018. Children were categorized as having ASD, DD, or as general population controls (GP) based on diagnoses in electronic health records (EHR). GDM was defined according to two-step Carpenter and Coustan diagnostic criteria based on laboratory testing in maternal EHR and categorized into early and standard subgroups by gestational age (early: ≤ 26 weeks; standard: >26 weeks). Impaired glucose tolerance (IGT) was separately defined by elevation of 50-gram glucose screening and/or one glucose elevation for the diagnostic test, with GDM diagnosis. We estimated risk of ASD and DD associated with prenatal exposures using logistic regression models adjusted for child sex, birth year, parity, maternal age at birth, race, education, and pre-pregnancy BMI. Effect modification by child sex was evaluated using stratified analyses and models including sex-by-exposure interaction terms.

Results: The study sample of 4,716 mother-child pairs included 710 children with ASD, 2,135 with DD and 1,871 GP controls; there were 573 (12.1%) mothers with GDM and 64 (1.4%) with impaired GT. There was no evidence for increased risk of ASD or DD associated with GDM diagnosed at any gestational age (ASD OR [95% CI]=1.12 [0.84-1.48]; DD OR=1.20 [0.98-1.47]). Risk of ASD associated with exposure to GDM ≤ 26 weeks was increased among females (OR=2.21 [0.96-4.80]) but not males (OR=0.88 [0.51-1.50], sex-by-exposure interaction $P < 0.05$). GDM diagnosed >26 weeks' gestation was associated with elevated risk of DD, also among females only (OR=1.42 [0.99-2.04]). Children born to mothers with IGT had significantly increased risk of DD among the full sample (OR=1.81 [1.01-3.34]) and this risk was further elevated among females (OR=3.23 [1.33-8.61]) but not males (OR=1.10 [0.51-2.45]).

Conclusions: Risks of ASD and DD were associated with prenatal glucose intolerance—both GDM and IGT—in a timing- and sex-specific manner. Earlier GDM diagnosis was associated with increased ASD risk only among females, suggesting possible sex differences in the relevant exposure window for fetal programming mechanisms underlying risk. This is also the first study to identify sub-clinical impaired glucose tolerance as a risk factor for NDDs separate from non-GDM referent. Expanding treatment recommendations to include this group may have implications for child health, including primary prevention of NDDs.

429.149 The Association between Motor and Social Skills in Young Children with Autism Enrolled in the Study to Explore Early Development

O. M. Pokoski¹, H. Engel¹, P. Powell², N. Reyes³, L. Wiggins² and M. S. Durkin⁴, (1)University of Wisconsin-Madison, Madison, WI, (2)Centers for Disease Control and Prevention, Atlanta, GA, (3)University of Colorado, Anschutz Medical Campus, Aurora, CO, (4)Population Health Sciences, University of Wisconsin-Madison, Madison, WI

Background: The attainment of motor milestones is often more easily observable than social skill milestones early in child development. Previous research investigating the relationship between motor and social skills in autism has found a reciprocal relationship, with motor development allowing for increased social opportunities, and social skills playing a role in activity participation for strengthening motor skills. A better understanding of the association between motor and social skills could lead to interventions to improve skill acquisition and developmental outcomes for individuals with autism.

Objectives: 1) To describe motor and social impairments among preschool-aged children with autism; and 2) to evaluate whether motor skills are positively associated with social skills.

Methods: We analyzed cross-sectional data from children aged 2-5 years recruited between 2007 and 2020 for a multi-site, multi-year, case-control study exploring risk factors and developmental characteristics of autism in the United States. Children were confirmed to have autism based on the Autism Diagnostic Interview-Revised and the Autism Diagnostic Observation Schedule. Caregivers completed the Social Responsiveness Scale (SRS) questionnaire to assess their child's social skills in relation to autism. An SRS Total t score ≥ 76 indicated severe impairment. Caregivers also reported adaptive behavior using the Vineland Adaptive Behavior Scales (Vineland). A score of ≤ 70 on the Vineland Socialization domain or Motor Skills domain indicated low social or motor skills, respectively. Linear regression models were built to evaluate the association between motor skills (primary predictors: Vineland Motor Skills standard score, Vineland Gross Motor subdomain v-scale score, or Vineland Fine Motor subdomain v-scale score) and social skills (outcome variables: SRS total t-score or Vineland Socialization standard score).

Results: Among the 2,052 children meeting study autism criteria, the average Vineland Motor Skills standard score was 79.1 (standard deviation, SD=13.1), with 29.0% classified as having low motor skills. Average social skills were 72.5 (SD=10.9) on the SRS Total t score and 71.8 (SD=12.1) for the Vineland Socialization domain standard score. Severe impairment (SRS) and low social skills (Vineland Socialization) were observed in 39.9% and 49.6% of the sample, respectively. Each motor score was positively associated with higher Vineland Socialization scores, with the strongest association observed between Vineland Motor Skills and Vineland Socialization standard scores ($R^2=0.368$; $p\text{-value} < 0.001$). Motor scores were negatively associated with SRS scores, indicating that higher motor ability was associated with lower social impairment. Compared to gross motor skills scores, fine motor skills had stronger associations with both the Vineland and SRS measures of social skills.

Conclusions: This study found almost a third of preschool-aged children with autism had motor impairment and a significant association between motor and social skills. These findings underscore the potential importance of considering motor skills in diagnostic assessments of autism and in developing appropriate interventions and therapies. Future research could explore how the association between motor and social skills evolves across the lifespan and investigate its implications for developmental outcomes.

429.150 The Design Research of Mapa Autismo Brazil - Mab: Sociodemographic and Clinical Profile of Autistic People

A. C. Steinkopf¹, R. Vieira², E. Silva Souza¹, V. R. D. J. Reis³, Y. A. Gadelha⁴, J. Seles¹, R. Arruda⁵, L. Lopes¹, W. Silvestre¹ and V. R. D. Gomes²,
 (1)Steinkopf Institute, Brasilia, Federal District, Brazil, (2)University of Brasilia, Brasilia, Federal District, Brazil, (3)UNIFESP, Brasilia, Federal District, Brazil, (4)University of Brasilia, Brasilia, Federal District, Brazil, (5)Neuroscience, Instituto Glia, Ribeirao Preto, SP, Brazil

Background:

In 2023, MAB (Autism Map Brazil), a non-governmental research was carried out in the Federal District. This study aimed to fill the gap in sociodemographic data on the country's autistic population. This presentation is MAB's design to be carried out nationwide in the 27 states in 2025.

Objectives:

The purpose of this study is to collect data and analyze the sociodemographic and clinical profile of autistic people looking at issues such as age, income, economic class, schooling, employability, access to health services and public policies, diagnostic data, symptoms, comorbidities, and the types of services used in Brazil.

Methods:

The MAB is a quantitative, cross-sectional, and non-probabilistic convenience sampling research. It uses online surveys presented via the SurveyMonkey platform. The first one will be aimed at autistic individuals aged 18 or over with autonomy to answer. The other will be aimed at caregivers or guardians of autistic individuals who are minors or unable to answer the questionnaire independently.

These surveys will be published on websites, and social media and through institutional partnerships with associations that work with autism audiences, universities, schools, research centers, companies, hospitals and clinics, and research volunteers.

The sample will be distributed proportionally among the Brazilian geographic meso-regions to ensure that all areas are represented. It takes into account regional differences in terms of access to services and diagnosis. Data collection will be segregated by biological gender to identify differences in prevalence and sociodemographic characteristics between boys and girls, as well as men and women.

Considering the prevalence rate of 2.1%, the estimated population of autistic people in Brazil is 4.264.696 individuals. The sample calculation used stricter criteria, with a 95% confidence level and a 5% margin of error, resulting in a desired sample of 10.320 respondents. This number was distributed proportionally to each Brazilian state.

For data analysis, machine learning algorithms such as clustering analysis and others could be used to identify profiles and explore the data. This approach can make it possible to discover significant patterns and relationships, enriching the understanding of the data collected.

Results:

The project was approved by the Ethics Committee of the University of Brasilia (CAAE: 70226623.9.0000.5540). In the current phase, 455 institutional partnerships have already been established, distributed among the 27 states, to disseminate the data collection instruments. The data collected will take place between March and April 2025. The data from the pilot study has already been published on the website <https://www.mapaautismobrasil.com.br/> in Portuguese and English, and will be updated as soon as the new data collected is analyzed.

Conclusions:

The MAB results are fostering different academic research. In addition, MAB has supported the development and updating of public policies and services aimed at the autistic population. The data collection will be repeated every two years to update the information based on the sociodemographic and clinical profile of autistic people in Brazil.

429.151 The Impact of Maternal Depression, Anxiety, and Stress on Early Autism-Related Traits

Z. L. Chen¹, T. Ren² and F. Li³, (1)Xinhua Hospital, Shanghai Jiao Tong University School of Medicine, Shanghai, China, Shanghai, Shanghai, (2)Developmental and Behavioral Pediatric Department & Child Primary Care Department, Brain and Behavioral Research Unit of Shanghai Institute for Pediatric Research and MOE Shanghai Key Laboratory for Children's Environmental Health, Xinhua Hospital, Shanghai, Shanghai, China, (3)Department of Developmental and Behavioral Pediatric and Child Primary Care & Ministry of Education-Shanghai Key Laboratory for Children's Environmental Health, Xinhua Hospital, Shanghai Jiao Tong University School of Medicine, Shanghai, 200092, China., Shanghai, Shanghai, China

Background: Perinatal mental health is increasingly recognized as a significant environmental factor influencing offspring neurodevelopment, particularly in relation to autism. However, its effects on autism-related traits in offspring remain uncertain.

Objectives: N/A

Methods: We obtained data from 2,207 healthy mother-child pairs in the Shanghai Birth Cohort (SBC). Maternal mental health was assessed at mid-pregnancy using the Center for Epidemiological Studies-Depression Scale (CES-D), Zung Self-Rating Anxiety Scale (SAS), and Perceived Stress Scale (PSS). Autism-related traits in offspring were evaluated at 4 years using the Social Responsiveness Scale-Short Form (SRS-SF), which included factors of social cognition, social communication, and autistic mannerism. Pearson correlation and multiple linear regression analyses were used.

Results: Associations were observed between maternal depression, anxiety, elevated stress, and offspring SRS-SF total scores at age 4 ($r = 0.14$, $P < 0.001$; $r = 0.08$, $P = 0.002$; $r = 0.09$, $P = 0.002$, respectively). After adjusting for maternal factors (age, socioeconomic status, smoking, alcohol use) and child factors (gender, gestational age at birth), each 1SD increase in maternal mental health scores was associated with an increase in offspring's SRS-SF total score: 0.19 (95% CI: 0.06, 0.32) for depression, 0.09 (95% CI: 0.06, 0.13) for anxiety, and 0.08 (95% CI: 0.03, 0.11) for stress. Associations were also observed for SRS-SF social cognition and social communication subscales.

Conclusions: Prenatal maternal depression, anxiety, and stress were associated with increased autism-related traits in early childhood. These findings enhance our understanding of the role of maternal prenatal mental health in the neurodevelopmental origins of non-clinical autism-like traits.

429.152 The Prevalence and Cumulative Incidence of Autism across Utah's Local Health Districts 2018

C. Nicholls¹, M. Al-Saedy², C. Kingsbury³, D. A. Bilder⁴ and A. V. Bakian¹, (1)University of Utah Huntsman Mental Health Institute, Salt Lake City, UT, (2)University of Utah, Salt Lake City, UT, (3)Children with Special Health Care Needs, Utah Department of Health, Salt Lake City, UT, (4)Psychiatry, University of Utah, Salt Lake City, UT

Background: The Utah Registry of Autism and Developmental Disabilities (URADD) was established in 2002 as a joint effort between the Utah Department of Health and Human Services and the University of Utah Department of Psychiatry. URADD uses a passive, population-based system to identify persons across the lifespan with autism based on a community medical diagnosis of autism and/or an autism special education eligibility. While autism prevalence is frequently reported statewide in Utah, little is understood about how autism prevalence and incidences vary at the local health district (HD) level. An improved understanding of differences in autism prevalence and incidence across HDs is essential for meeting the service needs of autistic individuals in Utah.

Objectives: Determine and compare autism prevalence and cumulative incidence across Utah's local health districts and examine differences in prevalence across demographic factors.

Methods: The number of autistic individuals aged 5-24 (youth) in 2018 living in Utah were identified by URADD. Local health district population estimates were acquired from the Utah Indicator-Based Information System for Public Health. For the crude prevalence estimates, the Wilson score method with continuity correction was used to estimate 95% confidence intervals (CI). Prevalence ratios (PR) and 95% confidence intervals were estimated across race/ethnicities and HDs using Wald's method. A single birth cohort of youth born in 2002 was selected to estimate cumulative incidence of the age of first ICD identification of autism by HD. Cumulative incidence at ages 4, 8, 12 and 16 years in the 2002 birth cohort were compared across HDs using risk ratios. Salt Lake City Health District (SLCHD) was chosen as the reference group.

Results: Autism prevalence in 2018 in SLCHD was 23.9 per 1000 youth (95% CI: 23.4, 24.4). Davis County HD had the highest autism prevalence (PR: 1.12, 95% CI: 1.08, 1.16; Table 1). Except for Tooele County HD, all other HDs had significantly lower autism prevalence than SLCHD (PRs: 0.32 – 0.86). The prevalence ratios across White Non-Hispanic (NH) and Hispanic individuals among HDs mostly reflected the overall HD prevalence ratios; however, autism prevalence amongst Black NH individuals was only different from SLCHD in Davis County HD (PR: 1.54, 95% CI: 1.08, 2.22). Hispanic autism prevalence was significantly lower than White NH autism prevalence in 9 of the 13 HDs. Cumulative incidence (Figure 1) among 4-year-olds did not statistically differ across HDs. However, cumulative incidence differed by some HDs at 8 and 12 years of age (RR: 0.08 - 0.66). At 202 months, Bear River, TriCounty, Utah County, Wasatch County, and Weber Morgan HDs' cumulative incidence were significantly lower than SLCHD.

Conclusions: Autism prevalence among school age children and young adults varied considerably across HDs and by race/ethnicity suggesting potential regional differences in access to autism diagnostic services and/or ascertainment completeness. In contrast, the likelihood of being identified with autism was consistent across Utah HDs at younger ages. Study findings merit further investigation into factors leading to regional discrepancies in autism identification and ascertainment to inform HD-level autism diagnostic and service needs.

429.153 Trends in the Presentation of Children with Autism Spectrum Disorder to a Tertiary Multidisciplinary Setting in Lower Middle Income Country

D. V. Vipulaguna^{1,2}, H. Iranthika³, N. A. Muttiah⁴, S. Sumanasena⁵, A. Nuwan² and R. Gurusinghe⁵, (1)Ministry of Health, Sri Lanka, Colombo, Western, Sri Lanka, (2)Ayati National Centre for Children with Disabilities, Ragama, Western, Sri Lanka, (3)Ministry of Health, Sri Lanka, "Ayati" Center National Center for Children with Disabilities, Ragama, Sri Lanka, (4)Department of Disability Studies, Faculty of Medicine, University of Kelaniya, Ragama, Sri Lanka, (5)Department of Disability Studies, Faculty of Medicine University of Kelaniya, Ragama, Sri Lanka

Background: The global burden of diseases suggests an increase in the prevalence and incidence of autism spectrum disorder. Studies indicate that socio-demographic factors, associations, and clinical presentations have evolved in different dimensions over the years.

Objectives: This study aims to describe and compare the sociodemographic factors, risk factors, and clinical presentation of children with autism in a tertiary multidisciplinary setting in Sri Lanka, at two time points five years apart.

Methods: We carried out a secondary data analysis of the autism database of the National Centre for Children with Disabilities in Sri Lanka and compared data sets in 2017 and 2022. Any child (0-18 years) with a specialist-made diagnosis of autism spectrum disorder according to DSM V criteria was included in the analysis. SPSS 28.0 software was used for the analysis of data.

Results:

In 2017, 54 children with autism presented to the centre compared to 326 in 2022. The male-to-female ratio was 13:1 in 2017 while it was 3.2:1 in 2022. The mean age at presentation was not significantly different in the two-time points. In 2017, the average age at presentation was 54.83 months (SD 35.19, median 45.5 months), compared to 53.05 months (SD 32.67, median 44 months) in 2022. Only 48.3% presented before 48 months in 2017 and 62% did so in 2022 ($p < 0.001$). Most of the children with autism were firstborns.

Perinatal risk factors were observed at higher percentages in 2017 compared to 2022.

	2017	2022	p
Antenatal risk factors (diabetes, hypertension)	10 (17.9%)	15 (4.6%)	<0.001
Neonatal sepsis	3 (5.4%)	11 (3.4%)	0.405
Neonatal jaundice	14 (25%)	40 (12.3%)	0.028
Low birth weight	6 (10.7%)	23 (7.1%)	0.348
Prematurity	3 (5.4%)	17 (5.2%)	0.505

A higher percentage had co-morbid epilepsy 6/56 (10.7%) and attention deficit hyperactivity disorder (ADHD) 4/56 (7.1%) in 2017 in comparison to 10/326 (3.1%) and 7/326 (2.1%) respectively in 2022 ($p < 0.05$).

Conclusions: The number of children presented with autism was six times higher in 2022 compared to 2017. This may reflect the increasing numbers as well as the better establishment of the centre in the National system, allowing more patients to come. The number of females with the diagnosis has gone up fourfold within five years. These findings are compatible with the secular trends globally.

There was no significant difference in the mean age of presentation to the services, but more than half of the population in 2022 presented before 48 months. The presence of demonstrable perinatal risk factors was higher in 2017 than in 2022, raising important questions about epigenetics.

Particularly, neonatal jaundice and antenatal risk factors were present in significantly higher percentages in 2017. Associated comorbid conditions were observed more frequently in 2017 compared to 2022.

We recommend larger population-based studies to understand trends in underlying socio-ecological, aetiological factors, and clinical presentations of children with autism.

429.154 Trends in the Prevalence of Autism By Adaptive Level between 2000-2016: Evidence from a Population-Based Sample of 8-Year-Old Children in the United States

S. M. Furnier^{1,2} and M. S. Durkin^{1,2}, (1)Population Health Sciences, University of Wisconsin-Madison, Madison, WI, (2)Waisman Center, University of Wisconsin-Madison, Madison, WI

Background: As the prevalence of autism has increased in recent decades and continues to rise, and as identification strategies have improved, the heterogeneity of the autistic population has also grown. A challenge in autism policy and research is how to accurately and adequately describe variability in functioning, disability, and support needs in this population. The Center for Disease Control and Prevention's Autism and Developmental Disabilities Monitoring (ADDM) Network provides biennial estimates of autism prevalence and the percentage with IQ ≤ 70 based on information in children's health and education records. Adaptive test scores, which can also be found in health and particularly education records, may provide better insights than IQ scores do into functional variation in the autistic population.

Objectives: Describe: (1) the availability of adaptive scores in health and education records from a multisite autism surveillance network; and (2) trends in autism prevalence by adaptive level between 2000 and 2016.

Methods: The ADDM Network is a multisite surveillance system that monitors the prevalence of autism in children in the United States; we limited our analysis to 8-year-old children from study years 2000-2016. Abstracted health and educational records were reviewed by clinicians to determine autism case status based on Diagnostic and Statistical Manual of Fourth Edition-Text Revision (2000-2016) and Fifth Edition (2016) criteria. Adaptive behavior was measured using Vineland Adaptive Behavior Scales scores from tests administered between the ages of six to eight years (VABS 6-8yrs). We used multiple imputation to account for missing adaptive scores and estimated population prevalence with 95% confidence intervals (CI) stratified by adaptive impairment level (moderate to profound impairment [VABS 6-8yrs score ≤ 50], mild [51-70], borderline [71-85], and none [>85]) using population census denominators.

Results: Overall, 16,164 (65.5%) children had adaptive test results recorded, with scores for the remaining 8,505 estimated using multiple imputation. Availability of scores differed by child and sociodemographic characteristics. In 2000, the prevalence of autism was highest in those with mild adaptive impairment (3.1 per 1,000 8-year-old children [95% CI: 2.7-3.4]), followed by those with borderline (1.4 [1.2-1.7]), moderate to profound (1.5 [1.2-1.7]), and those with no adaptive impairment (0.6 [0.4-0.8]). Over time, prevalence rose only for autism with mild to no adaptive impairments. In 2016, the prevalence of autism with moderate to profound adaptive impairment (1.2 [1.1-1.4]) was similar to that in 2000; for every other adaptive level, the prevalence had increased substantially. The largest increase was observed among children with no adaptive impairment (3.4 [3.2-3.7], a 464% increase), followed by borderline (6.9 [6.5-7.2], a 382% increase), and mild impairment (7.3 [7.0-7.7], a 139% increase).

Conclusions: Using adaptive scores available in health and education records, we estimated the population-based prevalence of autism by adaptive level. The increase in autism prevalence between 2000 and 2016 among children with mild, borderline, or no adaptive limitations could indicate improved identification of those with milder limitations as well as increased access to effective therapies. This study demonstrates the feasibility and value of incorporating adaptive behavior scores into epidemiologic studies and public health surveillance of autism.

Poster Session**430 - Interventions - Social, Cognitive, Behavioral and Educational – Preschool & Infant II**

May 2nd, 2025, 6:00 PM - 7:00 PM - Hall 4A

430.156 Factors Related to Parents' Frequency of Practice in the Part C Early Intervention System

N. Alvarado¹, H. Tokish², B. R. Ingersoll³, N. Wrobel³ and R. Loeb³, (1)Clinical Psychology, Michigan State University, East Lansing, MI, (2)Psychology, Michigan State University, East Lansing, MI, (3)University of Michigan Dearborn, Dearborn, MI

Background: Studies have shown that parent engagement in their child's intervention leads to better child outcomes; this is especially true for parent-mediated interventions, in which parents are expected to practice strategies between sessions in order to help their child generalize communication skills to their home. A number of demographic and psychological factors (Gopalan et al., 2010; King et al., 2014; Pereira & Barros, 2019) have been identified as predictors of caregiver engagement in general child psychotherapy, but much less is known about factors that influence caregiver engagement in Part C Early Intervention (EI) system for children with early signs of autism.

Objectives: The current study aims to examine how family demographics, parent self-efficacy, and parent motivation influence parent engagement as measured by caregiver-reported between-session practice, in the Part C (EI) system.

Methods: Parents of young children with social communication delays ($n=106$) were recruited from an ongoing randomized controlled trial examining the effectiveness of a parent-mediated intervention in the Part C EI system. Parents completed a family demographics questionnaire, the Parenting Efficacy Scale (PES), and the Readiness to Change Subscale of the Parent Motivation Inventory (PMI) at intake. Parents participated in weekly EI sessions with their child for four months of active study participation. Once a month, parents reported on their frequency of practice of content learned in EI sessions, which was averaged to yield a mean parent-reported practice score. Multiple regression was used to examine whether parent characteristics at intake predicted frequency of practice.

Results: Parent motivation, parent age, and number of children in the household explained a significant amount of variance of frequency of practice ($F(4, 102) = 6.158, R^2 = .195, R^2_{adjusted} = .163, p < .001$). Specifically, higher motivation ($t(102) = 3.19, b = .041, p < .001$), younger parent age ($t(102) = -2.48, b = -.003, p < .05$), and a lower number of children in the household ($t(102) = -2.14, b = -.23, p < .05$) significantly predicted higher frequency of practice. Parent self-efficacy was not a significant predictor ($t(102) = 1.1, b = .026, p = .27$). Additionally, neither parent age nor number of children in the household significantly moderated the influence of parent motivation on frequency of practice.

Conclusions: Preliminary findings suggest that highly motivated parents report greater frequency of practice between EI sessions, and older parents and parents with multiple children face greater barriers to at-home practice. Providers may need to provide additional support for older parents and those with multiple children in their household. Further, providers should consider incorporating motivational strategies such as motivational interviewing to promote parent practice between sessions.

430.157 Feasibility and Acceptability of Telehealth Intervention with Caregivers and Younger Siblings of Children with Autism

A. Garza¹, L. H. Hampton¹, J. Franco², O. Helm¹, E. Rodriguez¹ and E. Schmitgen¹, (1)The University of Texas at Austin, Austin, TX, (2)Department of Speech, Language, and Hearing Sciences, The University of Texas at Austin, Austin, TX

Background:

There is growing research on telehealth interventions for autistic children with few focused on the younger biological siblings of autistic siblings (sib-aut). Providing Project ImPACT via telehealth (tele-ImPACT) is as effective as in-person for improving child language skills and parent implementation of the strategies (Hao et. al 2020). However, participation in parent-mediated tele-health intervention is inconsistent. According to Ingersoll et. al (2017), only 28.5% of caregivers of autistic children enrolled in an ImPACT online intervention program after their child's referral and diagnosis. Additionally, in Bradshaw et al. (2020), 44% of caregivers with a sib-aut child, declined to enroll in a parent-mediated telehealth intervention study. Therefore, it is important to investigate how telehealth intervention impacts the caregiver perspective and how telehealth implementation is perceived for younger populations such as sib-aut. The purpose of this study is to understand the feasibility and acceptability of tele-ImPACT for caregivers and their sib-aut children.

Objectives:

- (1) Is it feasible to conduct intervention with caregivers and their sib-aut children via telehealth?
- (2) Are the telehealth intervention procedures, as designed, acceptable to families?
- (3) Can therapists provide telehealth intervention to caregivers with high rates of fidelity?

Methods:

32 primary caregivers (30 mothers; 1 father; 1 grandmother), from an ongoing clinical trial, who had a sib-aut infant toddler (11-18 months of age), were selected to participate in a telehealth intervention. Caregivers were predominantly White (34.4%) and Hispanic/Latino (18.8%), with 11 stay-at home parents and 17 being full-time employed. Their average household size was 4.88, and household income varied, with 28.1% receiving government assistance.

Randomly selected intervention dosages ranged from 11-24 sessions, with some caregivers receiving 1-hour sessions twice a week for 6-8 weeks with or without weekly 30-minute booster phone calls, and/or 1.5-hour sessions twice a week with video feedback for 6-8 weeks. Interventionists rated therapist fidelity of sessions that were not their own by rating the therapist's preparation, strategy demonstration, coaching/feedback, reflection and planning, and overall coaching quality. Post-intervention, caregivers completed surveys regarding their satisfaction with the intervention, telehealth-specific procedures, and their parent-therapist alliance (adapted from Wheat, 2017).

Results:

21 out of 32 primary caregivers completed their intervention dosages during the ongoing clinical trial, with 3 caregivers declining participation in intervention sessions after selected. Incomplete intervention dosages were due to caregiver scheduling conflicts, personal family matters, or internet connection issues. Caregivers' number of completed sessions ranged from 1 to 24. Most caregivers' telehealth intervention experiences and parent-therapist alliances were positive. However, some caregivers cited the substantial time commitment as a barrier to participation. Regarding the therapist intervention fidelity, 74 out of 420 sessions were rated, with 92.53% fidelity ($SD = 5.11$), and with high reliability.

Conclusions:

It is recommended to offer telehealth intervention with caregivers who have a child who is a sib-aut with specific telehealth dosages that are adapted to meet each families' needs. Although parent-therapist alliance may align and therapists may have high intervention fidelity, it is important to have intervention program flexibility to provide feasible and acceptable telehealth intervention for families.

430.158 Feasibility of a Pre-Emptive Parent Mediated Intervention for Infants with Prodromes of Autism Spectrum Disorder (ASD) during the First Year of Life within an Italian Community

C. Colombi¹, N. Chericoni², F. Apicella³, S. Calderoni⁴, I. Colombino⁵, E. Conti⁶, V. Costanzo⁷, G. Guaini⁸, V. Marchi⁹, B. Riva⁸ and A. Guzzetta⁹,
 (1)Costanza Colombi, Pisa, MI, Italy, (2)IRCCS Fondazione Stella Maris, Calambrone (Pisa), Italy, (3)IRCCS Fondazione Stella Maris, Pisa, Italy, (4)Department of Clinical and Experimental Medicine, University of Pisa, Pisa, Italy, (5)IRCCS Stella Maris, Pisa, Pisa, Italy, (6)IRCCS Stella Maris Foundation, Pisa, Italy, (7)IRCCS Stella Maris, Calambrone Pisa, Italy, (8)IRCCS Stella Maris, Calambrone, Pisa, (9)IRCCS Stella Maris Foundation, Calambrone (Pisa), Italy

Background: ASD prodromes emerge during the first year of life, a time when brain plasticity is at its maximum level. Pre-emptive Intervention for infants with ASD prodromes seems more efficacious in supporting development and diminishing symptomatology in comparison to starting treatment later in life. Despite this evidence, professionals tend to have a 'wait and see' approach, rather than targeting areas of impairment with early intervention. Currently, the clinical model of ASD in Italy requires a diagnosis to receive services, while the identification of ASD prodromes generally is not sufficient to access early intervention, thereby missing the developmental window of maximum brain plasticity.

Objectives: This study aims to evaluate feasibility and exploratory efficacy of FIRRST (Fostering Infant Responsivity and Reciprocity – Support to Thrive), a parent mediated pre-emptive intervention based on the Infant Start in symptomatic infants under 15 months of age.

Methods: To date, 32 infants (M/F = 21/11; age: M [SD] = 10.78 [2.97], range = 7–14 months) have been enrolled into the program after meeting at risk criteria on two subsequent administrations of the SACS-R. The parent mediated intervention consists in 1-hour weekly sessions for a period of 6 months delivered through tele-health. Assessments are conducted prior the beginning of intervention (T0), after 3 months from the start of the intervention, and after 6 months from the start of the intervention (T2). Assessments include measures of ASD symptoms, developmental levels, parent fidelity, and parent-child interaction. The analysis of the differences between time points is performed using a repeated measures ANOVA.

Results: In terms of feasibility, all families enrolled attended at least 80% of sessions and only 1 family dropped out of the program. Parents obtained at least 80% of fidelity in intervention implementation and significantly improved in their interaction strategies (MONSI-CC Total score $F=19.94$; $p=0.001$). Preliminary results on the 10 children who have concluded the program show significant improvements in the social-communication domain, both during interaction with parents (BOSCC Total score $F=49.69$; $p=0.001$) and at developmental assessment (Griffiths III Language and Communication DQ $F=13.46$; $p=0.006$; Personal-Social-Emotional DQ $F=20.07$; $p=0.002$). Both Griffiths General Quotient scores and Vineland II Adaptive Behavior Composite Scores show a significant improvement in children's overall development and adaptive functioning (respectively $F=9.66$; $p=0.01$ and $F=6.69$; $p=0.03$).

Conclusions: Our preliminary findings support feasibility of a parent mediated pre-emptive intervention as demonstrated by access to the program and 97% retention. Significant improvement in socio-communication skills and developmental levels suggest that our program may be successful in improving outcomes of individuals with ASD prodromes within the Italian Health System. After this encouraging pilot phase, FIRRST will be evaluated through a funded multisite RCT.

430.159 Improving Child Social Engagement through Early Autism Intervention: Results from the Pivotal Response Treatment App-Based Clinical Trial

S. Licona¹, E. F. Ferguson², M. Jimenez Munoz² and K. M. Russell¹, (1)UCSB Koegel Autism Center, Santa Barbara, CA, (2)Department of Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA, (3)UC Santa Barbara, Santa Barbara, CA

Background: High levels of early child engagement are associated with a host of favorable developmental and cognitive outcomes (Bakeman & Brown, 1980; Kawamichi et al, 2016). Naturalistic Developmental Behavioral Interventions (NDBI) are a contemporary class of early autism intervention models designed to use child interests, natural routines, and shared control to engage young autistic children and promote engagement in the form of social communicative initiations and responses. These therapeutic targets are crucial, as limited engagement is a recognized core vulnerability of autism that have downstream implications for social engagement, relationships, and learning (Watkins et al., 2015). Motivation-based NDBI models such as Pivotal Response Treatment use child selected and preferred activities as a means to increase attention to social partners and increase the likelihood that a child will engage (Verschuur et al, 2014). The current study targeted parent intervention skills in the context of a self-directed app-based training program called Pivotal.

Objectives: To evaluate improvements in child social engagement spanning a range of verbal and nonverbal social behaviors (verbal initiations, verbal responses, eye contact, direct facial expression during parent-child intervention sessions between pre- and post-program 5-minute intervention probes.

Methods: Participants included 34 parent-child dyads recruited nationwide and randomized to two versions of the Pivotal app. For this study, they were analyzed as a single cohort. Child participants (12 to 56 months) have an existing diagnosis of ASD and a language delay. Parents complete intake and follow-up assessments, eight PRT lessons, and record and review parent-child videos in-app after each lesson, which are then reviewed by the research team for analysis. Research assistants, masked to study condition, coded each parent-child video submissions (5-minute videos) for the presence of intervention components and child behaviors. Child responsiveness was defined as a percent of parent-initiated PRT antecedent bids that were immediately followed by an appropriate child verbal response.

Results: Using a series of paired-samples T-test, the entire project cohort of children with autism significantly improved in their number of social initiations ($M_{pre} = 8.0$ [$SD = 10.7$], $M_{post} = 15.1$ [13.0], $p = .007$, Cohen's $d = 1.16$), and responses to social bids ($M_{pre} = 7.53$, $M_{post} = 12.91$, $p = .005$, Cohen's $d = 1.26$). Behavioral coding and analysis of nonverbal social behaviors (eye contact and directed facial expressions) is ongoing and will be complete by February 2025, with preliminary outcomes indicative of clinically meaningful improvements. Overall, these improvements to child social engagement were not simply due to increases in the number of parent-initiated social communication bids, which did not significantly differ between intake and program completion ($p = .152$), suggesting that the quality (rather than quantity) of parent bids drove increases in child responsiveness as parents learned the intervention strategies.

Conclusions: Parents who participated in this app-based clinical trial appear to have learned effective strategies for engaging their child in intervention efforts. Motivation-based early intervention efforts that increase child responsiveness may have a significant impact on child developmental outcomes.

430.160 Improving Parent Early Intervention Mastery: App-Based Training & Fidelity Self-Scoring in Pivotal Response Treatment

T. W. Vernon¹, S. Licona¹, K. M. Russell¹, E. F. Ferguson² and M. Jimenez Munoz², (1)UCSB Koegel Autism Center, Santa Barbara, CA, (2)UC Santa Barbara, Santa Barbara, CA, (3)Department of Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA

Background: Self-directed autism intervention parent training models have the advantage of not requiring professional service providers and thus have significant potential for scalability and mass dissemination. Unfortunately, the lack of in-person training and personalized feedback means that outcomes associated with self-directed models are inferior to professionally-led training efforts (Ingersoll et al., 2016). In order to improve self-directed learning outcomes, we examined the potential benefits of including an interactive fidelity self-scoring feature within an app-based training program for the Pivotal Response Treatment (PRT) early autism model, which is a well-established Naturalistic Developmental Behavioral Intervention (Minjarez, Bruinsma, Stahmer, 2020)

Objectives: To examine the additive benefit of parent self-scoring of fidelity on intervention mastery in the context of an app-based parent training RCT.

Methods: Participants included 34 parent-child dyads across the U.S. (randomized to either the self-scoring PRT app and a non-self-scoring version of PRT app). Child participants (1 - 4.5 years) had an diagnosis of autism and delayed language development. Parents completed intake and follow-up assessments, eight PRT lessons, and recorded 5-min parent-child PRT videos every two lessons. Families in the self-scoring condition completed an in-app review of their videos by pausing after each trial and answering questions about strategy use in order to receive automated feedback on scored results. Research assistants, masked to the treatment condition and video sequence, also scored videos for multiple measures of PRT fidelity, including (1) mean percentage of PRT component use, (2) percent of trials with *all* PRT components (a more stringent measure of fidelity), and (3) number of PRT ABC trials per video.

Results: A series of mixed Group x Time ANOVAs revealed superior outcomes associated with parents randomly assigned to the fidelity self-scoring app condition.

For Mean PRT fidelity, there was a significant interaction between the app condition and time on mean fidelity percentage, $F(1,32) = 12.86$, $p < .0005$, partial $\eta^2 = .218$. Participants in the self-scoring condition demonstrated evidence of increased mastery post-trial (mean 79.25%; SD 15.24%) when compared to the non-scoring condition (mean 72.75%; SD 15.23%). Results are depicted in Figure 1. For Trials with All PRT components, there was also a significant interaction between the app condition and time, $F(1,32) = 6.06$, $p = .018$, partial $\eta^2 = .116$. Participants in the self-scoring condition demonstrated increased use of all components post-trial (mean 51.33%; SD 32.47%) versus the non-scoring condition (mean 41.67%; SD 27.86%). Results are depicted in Figure 2.

For Number of PRT ABC Trials, there was *not* a significant group x time interaction, with a comparable number of ABC trials post-trial across self-scoring (mean 3.92; SD 3.96) and non-scoring (mean 6.5; SD 7.85) conditions.

Conclusions: Parents randomly assigned to the self-scoring PRT condition experienced moderately superior gains in fidelity mastery when compared to those in the non-scoring condition. Such findings suggest that self-analysis of intervention delivery may hold promise as a means to bolster self-directed training efforts and enhance parent fidelity mastery and corresponding child outcomes in self-directed mass dissemination efforts.

430.161 Inclusive Community Music Program for Autistic and Neurotypical Children and Their Families

E. Hernandez-Ruiz¹, E. Tobias², T. Hoover³, A. Sorensen³ and Z. Gao³, (1)Music Therapy, Arizona State University, Tempe, AZ, (2)Music Learning and Teaching, Arizona State University, Tempe, AZ, (3)Arizona State University, Tempe, AZ

Background: In conversations with local children's museums, we learned that young autistic children did not typically attend museum offerings. Although the reasons have not been investigated, the staff considered that the lack of tailoring for autistic children's needs was at the root of the problem. Interventions that use music to support development (i.e., music-mediated interventions) and parent-mediated interventions are currently considered evidence-based practices for autistic youth (Steinbrenner et al., 2020; Hernandez-Ruiz & Braden, 2021). By creating a program tailored to these children's needs and strengths, based on music therapy practices, we created an inclusive early music program to encourage participation from autistic children and their families.

Objectives: This study explored parental perceptions of usefulness, acceptability, and satisfaction of the program.

Methods: The community music program entailed six weekly 30-min music sessions. The music sessions combined active music making, movement, and visual supports for motor, social, cognitive and language learning. Participants included eleven children (aged 1 to 5) and nine parents (N = 20). Parents were active participants who learned the music strategies to implement at home. To avoid bias from all parties, we confirmed autism diagnosis only at the end of the program (n=2). A play area outside the session room provided a safe space for children who needed a sensory break. Parental perspectives were captured by a faculty member and doctoral students from another department through focus groups after each music session, and an exit *ad hoc* survey. The survey asked about parents' (1) perception of the usefulness of the content; (2) confidence in their ability to use what they learned; (3) satisfaction around music therapy students' interest and concern for their family; (4) feeling respected; and (5) potential recommendation of the program.

Results: Eight of the nine families completed the final satisfaction survey. All participants felt that their family and themselves were respected (i.e., *strongly agreed*, score of 5, n = 8, 100%), and all would *definitely* recommend the program to others (score of 5, n = 8, 100%). Participants felt *satisfied* (score of 4, n = 1, 12.5%) or *very satisfied* (score of 5, n = 7, 87.5%) with the program overall. They also felt *satisfied* (score of 4, n = 1, 12.5%) or *very satisfied* (score of 5, n = 7, 87.5%) with graduate students' interest and concern for them and their goals. Participants considered the program *useful* (score of 4, n = 4, 50%) or *very useful* (score of 5, n = 4, 50%). Similarly, participants felt *moderately confident* (score of 3, n = 1, 12.5%), *confident* (score of 4, n = 2, 25%) or *very confident* (score of 5, n = 4, 62.5%) in their ability to use what they learned at home. Qualitative results were consistent with the survey, highlighting parents' requests for more programming.

Conclusions: Inclusive community music programs based on evidence-based music therapy strategies seem acceptable and highly regarded by parents of autistic and neurotypical children. Music-mediated intervention principles are recommended to encourage participation from the autistic community.

430.162 Incredible Years® (IY-ASLD): Pilot Study Examining Effects on Parent-Child Dyads' Proportion of Time in High and Low Joint Engagement

L. Lerna¹, L. B. Jahromi², M. Brassard³, J. Dudek⁴ and I. Knoll⁵, (1)Teachers College Columbia University, New York, NY, (2)Teachers College, Columbia University, New York, NY, (3)Brassard Practice, New York, NY, (4)Department of Health and Behavior Studies, Teachers College, Columbia University, New York, NY, (5)Barnard College, New York, NY

Background: The Incredible Years® Autism Spectrum and Language Delays (IY-ASLD) program is an empirically supported psychoeducational intervention developed to address the specific needs of raising children with autism (Webster-Stratton, Dababnah, Olson, 2018). The program emphasizes work on sensory routines through joint attention and communication skills (Webster-Stratton et al., 2018) through strategies likely to sustain social interactions and communication and, thus, joint engagement (JE), a state of prolonged shared interest between two people. Children's sustained experiences in JE states are linked to later expressive language outcomes (Adamson et al., 2019). JE is facilitated in IY-ASLD through strategies where the parent gets into their child's "attention spotlight." We hypothesized that by emphasizing these strategies, the program would lead to the dyad spending more time in higher as opposed to lower states of JE from baseline to post-intervention.

Objectives: This study addresses these questions: a) is there an overall increase in the proportion of time spent in a higher versus lower form of JE, and does this differ by children's level of support needs? b) For dyads in low JE more than 50% of the time, is there a significant increase in time spent in high JE from baseline to post-intervention? c) do dyads already in high JE at baseline maintain this from baseline to post-intervention?

Methods: Data from a waitlist-controlled RCT of N = 58 dyads will be reported. Preliminary analyses are from a pilot study of N=17 mother-child dyads (ages 2-5 years) whose children had a diagnosis of ASD or language delay. The intervention included 12 weekly telehealth sessions lasting 90 minutes. Joint engagement was measured using an adaptation of the Communication Play Protocol (Adamson, 2004), consistent with Kasari et al., 2010. High and low-supported engagement were coded using definitions from previous work on parent-mediated joint engagement interventions (Bottema-Beutel et al., 2014). The 12-minute parent-child interaction was recorded on Zoom at baseline and post-intervention. Children's support needs level was measured using Vineland Adaptive Behavior Scale-3, Teachers Report Form Composite score (below a standard score of 70 vs. a score of 70 and higher).

Results: Pilot data revealed that children with relatively higher adaptive behavior scores spent a greater proportion of time in high JE than low JE at baseline, and this remained the case post-intervention. Children with low adaptive behavior spent time in both low and high JE, and this did not change over the course of intervention. Findings from the waitlist-controlled RCT will be reported.

Conclusions: Our results show that even in a sample of children with low adaptive behavior overall, higher adaptive behavior was associated with a high average proportion of time in high JE and low adaptive behavior with low levels of high JE. Neither group changed significantly from baseline to post-treatment. This was unsurprising in the high adaptive behavior group as they were near the ceiling on the high JE measure. However, the low adaptive behavior group had considerable room for improvement, but the intervention did not change levels of high JE.

**430.163** International Deployment of Evidence-Based Intervention: Jasper in Family Support Centers

E. D. Yoque Gonzalez¹, J. Panganiban² and C. Kasari³, (1)Semel Institute for Neuroscience and Human Development, University of California, Los Angeles, Los Angeles, CA, (2)Semel Institute, University of California Los Angeles, Los Angeles, CA, (3)Education and Psychiatry, University of California Los Angeles, Los Angeles, CA

Background: Implementation of evidence-based interventions are a critical tool in supporting the development of autistic children. Joint Attention, Symbolic Play, Engagement, and Regulation (JASPER) is an evidence-based intervention with extensive support in research settings. Recently, its efficacy has been proven shown in community-based preschool contexts (Chang et al., 2016). However, differences in population characteristics, practice context, and treatment fidelity (Weisz, 2004) highlight the need to further examine the deployment of evidence-based interventions by community partners across various contexts.

Objectives: The current study examines the outcomes of a community-based implementation of JASPER in a preschool setting, through the deployment of trained, international partners that received a hybrid of in-person and virtual support.

Methods: Specialists in the family support centers participated in a five-day in-person seminar, followed by monthly virtual meetings until they achieved JASPER fidelity. A total of 15 specialists achieved fidelity. In the current study we analyze treatment outcomes for 70 child participants from a network of family support centers across 4 cities in Russia, including Moscow, Nizhny Novgorod, Saint-Petersburg, and Tula. Included students were between 1.5 – 6 years old with a confirmed diagnosis of autism. JASPER was provided two times a week for one hour across the program duration of 3 - 6 months. Specialists administered the Short Play and Communicative Evaluation (SPACE, Shire et al., 2013), which provides scores on joint engagement, joint attention skill, expressive language ability, and play skills. The SPACE was administered when children entered the JASPER program, and again, after completion. Change scores in joint engagement, joint attention skills, expressive language ability, and play skills were calculated and analyzed using Wilcoxon signed-rank tests to compare scores before and after completing the JASPER program.

Results: Wilcoxon signed-rank tests showed significant improvements in joint engagement ($V = 11.5$, $p < 0.001$), joint attention ($V = 78$, $p < 0.001$), play skills ($V = 19.5$, $p < 0.001$), and expressive language ability ($V = 16$, $p < 0.001$) after completing the JASPER program.

Conclusions: This study scales community-based deployment of evidence-based interventions in a preschool setting, across an international context. Trained, international community partners can effectively implement JASPER to target significant improvements in core deficits developmental behaviors in autistic children. A hybrid training model, that included initial in-person support and regular virtual follow up support, effectively trained specialists to provide JASPER at high fidelity. Furthermore, follow up observations show that specialists maintain fidelity after virtual support is ended ($M = 95\%$). Future studies should continue to examine evidence-based interventions in consideration with various community contexts.

430.164 Investigating the Impact of Internalizing Symptoms on the Efficacy of Pivotal Response Treatment

E. Gray¹, S. Park² and P. E. Ventola³, (1)Ventola Lab - Yale Child Study Center, New Haven, CT, (2)Yale Child Study Center, Yale School of Medicine, New Haven, CT, (3)Yale Child Study Center, Yale University School of Medicine, New Haven, CT

Background:

Autistic children have elevated rates of internalizing problems, such as depression and anxiety (DeFilippis, 2018). Pivotal Response Treatment (PRT) is an evidence-based behavioral intervention for children with ASD focused on improvement in the social communication domain.

Objectives:

This study aimed to examine whether internalizing symptoms commonly comorbid with ASD (anxiety, depression, and emotional dysregulation) significantly impact the efficacy of PRT, particularly its ability to improve outcomes in social communication.

Methods:

This study included 58 autistic participants between the ages of 4 and 9 years old. Diagnosis was confirmed by the ADOS. Social communication skills were assessed using the SRS-2, anxiety and depression were measured using the CBCL, and emotional regulation was measured by subdomains of the BRIEF-2. Each participant participated in 16 weeks of PRT for 6 hours weekly. Each assessment was administered at baseline and at the end of treatment.

Results:

Participants made significant progress in social communication skills following a trial of PRT, as measured by the SRS-2 Total Raw Score ($t = 3.087$; $p = .002$). Additionally, there was a relationship observed between overall social communication functioning and baseline emotional regulation, as measured by BRIEF-2, at both baseline (Inhibit ($r = .448$; $p = .002$), Shift ($r = .608$; $p < .001$), Emotional Control ($r = .535$; $p < .001$)) and end of treatment (Inhibit ($r = .425$; $p = .005$), Shift ($r = .654$; $p < .001$), Emotional Control ($r = .575$; $p < .001$)). There was not, however, a significant correlation between magnitude of change in social communication skills and emotion regulation, as measured by Inhibit ($r = -.072$; $p = .647$), Shift ($r = -.043$; $p = .782$), and Emotional Control ($r = -.026$; $p = .867$) of the BRIEF-2.

Similarly, when groups were divided by baseline level of internalizing symptoms (T-Score above/below 60), CBCL Anxiety/Depression ($F(1,46) = 14.301$; $p < .001$), Internalizing Problems ($F(1,46) = 25.072$; $p < .001$), and Anxiety Problems ($F(1,46) = 15.544$; $p < .001$) subscale scores were significantly related to the participants' end of treatment raw SRS-2 scores. However, these same measures were not significantly related to the magnitude of change between baseline and end of treatment SRS-2 scores (Anxiety/Depression ($F(1,46) = 1.321$; $p = .256$), Internalizing Problems ($F(1,46) = 729$; $p = .398$), Anxiety Problems ($F(1,46) = .913$; $p = .344$)).

Conclusions:

Participants evidenced significant improvements in social communication skills following a trial of PRT, supporting the efficacy of the intervention. Additionally, children with higher levels of emotional dyscontrol and internalizing symptoms had more impaired social communication skills at both baseline and end of treatment. However, these comorbid symptoms did not have an effect on the magnitude of change in social communication skills following a trial of PRT. Therefore, PRT can be an effective treatment approach for children with ASD with and without comorbid emotional dyscontrol and internalizing symptoms.

430.165 Mechanisms of Change in Language and Cognition By Early Intervention

Z. Kim¹, N. Bast², J. Kitzerow-Cleven¹, K. Teufel¹, S. K. Kleber³, L. Polzer⁴, N. Raji¹, C. Lemler¹, M. Noterdaeme⁵, U. Fröhlich⁶, V. Roessner⁷, J. Geissler⁸, R. Taurines⁸ and C. M. Freitag⁹, (1)Autism Research and Intervention Center of Excellence Frankfurt, Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, University Hospital Frankfurt, Goethe University, Frankfurt, Germany, (2)Autism Research and Intervention Center of Excellence Frankfurt, Goethe University Frankfurt / Department of Child and Adolescent Psychiatry, Frankfurt, Germany, (3)Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, Goethe Universität Frankfurt, Frankfurt, Hessen, Germany, (4)Autism Research and Intervention Center of Excellence Frankfurt, Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, University Hospital Frankfurt, Goethe University, Frankfurt, Hessen, Germany, (5)Child and Adolescent Psychiatry, Augsburg, Germany, (6)Josefinum, Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, Augsburg, Augsburg, Bavaria, Germany, (7)Department of Child and Adolescent Psychiatry, University Hospital Carl Gustav Carus, Technische Universität Dresden, Dresden, Germany, (8)Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, Centre for Mental Health, University Hospital of Würzburg, Würzburg, Bavaria, Germany, (9)Autism Research and Intervention Center of Excellence Frankfurt, Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, JW Goethe University, Frankfurt, Hessen, Germany

Background: Treatment mechanisms of therapist-mediated interventions have rarely been studied. Joint attention and fine-motor skills as well as executive functions have been described as early developmental skills longitudinally related to language and cognitive development in children with Autism-Spectrum-Disorder (ASD). Thus, we studied these skills as possible mediating mechanisms of change in language and cognition through 12 months early intervention.

Objectives:

- 1) Do children who show an improvement in joint attention, fine-motor and executive function skills also show a better outcome in language and cognition after 12 months?
- 2) Is the improved outcome influenced by a particular type of intervention?

Hypotheses:

First, we expected to find a positive correlation between 12-months gain in language and cognition and the time course of improvements in joint attention, fine-motor and executive function skills during intervention. Second, we expected that the Frankfurt early intervention program A-FFIP will induce earlier and larger changes in joint attention, fine-motor and executive function skills than early intervention as usual (EIAU).

Methods:

Data were collected as part of the confirmatory phase-III, prospective, randomised, controlled, parallel-group A-FFIP study with two treatment arms, an allocation ratio of 1:1 and six measurement points every 3 months over 12 months. Mediation analyses of the child's joint attention, fine-motor skills and executive function on changes in language and cognition were conducted by using Latent Change Score Models (LSCM). Most mediators and outcomes were assessed by blinded testers and raters. Responsive joint attention was taken from the Early Social Communication Scales, fine-motor skills were assessed by the Bayley-III scales, language and cognition were taken either from Bayley-III or WPPSI developmental and cognitive tests. Executive function was assessed by the parent rated BRIEF-P.

Results:

A total of 134 children were included (A-FFIP: n=68, EIAU: n=66), mean age was 49 (SD 10) months, mean developmental age 23.3 (SD 13.6) months, and 26 (19.4%) were female; 43 (66.2%) of families in the A-FFIP group and 37 (58.7%) in the EIAU group had at least one parent who had immigrated to Germany as an adult. Higher changes in responsive joint attention and fine-motor skills were associated with higher changes in cognition (0.18/1.17) and language (0.14/0.64). No differential effects of A-FFIP versus EIAU were observed. There was no association between change in executive function and change in cognition or language over one year. Across models, A-FFIP was associated with positive changes in language compared to EIAU (~ 0.15 - 0.18).

Conclusions:

Children who showed improvements in responsive joint attention and fine-motor skills also showed improvements in cognition and language, independent of intervention. These results replicate previous findings from longitudinal studies showing a positive correlation between joint attention, fine-motor skills and language and cognition. As the longitudinal positive correlation did not differ between A-FFIP and EIAU, it remains an open question, if joint attention and fine-motor skills may be mediators of intervention effects, or independent longitudinal predictors of language and cognitive development in toddlers and preschool aged children with ASD.

430.166 Multivariate Insights into Child Engagement and Behavioral Fluctuations in Early and Intensive Autism Intervention: Implications for Outcomes

N. Kojovic¹, M. Franchini², C. Bouamri³ and M. Schaefer⁴, (1)Developmental Imaging and Psychopathology Lab, University Of Geneva, Geneva, Switzerland, (2)Dalhousie University / IWK Health Centre, Halifax, NS, Switzerland, (3)Fondation Pole Autisme, Geneva, Geneva, Switzerland, (4)Department of Psychiatry, University of Geneva, Geneva, Geneva, Switzerland

Background:

Strong evidence supports the efficacy of prompt, intensive behavioral interventions in improving outcomes for individuals with ASD (Dawson et al., 2010; Reichow, 2012; Daniolou et al., 2022). Research indicates that early and intensive interventions focusing on social skills can significantly reduce autistic symptoms and provide substantial cognitive benefits (Dawson et al., 2010; Klintwall et al., 2015). These interventions present a transformative opportunity for children who might otherwise face intellectual challenges. Early detection and tailored interventions during the critical period of cerebral plasticity are crucial (Dawson, 2008). While gains are most significant when intervention begins before 24 months (Lombardo et al., 2021), variability in outcomes highlights the need to identify predictive features influencing intervention success.

Objectives: The objective of this study was to identify early indicators that could be informative of the intervention outcomes in young children with ASD based on the observations during early intervention sessions.

Methods:

We analyzed a unique dataset of psychologist reports from an intensive early intervention program (Early Start Denver Model). Weekly intervention sessions were filmed, and psychologists assessed each child's overall state (e.g., fatigue, irritability, engagement), session quality, and symptoms (such as communicative attempts, sensory behaviors, mannerisms). Data were collected from 42 children (10F, aged 2.49 ± 0.68), each with an additional assessment after 12 months. Progress was measured using a symmetrized percentage of change (SPC). A k-means cluster analysis based on baseline DQ and SPC identified three groups: Minimal Responders, Optimal Responders, and Higher Cognitive, consistent with our previous findings (Godel et al., 2022). Children with higher initial cognitive and social competence showed greater improvements, while those with lower scores at baseline divided into two subgroups—optimal responders with substantial progress, and minimal responders facing persistent challenges. We further employed a PLS-C approach to explore multivariate relationships between the psychologists reports and key design variables (outcome group and age).

Results:

The PLS-C analysis yielded one significant component ($P = 0.001$), reflecting an effect of group and age. The behavioral patterns observed in older children at intake who showed an optimal response to intervention included higher engagement, a better general state, and greater communication skills (Figure 1). By the end of the second month, sensory behaviors emerged as a significant negative factor impacting learning readiness and social engagement.

Conclusions:

This unique, densely sampled assessment of intervention progress in young children with ASD demonstrates how initial assessments relate to subsequent developmental trajectories. A key finding, beyond the initial level of communicative skills, is the importance of the child's general state and engagement, as well as the negative impact of sensory behaviors on learning readiness and social engagement.

Closely monitoring the child's state and behavioral fluctuations throughout intervention is essential for understanding factors driving heterogeneous outcomes, even with standardized intervention. These insights can pave the way toward more personalized approaches, enabling tailored support that addresses each child's unique profile and maximizes their potential. By embracing a personalized approach, practitioners can refine interventions to better align with each child's evolving needs, optimizing immediate and long-term developmental outcomes in children with ASD.

430.167 Outcomes of a Group-Based Social-Emotional Skills Intervention Incorporating the Ndbi Approach for Preschool Children with High-Functioning Autism Spectrum Disorder in Taiwan: Preliminary Findings

P. C. Wang¹ and **T. L. Lin²**, (1)Behavioral Medicine, National Cheng Kung University, Tainan, Taiwan, (2)Institute of Behavioral Medicine, National Cheng Kung University, Tainan City, Taiwan

Background: A core symptom of autism spectrum disorder (ASD) is a persistent deficit in social communication and interaction. This deficit constitutes a significant source of impairment for individuals, regardless of their cognitive function or language ability. Early social skills intervention, starting from preschool, can enhance future social adaptation outcomes among children with ASD. Recently, several studies suggest that Naturalistic Developmental Behavioral Intervention (NDBI) is an important trend in early intervention for children with ASD. However there is currently limited published research on using the NDBI approach in group intervention for preschool children in Taiwan.

Objectives: This study aims to develop a group-based intervention adopting NDBI approach to enhance social-emotional skills and to examine its effects on preschool-age children with high-functioning ASD.

Methods: Eight children diagnosed with high-functioning ASD (average age = 4.6 years; average FSIQ = 94.4, VCI = 90.9), according to DSM-5 criteria and the Autism Diagnostic Observation Schedule, Second Edition (ADOS-2), were recruited. The group-based intervention focused on improving social-emotional skills, including appropriate verbal and nonverbal social initiations and responses, emotion recognition, and emotion regulation through various play activities, including stacking blocks, card games, and ball games.

Key features of NDBI were implemented in group-based intervention. These included providing learning opportunities for all targeted social-emotional skills within each play activity, and allowing each child to independently choose and express preferred reinforcers to enhance children's participation in each session. Additionally, prompts were given based on individual performance levels, incorporating various levels of instruction such as modeling, verbal or visual cues, and natural responses from two group leaders, which consisted of a licensed clinical psychologist and a clinical psychology graduate student.

Each intervention group was designed to include four children to ensure sufficient engagement and interaction opportunities for each child. The intervention involved one hour per week over eight weeks. Pre- and post-intervention outcome measures included parent- and teacher-rated assessments, including the Chinese Social Responsiveness Scale (Chinese SRS), Child Behavior Checklist for School-Aged Children (CBCL/6-18), and the Vinland Adaptive Behavior Scale, Third Edition (VABS-3). The intervention effects were evaluated using various scores, including raw scores of the Chinese SRS, T scores for social, internalizing, and externalizing problems in the CBCL, and standard scores for communication and socialization domains in the VABS-3. Additionally, parent-rated satisfaction surveys were collected.

Results: The analysis, using Wilcoxon Signed Rank Tests, showed significant improvements in communication domain of the parent form VABS-3 (Wilcoxon $Z = -1.973$ $p = 0.049$), socialization domain of the teacher form VABS-3 (Wilcoxon $Z = -1.963$, $p = 0.050$), and social-emotional problem factor scores on parent-rated Chinese SRS (Wilcoxon $Z = -2.521$ $p = 0.012$). Parent-rated satisfaction scores averaged 4.5 on a five-point scale.

Conclusions: This study provides valuable insights into implementation of a group-based NDBI intervention for social-emotional skills in Taiwan. The findings suggest that an eight-session group-based NDBI program may positively impact communication adaptation and social/social-emotional challenges in preschool-aged children with high-functioning ASD, along with a high participant satisfaction.

430.168 Outcomes, Experiences, and Perceptions of Inclusive Early Childhood Education for Children without Disabilities: A Systematic Review

E. H. Keck¹, A. S. Nahmias², V. H. Warnakulasooriya Fernando¹, K. Nelson³, T. S. Munro¹, S. Belanger¹ and A. Jobin^{3,4}. (1)California State University San Marcos, San Marcos, CA, (2)AJ Drexel Autism Institute, Drexel University, Philadelphia, PA, (3)California State University, San Marcos, San Marcos, CA, (4)Child and Adolescent Services Research Center, San Diego, CA

Background: Some research supports the effectiveness of inclusive early childhood education (ECE) programs for children with autism (Jobin et al., 2023; Siller et al., 2021), involving enrollment of children with and without disabilities, and the embedding of evidence-based interventions into naturalistic settings. However, there are low rates of inclusion within usual care ECE programs, and caregivers of children with autism and other developmental disabilities report barriers to quality early care and education (Houser et al., 2014; Vanegas & Abdelrahim, 2016). The attitudes, perceptions, and experiences of children without disabilities and their families in these programs are important to informing research addressing the scalability and implementation of inclusive ECE programs for autism within community settings. However, no recent syntheses of the literature for this population are available.

Objectives: This systematic review aimed to synthesize the empirical literature on (1) outcomes of children without disabilities in inclusive ECE programs for children with autism and other disabilities, and (2) child and caregiver beliefs, attitudes, perceptions, and experiences of inclusive ECE.

Methods: A systematic review was conducted using PubMed, ERIC, and PsycINFO. Searches were limited to peer-reviewed articles reporting original empirical data and published between 1975-2024 reporting on the outcomes or child/caregiver beliefs, attitudes, perceptions, and experiences of inclusive ECE for children without disabilities. Broad search terms were utilized due to the varied nature of terms used to analyze and report upon these constructs. Forward and backward ancestral searches of key articles and related reviews were applied to increase this review's comprehensive nature. Inclusion criteria were related to source and study characteristics, population (children under 6 years old without identified disabilities), intervention/exposure, and outcomes. All abstracts were coded independently by two coders and disagreements were resolved via consensus, with all consensus decisions involving a doctoral-level researcher.

Results: The literature search yielded 1,324 articles. After removing 225 duplicates, title and abstract screening yielded 116 articles that advanced to full-text review. Some programs evaluated in the articles involved inclusive settings for children with disabilities in general, while others focused specifically on supporting autistic children. Programs were implemented in both the U.S. and internationally. The final extraction results presented in this poster will include analyses of inclusive program type, as well as reported child outcomes and child or caregiver beliefs, attitudes, perceptions, and experiences of inclusive ECE.

Conclusions: The results of the systematic review offer a synthesis of what is known regarding outcomes, experiences, and perceptions/beliefs around inclusive ECE for young children without disabilities. While there is growing evidence in support of embedding evidence-based interventions in naturalistic settings such as early care settings and preschools, there is no clear research synthesis on the impacts of these programs on all children. Improved understanding of these factors in the context of inclusive ECE programs for autism and other disabilities can provide critical information to key stakeholders (e.g., ECE leaders, policymakers, caregivers) and inform strategies to address barriers to the scalability and community implementation of inclusive programming for young children with autism, ultimately facilitating community-based delivery more broadly.

430.169 Parent Strategy Uptake in the Incredible Years® Autism Spectrum Program: A Mixed-Methods Study on Descriptive Commenting, Emotion, Social, and Persistence Coaching

J. Pattammady¹, **L. B. Jahromi²** and **M. Brassard³**, (1)Health Studies & Applied Educational Psychology, Teachers College Columbia University, New York, NY, (2)Teachers College, Columbia University, New York, NY, (3)Brassard Practice, New York, NY

Background:

Parents of autistic children find navigating developmental delays to be challenging. Parent-focused interventions play an important role in increasing understanding and use of strategies that improve parent-child interactions. However, more research is needed to understand parents' experiences with these intervention programs and the factors that influence their usage and implementation of these strategies. The Incredible Years® Autism Spectrum and Language Delays Program (IY-ASLD), a group-based parent training intervention designed for parents of autistic children with speech and language delays (Webster-Stratton, Dababnah, Olson, 2018), has been shown to significantly improve both parent wellbeing and child behaviors (Dababnah & Parish, 2016; Williams et al., 2020; Hutchings et al., 2016). The current randomized control trial examines parents' strategy uptake and narratives during sessions. This study focuses on key strategies that are discussed early in the program which include: descriptive commenting, emotion, social, and persistence coaching. By focusing on these foundational strategies, valuable insights can be gained into how parents adopt and implement them, as these strategies form the basis for more advanced strategies introduced later.

Objectives:

This study aims to (1) assess changes in parent use of several key strategies (descriptive commenting, emotion, social, and persistence coaching) during parent-child interactions before and after participation in the IY-ASLD program and; (2) to examine parent narratives during intervention sessions about descriptive commenting, emotion, social, and persistence coaching strategy-use and implementation.

Methods:

Caregivers ($N=58$) with preschool-aged children with autism or language delays participated in the study. All children had an Individual Family Service Plan (IFSP) or an Individual Education Plan (IEP) and a verified autism or language delay diagnosis. Caregivers completed 14 weekly sessions of the IY-ASD tele-health program in a group-based setting with two trained lead interventionists. A mixed-methods approach is used, combining observations of strategies used during parent-child interaction (Table 1), and reflections during weekly intervention check-ins (Table 2).

Results:

Observations of parent behaviors during 12-min naturalistic play interactions conducted before and after intervention were coded for strategy utilization. Analysis of the pilot data of the RCT show a significant increase in *descriptive commenting* ($M = -1.71$, $SD = 3.69$) whereas the coaching strategies did not show a significant increase. Analysis of transcripts from weekly check-ins provide insights into experiences, highlighting challenges faced, and changes in interactions. During weekly check-ins of the group sessions, parents reflected on the use of intervention strategies. The topics discussed were coded to identified themes which include: *parent strategy utilization*, *parent cognition*, and *child development/parent-child outcomes* (See Table 2).

Conclusions:

IY-ASLD offers a framework for applying effective strategies. In the observational measure, descriptive commenting showed a significant increase suggesting that the intervention effectively supported this strategy. Coaching strategies did not show improvements which could indicate that observational data was the not best measure of this skill. However, qualitative data from weekly check-ins revealed that parents are still navigating the process of learning and applying coaching strategies. The results indicate the need for attention to addressing barriers of strategy use, ensuring that parents can implement strategies from the program.

**430.170** Pivotal Training App: Analyzing Specific Components Driving Improvements to Intervention Fidelity

A. Espinel¹, **S. Licon¹**, **K. M. Russell¹**, **E. F. Ferguson¹**, **M. Jimenez Munoz³** and **T. W. Vernon¹**, (1)UCSB Koegel Autism Center, Santa Barbara, CA, (2)UC Santa Barbara, Santa Barbara, CA, (3)Department of Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA

Background: Proper delivery of a parent-mediated Naturalistic Behavioral Intervention (NDBI) requires successful use of all key intervention components (Ingersoll & Wainer, 2013). Pivotal Response Treatment (PRT) is an NDBI that combines motivational and behavioral principles to develop social communication skills in autistic children (Verschuur et al., 2014). To determine if the parent has mastered the components of the intervention, it is important to track parent fidelity of implementation over the course of training efforts. Due to diverse parenting profiles and prior training, parents might start an intervention program with existing use of some intervention strategies. Therefore, it is important to understand these pre-intervention parent fidelity profiles to be able to efficiently target key fidelity components that parents do not already use and still need to master.

Objectives: To understand how parent profiles of fidelity implementation improve after participation of the *Pivotal* App Clinical Trial and how training efforts improve skill mastery in specific intervention domains.

Methods: Participants include 34 parent-child dyads across the U.S. who participated in an RCT for *Pivotal*, a self-directed app-based training program (randomized to either a video self-scoring PRT app version or to a standard PRT app without self-scoring functionality). Child participants (1 - 4.5 years) had a diagnosis of autism and language delays. Parents completed intake and follow-up assessments, eight PRT lessons, and recorded parent-child videos in-app after each lesson, which were then reviewed by the research team for analysis. For the purposes of this study, we analyzed all participants in a single cohort to analyze parent fidelity profiles and gains across PRT fidelity components (see Table 1) during baseline and final videos.

Results: Dependent sample T-tests were used to evaluate changes to PRT fidelity components. For Child Choice, demonstrated use at pre-intervention met fidelity and maintained without a significant change ($p = .151$, $Mpre = 87.4\%$, $Mpost = 91.4\%$). A similar trend was noted for Child Attention starting high with no significant change ($p = .204$, $Mpre = 89.4\%$, $Mpost = 85.4\%$). For Clear Learning Opportunity there was a significant improvement after use of the app ($p < .001$, $Mpre = 57.2\%$, $Mpost = 81.9\%$, $d = .84$). Similarly, for Contingent Reinforcement there was a significant improvement ($p = .009$, $Mpre = 32.0\%$, $Mpost = 56.8\%$, $d = .58$). Finally, for Natural Reinforcement, there was also a significant improvement ($p = .026$, $Mpre = 43.9\%$, $Mpost = 65.2\%$, $d = .54$).

Conclusions: The *Pivotal* app was linked to promising improvements on multiple PRT fidelity components. Parents already demonstrated a high degree of Child Choice and Child Attention during baseline videos, suggesting that many parents intuitively attended and engaged with their children. The use of Clear Opportunities, Contingent Reinforcement, and use of Natural Reinforcement all improved significantly and appeared to drive global improvements of overall fidelity scores. These data suggest that training programs may need to spend more time analyzing initial parent strengths related to intervention delivery and focus on specific unmastered components. Such knowledge would have implications for the development of parent and professional training models that can reallocate the focus towards these components.

430.171 Preliminary Analysis of a Four-Year Follow-up Study on the Implementation of a Short-Term, Low-Intensity Early Start Denver Model Program for Autistic Children in Taiwan: Parental Outcomes

I. S. Cheong¹, T. H. Tseng², Y. S. Tang³ and C. H. Chiang², (1)Department of Psychology, National Chengchi University, Taipei, Taipei, Taiwan, (2)Department of Psychology, National Chengchi University, Taipei, Taiwan, (3)Department of Psychology, National Chengchi University, Taipei, Taipei

Background: Autism Spectrum Disorder (ASD) is a neurodevelopmental disorder characterized by deficits in social communication and interaction, along with restricted and repetitive behaviors or interests. Children's autism symptoms can increase parenting stress and negatively affect caregivers' parental self-efficacy and quality of life. The evolution from traditional Applied Behavior Analysis (ABA) models has led to significant advancements. In 2015, scholars categorized several empirically supported ASD early intervention models implemented in natural settings under the category of Naturalistic Developmental Behavioral Interventions (NDBI). Among these, the Early Start Denver Model (ESDM) has shown significant improvements in children's cognitive and communication abilities. Lin et al. (2020) conducted the first study of ESDM in Taiwan. Results showed significant differences in pre- and post-intervention scores on the parenting stress subscale for the ESDM group, while the control group showed no change. Long-term studies on the impact of ESDM interventions on parents' mental health are relatively limited, both internationally and in Asia; therefore, we aim to explore this topic in Taiwan.

Objectives: This study aims to extend the findings of Lin et al. (2020) by conducting a four-year follow-up study to examine the long-term effects of ESDM intervention on parenting stress, parental self-efficacy, and quality of life.

Methods: A quasi-experimental design was used, utilizing longitudinal data from Lin et al. (2020) (Time 1 to Time 3) to assess the same children during their school-age years (Time 4). The children were divided into two groups: an ESDM group ($n=17$), which received individual ESDM interventions for six months (approximately 8 to 9 hours per week) while parents attended bi-weekly, 1-hour parent group-based parent-education sessions, and a control group ($n=17$) that received standard community treatment. Parents completed several questionnaires, including the Parenting Stress Index, Fourth Edition (PSI-4), the Chinese Version of the Maternal Parental Self-Efficacy Scale (MPSES), and the Brief Version of the World Health Organization Quality of Life Instrument in Taiwan version (WHOQOL-BREF), and the Depression, Anxiety and Stress Scale - 21 Items (DASS-21).

Results: Both groups showed a significant reduction in parenting stress from Time 1 (T1) to Time 4 (T4) ($F=27.238$, $p<.001$), and from Time 3 (T3) and Time 4 ($F=31.090$, $p<.001$), as well as quality of life (T4-T1: $F=32.589$, $p<.001$; T4-T3: $F=28.863$, $p<.001$), by the Group interaction different. However, the Group-by-Time interaction differences were not sustained during the four-year follow-up. Parents in the ESDM group reported significantly higher levels of parental self-efficacy (T4-T1: $F=18.288$, $p<.001$; T4-T3: $F=13.093$, $p<.001$), and lower depressive symptom levels compared to the control group ($t = -2.053$, $p=0.049$).

Conclusions: The current study is among the few to conduct long-term follow-up on the impact of ESDM interventions on the mental health of parents of autistic children. The results indicate that ESDM has lasting effects, reducing parenting stress, enhancing parental self-efficacy, and improving quality of life. These findings suggest that ESDM not only benefits children but also plays a crucial role in supporting parental mental health, further reinforcing its long-term value as an effective intervention.

430.172 Preliminary Effects of Pivotal Response Treatment in a Diverse Sample of Preschoolers with Developmental Disorders

A. C. Offit¹, M. Clark¹, E. F. Ferguson¹, S. Brogno¹, H. Komaki¹, D. M. Slap², A. Y. Hardan² and G. W. Gengoux², (1)Stanford University, Palo Alto, CA, (2)Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA, (3)Department of Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA, (4)Stanford University, Stanford, CA

Background: Children with neurodevelopmental disorders (NDD) including autism spectrum disorder (ASD) exhibit greater social communication difficulties than the general population. Evidence suggests that early behavioral interventions that target child motivation, such as Pivotal Response Treatment (PRT), improve language and social behaviors in children with NDD. However, many children with NDD are excluded from early intervention research due to inclusion criteria or study requirements. For instance, children may be excluded if English is not the primary language spoken at home or they do not meet diagnostic criteria (e.g., ASD diagnosis). Additionally, families might be unable to meet the time and travel commitments of the study protocol. Importantly, very little research has focused on response to intervention in a diverse sample of youth who are excluded from more rigorous randomized controlled trials.

Objectives: To evaluate the effects of a 12-week PRT program on social communicative skills in a heterogeneous sample of children with NDD who did not qualify for other early intervention trials or their families were unable to meet study requirements.

Methods: Recruitment for this program is ongoing. Participants to date include 15 children with NDD aged 2-5:11 years ($M=2.6$ years; $SD=1.12$; 80% male; 27% White; 73% Asian) and their parents. Children received 12 hours weekly of PRT in an early intervention classroom ($n=13$) or in-home setting ($n=2$), for a total of 12 weeks. Parents received weekly PRT parent training sessions with a BCBA. At baseline and week 12, parents completed the Social Responsiveness Scale Second Edition (SRS-2), Stanford Social Dimensions Scale (SSDS), and the Repetitive Behavior Scale-Revised (RBS-R).

Results: Findings indicated significant improvements between baseline and week 12 in the SRS-2 total score ($t(14) = 1.77$; $p = 0.049$) and the social communication and interaction (SCI) subscale ($t(14) = 2.36$; $p = 0.017$). Youth with NDD also demonstrated significant improvements in the empirically-derived SRS-2 factors of attachment and affiliation ($t(14) = 2.54$; $p = 0.012$; Uljarević et al., 2021), emotion recognition ($t(14) = 2.027$; $p = 0.031$) and reduced social ($t(14) = 1.815$; $p = 0.045$; Frazier et al, 2014). Significant improvements were also observed in parent-rated scores on the SSDS in the social affiliation ($t(15) = -2.82$; $p = 0.006$), expressive social communication ($t(15) = -2.33$; $p = 0.017$), and social recognition subscales ($t(15) = -2.45$; $p = 0.013$).

Conclusions: Findings from this study suggest improvements in distinct facets of social functioning in a heterogeneous sample of youth with NDD participating in an early intervention program. Available parent-report data suggests that PRT shows efficacy for improving emotion recognition and reducing social avoidance, both signs of an improvement in social skills. Regarding future directions, the high number of bilingual children seeking early intervention highlights the need to develop and refine methods that capture treatment-related changes in a linguistically diverse sample. Ongoing research should also focus on optimizing the design of inclusive and accessible early intervention trials.

430.173 Preliminary Family Outcomes of a Community-Based Trial of Project Impact for Toddlers

S. R. Rieth^{1,2}, M. M. Chemotti^{2,3}, S. F. Vejnosa⁴, C. Orendain Soto^{2,3}, D. Quintanilla Rendon^{2,3}, J. Sherman⁴, T. Lind^{1,2}, A. C. Stahmer⁵ and S. Dufek⁶, (1)Child and Family Development, San Diego State University, San Diego, CA, (2)Child and Adolescent Services Research Center, San Diego, CA, (3)San Diego State University, San Diego, CA, (4)UC Davis MIND Institute, Sacramento, CA, (5)UC Davis MIND Institute, University of California at Davis MIND Institute, Sacramento, CA, (6)Psychiatry and Behavioral Sciences, UC Davis Health, MIND Institute, Sacramento, CA

Background: Evidence-based practices exist for supporting the development of toddlers at high-likelihood of autism, but high-quality delivery of these practices in community settings remains challenging. While there is considerable variability in publicly funded early intervention (EI) services, caregiver-mediated naturalistic developmental behavioral interventions (NDBIs) are considered best practice. The current study examines the efficacy of the NDBI Project ImPACT (Improving Parents As Communication Teachers; Ingersoll & Dvortcsak, 2019) in comparison to existing EI services across California in a randomized community-based trial.

Objectives: This study explored the efficacy of Project ImPACT (PI) in comparison to usual care EI services offered in community settings. Initial outcomes examined across groups include children's social and communication skills as well as caregiver's use of responsive parenting behaviors.

Methods: The sample includes 122 caregiver-child dyads who were actively enrolled in community-based EI to support social communication development. Children were 55% Latino ($n = 67$) with a mean age of 25 months ($SD = 5$) at entry, and 86% of caregivers were mothers ($n = 105$). Timing of therapist training in PI was randomized in a waitlist control design. Dyads participated in either usual care EI or PI, based on whether their participating therapist had received PI training at the time of service delivery. Study assessments were collected at intake and after approximately four months of intervention (approximate time for PI completion). At both timepoints, caregivers completed the Vineland-3 (Sparrow et al., 2016), the Communication and Symbolic Behavior Scales: Developmental Profile Infant-Toddler Checklist (CSBS DP ITC; Wetherby & Prizant, 2002), the Developmental Profile-3: Communication scale (Alpern, 2007), and a 10-minute caregiver-child play interaction. Play interactions were coded from video recording, using the Parenting Interactions with Children: Checklist of Observations Linked to Outcomes (PICCOLO; Roggman et al., 2013). Preliminary results were analyzed with a repeated measures analysis of variance to examine change over time across usual care versus PI groups.

Results: Results demonstrated a significant time by group interaction for the CSBS Social Composite ($F(1,70) = 5.1$, $p < .05$), VABS Communication ($F(1,71) = 3.89$, $p < .05$), and PICCOLO Responsiveness ($F(1,54) = 5.95$, $p < .05$), such that dyads receiving PI demonstrated more progress on these measures than dyads receiving usual care EI. Significant growth in both groups across time was demonstrated on other scales of the CSBS (Speech $F(1, 69) = 28.49$, $p < .05$) and Symbolic ($F(1,70) = 19.14$, $p < .05$) as well as the PICCOLO Teaching domain. ($F(1,54) = 11.77$, $p < .05$). Lastly, no significant change was demonstrated in either group for the remaining scales of the VABS (Daily Living Scales, Social, Motor, or Adaptive Behavior Composite), the DP-3 Communication or the Affection or Encouragement scales of the PICCOLO (all $p > .05$).

Conclusions: Analyses revealed positive effects for PI in key areas for children in need of social communication support. Children in both EI groups progressed equally on some measures. Differential changes on CSBS and PICCOLO subscales relative to usual care EI are consistent with pilot study results (Stahmer et al, 2020).

430.174 Preliminary Outcomes of a Randomized Controlled Trial of Center-Based Pivotal Response Treatment for Preschoolers with Autism Spectrum Disorder

D. M. Slap¹, E. F. Ferguson², R. Wachter³, L. Butler⁴, A. Y. Hardan¹, G. W. Gengoux¹ and S. Yalcinkaya⁵, (1)Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA, (2)Department of Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA, (3)Stanford Children's Health, Palo Alto, CA, (4)Stanford University, Palo Alto, CA, (5)Stanford University, Palo Alto, CA

Background: Many young children with autism spectrum disorder (ASD) demonstrate significant delays in social communication skills. Pivotal Response Treatment (PRT) employs strategies to improve child motivation and a growing body of literature supports the efficacy of PRT for improving language and social behaviors. However, research related to optimal treatment structure, location, and modality is limited.

Objectives: The aim of this randomized controlled trial is to evaluate the short-term benefits (12 weeks) of center-based PRT (PRT-C) on symptom severity in autistic preschoolers. This trial investigates whether children in the PRT group will show greater improvement in social communication skills compared to children in a delayed treatment control group (DTG). Changes in parent fidelity of treatment implementation and satisfaction with components of the training are also explored.

Methods: Recruitment for this trial is ongoing. Participants to date include 40 children with ASD, aged 2-4;11 years ($M=38.1$ months; $SD=6.5$) with significant developmental delays. Children were randomly assigned to PRT-C ($N=20$) or DTG ($N=20$). During PRT-C, children received 12 hours per week of PRT in an early intervention classroom setting, for a total of 12 weeks plus weekly parent training. An expert clinician naïve to treatment assignment completed the Clinical Global Impression Improvement rating (CGI-I) at week 12 and parents completed the MacArthur-Bates Communicative Development Inventory (CDI) and a treatment satisfaction survey at baseline and week 12. In addition, parent-child interaction videos were coded by blinded raters using the Brief Observation of Social Communication Change () protocol and using established definitions to assess parents' fidelity of PRT implementation.

Results: Preliminary analyses of ratings indicate that children in the PRT-C group show more overall improvement in symptom severity compared to children in the DTG ($\chi^2(3, N=30) = 14.46, p = .002$). On the CDI – Words Produced Score between baseline and week 12, there was a main effect of time, but no significant between group difference ($F(1,35) = 2.63; p = .114$). Additionally, there were no differences between groups between baseline and week 12 on the BOSCC total score ($F(1,36) = 2.07; p = .159$). Parents in the PRT-C group demonstrated statistically significant improvement in fidelity of PRT implementation compared to parents in the delayed treatment group ($F(1,31) = 13.12; p = .001$). Parents in the PRT group demonstrated mean increases in overall PRT fidelity from baseline ($M = 53.63\%$; $SD = 27.33\%$) to week 12 ($M = 82.31\%$; $SD = 16.02\%$). Overall, 93% of parents indicated satisfaction with their child's language development and 83% of parents indicated satisfaction with their child's improvement in other skill domains ($N=35$).

Conclusions: Available data suggest that the center-based model shows preliminary efficacy for improving child symptom severity. However, to date, the benefits on language and social communication measures are similar to those observed in the control group. Weekly parent training was effective in teaching the majority of parents to implement PRT with fidelity and parents expressed satisfaction with their children's progress. Future analyses will focus on predictors of differential treatment response in the full sample.

430.175 Probability of Intervention Benefit in an Early Intervention for Autistic Children

K. Sterrett¹, S. J. Rogers², A. M. Estes³, C. Lord⁴ and S. H. Kim⁵, (1)Pediatrics, University of Minnesota, Los Angeles, CA, (2)Department of Psychiatry and Behavioral Sciences, University California Davis, Sacramento, CA, (3)Speech and Hearing Sciences, UW Autism Center, Seattle, WA, (4)UCLA Semel Institute for Neuroscience and Human Behavior, Los Angeles, CA, (5)School of Psychology, Korea University, Seoul, Seoul, Korea, Republic of (South)

Background: Early intervention can help improve the outcomes of children, sometimes dramatically. RCTs of behavioral interventions for children with autism often show statistically significant differences between treatment and control groups. However, the effect sizes in those studies, and the outcomes they measure, can vary considerably (meaning their real-life significance can be hard to interpret; Sandbank et al., 2024). For this reason, it is a priority that clinicians help families understand and compare various intervention choices using data driven and/or probabilistic approaches.

Objectives: The objectives of this study were: (1) to evaluate the feasibility of applying a probabilistic approach to understanding the effectiveness of early interventions for young autistic children and (2) to evaluate the predictors of response in an evidence based intervention.

Methods: This is a secondary analysis of data from a randomized controlled trial of a parent-mediated intervention for young autistic children (Early Start Denver Model; ESDM- Rogers et al., 2019). From baseline to the final timepoint was 24 months (see Table 1 for demographics). Change in social communication was measured using the Brief Observation of Social Communication Change (BOSCC; Grzadzinski et al., 2016). Reliable change for each participant was measured by generating a Reliable Change Index (RCI; Jacobson & Truax, 1992). Children with an RCI score less than -1.96 were considered as making reliable change (i.e., decreases in BOSCC scores greater than expected by chance). Dichotomous predictors were generated based on median age, nonverbal DQ/IQ scores (less than or greater than 70), autism severity (ADOS CSS less than or greater than 7) and language level (no words or some words). Logistic regression was used to determine if the probability of reliable change differed between the treatment and control group based on the dichotomous predictors (see Lindhiem et al., 2012).

Results: Related to objective 1, 33 children in the intervention group saw reliable decreases (73%) in BOSCC scores (decreases signify improvements), 11 children did not make reliable change in either direction (24%), 1 saw a reliable increase (2%). 23 children in the control group showed reliable decreases in BOSCC scores (57%), 17 children did not make reliable change in either direction (43%), none saw reliable increases. Related to objective 2, the largest difference in the probability of reliable change between the intervention and control group was seen in those with nonverbal DQ/IQ scores of 70 or less (82% in ESDM compared to 25% in control). Children younger than 22 months (79% compared to 58%) and children with ADOS CSS scores greater than 7 (75% compared to 44%) were also more likely to make reliable change in the ESDM group. Differences in probabilities based on all predictors are presented in Figure 1.

Conclusions: These data provide proof of concept for the application of a probabilistic, individualized approach to data from RCT. Results point to the potential utility of analyzing data at an individual, rather than group level, using standardized assessment data. Prospective trials are necessary to replicate these findings to determine whether this approach can be used clinically.

430.176 Provider Implementation of RIT in Part C Early Intervention Settings: Results from a Randomized Controlled Trial

D. M. Tagavi¹, C. Perryman², E. R. Britsch³, C. Herrera² and W. L. Stone³, (1)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (2)University of Washington, Seattle, WA, (3)Psychology, University of Washington, Seattle, WA

Background: Although evidence-based interventions such as Naturalistic Developmental Behavioral Interventions (NDBIs) benefit autistic children (Zwaigenbaum et al., 2015), many families face barriers to accessing these services (Stadnick et al., 2015). The U.S. federally-mandated Part C early intervention (EI) system, which provides services to young children with developmental delays, is a promising setting for delivering NDBIs and training caregivers to use evidence-based intervention strategies with their child. Recent research has demonstrated the positive effect of implementing NDBIs, such as Reciprocal Imitation Training (RIT), with EI providers on outcomes such as adoption, feasibility, and self-efficacy (Ibañez et al., 2021). However, less is known about implementation efforts on provider fidelity of NDBIs and downstream effects of child and family outcomes.

Objectives: This study evaluated the implementation of Reciprocal Imitation Teaching (RIT), an NDBI focused on improving the pivotal skill of child imitation, within Part C EI settings across the United States.

Methods: The study utilized a pragmatic RCT design to examine the effect of an 8-hour RIT training workshop on a variety of implementation outcomes for Part C EI providers (e.g., adoption, sustainment, perceived effectiveness, feasibility, self-efficacy, RIT fidelity, and use of child-centered and parent coaching intervention skills) compared to a 4-hour active control training focused on improving daily routines (DR). Descriptive statistics were used to examine RIT adoption, RIT sustainability, RIT feasibility, and perceived RIT effectiveness. Hierarchical linear modeling (HLM) was used to examine the trajectory of change in provider outcomes across time points.

Results: Fifty-six EI providers enrolled in the study (RIT = 28, DR = 28). Providers completed measures online at 5 timepoints: Pre-Training, and 1-, 3-, 6-, and 12-months post-training. Analyses revealed that providers trained in RIT adopted RIT and used it with both autistic children and those without an autism diagnosis. Providers also sustained their use of RIT over the 12 months following the workshop. Providers consistently reported RIT as feasible and effective, with perceived effectiveness ratings increasing over the year following their training. Additionally, training in RIT significantly enhanced provider self-efficacy in working with children with social communication delays and their families. Providers in both the RIT and control groups self-reported the sustained use of RIT-specific strategies and child-centered intervention approaches post-training. Provider use of caregiver coaching strategies did not increase significantly.

Conclusions: These results underscore the potential for naturalistic early interventions such as RIT to be implemented effectively with providers serving autistic children and their families in community-based settings. Though beyond the scope of this current study, next steps include examining the effects of provider use of RIT or caregiver coaching in RIT on child and family outcomes. As fidelity and use of child-centered strategies were similar across both groups and neither group improved in their use of caregiver coaching strategies, future directions may include a more nuanced, behavioral examination of provider implementation with children on their caseload. Additionally, future research in this area may serve to examine whether booster sessions or expert consultation may further improve provider use of specific RIT and caregiver coaching strategies.

430.177 Quality of Life As an Outcome in Randomized Controlled Trials of Pivotal Response Treatment

E. Jevtic¹, R. K. Schuck², M. E. Millan³, K. Paszek³, H. Komaki⁴, J. M. Phillips³, G. W. Gengoux³ and A. Y. Hardan¹, (1)Stanford University School of Medicine, Palo Alto, CA, (2)Department of Psychiatry and Behavioral Sciences, Department of Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA, (3)Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA, (4)Stanford University, Palo Alto, CA

Background: Pivotal Response Treatment (PRT) is a naturalistic intervention aimed at building communication skills in young children with autism. Ultimately, PRT is hoped to improve autistic children's quality of life (QoL). The World Health Organization defines QoL as "an individual's perception of their position in life in the context of the culture and value systems in which they live and in relation to their goals, expectations, standards, and concerns." QoL thus encompasses an individual's health, well-being, social connectedness, and life satisfaction. However, few studies have investigated PRT's effect on QoL, despite community members identifying QoL as a highly important outcome.

Objectives: To assess whether PRT delivered to young children with autism impacts children's QoL as reported by caregivers.

Methods: Data from three positive PRT RCTs were combined to assess potential changes in QoL after PRT. Trials included a study of PRT parent training delivered in a group (PRT-G), a PRT package including individual parent training plus in-home, clinician-delivered PRT (PRT-P), and an individual telehealth parent training study (PRT-T). In total, 130 autistic children (2–6 years old; 104 male, 26 female) and their parents participated (n=67 randomized into the active PRT group). The Pediatric Quality of Life Inventory (PedsQL) was completed by parents at baseline and 12 weeks later; change scores (Week12-baseline) were computed. Differences in PedsQL change scores (total and subscales) between intervention and control groups were assessed using independent-measures t-tests. The study investigated item-level differences with the most intensive intervention (PRT-P).

Results: PedsQL scores were not significantly different between intervention and control groups at baseline ($t_s < 1.60$, $p_s > .050$). Across the three RCTs, there were no significant differences between the intervention and control groups with regard to PedsQL change scores across all subscales (see Table 1). There were also no significant differences in change over time between intervention and control groups in each of the individual studies ($p_s > .05$), though the Social QoL domain did show medium effects in PRT-P ($d = 0.583$) and PRT-T ($d = 0.621$). When looking at item-level changes in Social QoL within PRT-P, one item – *Getting teased by other children* – showed significant improvement in the intervention group compared to the control (see Table 2).

Conclusions: To our knowledge, this is one of the first investigations of PRT's impact on QoL. While we did not find significant differences between the intervention and control groups regarding the effect of PRT on QoL, there was some preliminary evidence of potential improvement in Social QoL. Though it is possible that PRT has a limited impact on QoL, it is also possible that other measures of QoL, such as those that focus specifically on Family QoL, might be better suited for capturing intervention-related changes. Additionally, QoL perceptions may vary between reporters (i.e., parent versus child). Longitudinal research is needed to understand the long-term effects of PRT on QoL. Further research with larger samples, varied measurement tools, and longitudinal data collection can provide more insights into intervention effects on QoL.

430.178 Real-World Insights: Tracking Communication Gains in Autistic Preschoolers in a Virtual Caregiver-Delivered Program

L. Denusik¹, B. Cunningham^{1,2}, A. Binns^{1,3} and J. Oram¹, (1)Western University, London, ON, Canada, (2)McMaster University, Hamilton, ON, Canada, (3)University of Toronto, Toronto, ON, Canada

Background: Caregiver-delivered programs are a best practice for supporting autistic preschoolers (Zwaigenbaum et al., 2015). While extensively evaluated in research settings, practice-based evidence from real-world implementation is needed. One method to achieve this involves using standard clinical information, where valuable research-relevant data can be found (Epstein et al., 2002). A second key need in the intervention field is moving beyond measuring overall effectiveness to exploring for whom different programs work best and for which goals, that is, identifying moderators (Trembath et al., 2019). In this practice-based research study, we capitalized on an opportunity to use existing clinical forms for autistic preschoolers participating in a virtual, community-based, caregiver-delivered program, More Than Words® (MTW), to explore changes in and moderators of communication development for use in future pragmatic (real-world) clinical trials.

Objectives: Our project objectives were to: (a) identify data that can be extracted from standard-of-care clinical forms to track autistic children's communication development during the program, and (b) explore if changes in communication development during the program was moderated by the social communication skills of the child at the start of the program.

Methods: Two forms already familiar to clinicians were completed pre- and post-program for 36 children (24 to 66 months) who participated in the virtual MTW program in Ontario, Canada. The MTW *Social Communication Checklist* (SCC), a program-specific form completed as part of the standard delivery of the program, was used to identify the child's social communication stage and changes in social communication skills during the program. The second was the *Focus on the Outcomes of Communication Under Six* (FOCUS-34), a valid and reliable criterion-referenced tool used widely in Ontario to measure changes in communicative participation due to intervention, that is, changes that are greater than would be expected due to the passage of time alone. The FOCUS-34 also tracked changes in different areas of communication (e.g., receptive and expressive language). Exploratory analyses examined changes in communication development during the program according to participants' social communication stage.

Results: Results from the SCC indicated that most children moved up a social communication stage ($n = 15$) or stayed in the same stage but gained new skills within that stage ($n = 15$). Of the 36 children who completed the program, 61% ($n = 22$) showed a meaningful clinical change on the FOCUS-34. Using the SCC to group children by social communication stage, those at the lowest stage showed the most gains in the category of social play on the FOCUS-34, while those in the highest stage group made the most gains in expressive language.

Conclusions: This practice-based research project demonstrates how existing clinical tools can be used to track development and explore individual differences. Preliminary evidence that the same program can impact different goal areas depending on the child's pre-program social communication skills. Even if not collected in a research setting, program-specific forms can provide data to describe participants' abilities when assessing program outcomes. Researchers should leverage real-world clinical data to develop practice-based evidence while prioritizing exploring moderating factors.

430.179 Self-Regulation in at-Risk Toddlers: Trajectories across a Parent-Mediated Intervention

G. M. Garcia, M. Garcia and A. Mastergeorge, Human Development and Family Sciences, Texas Tech University, Lubbock, TX

Background: Self-regulation is a pivotal skill in early development and refers to a child's capacity to manage behaviors across cognitive, emotional, and social domains. Self-regulation development in early childhood plays a crucial role in shaping future developmental outcomes. Since toddlers have limited self-regulatory abilities, they rely heavily on their caregivers to help them manage their responses to environmental stimuli. When a toddler struggles with self-regulation, caregivers actively support the child's regulation through a co-regulation process. Numerous studies have explored the progression of self-regulation in young children (e.g., Althoff et al., 2010; Garner & Waajid, 2012; Werner & Milyavskaya, 2019), highlighting early childhood as a pivotal period for acquiring and refining such skills. However, to date, there are limited studies examining the self-regulatory behaviors of toddlers with developmental risk.

Objectives: This study aimed to examine the changes in self-regulation trajectories among toddlers identified as developmentally at-risk over the course of a 16-week parent-mediated telepractice intervention. This study focused on the influence of parental responsiveness during self-regulatory actions in toddlers.

Methods: The study included six children aged 12-48 months, who were either diagnosed with or considered at risk for autism spectrum disorder (ASD). Participants were randomly assigned to one of two groups: (1) a parent-mediated intervention group; or (2) a parent-mediated intervention group with additional annotated feedback on home play intervention videos. Caregivers completed several assessments including the Brief Infant-Toddler Social Emotional Assessment (BITSEA), the Social-Emotional Assessment & Evaluation Measure (SEAM), and the Early Social Communication Scales (ESCS) as well as caregiver responsiveness coded through observations measured by the Parent-Child Interaction System (PARCHISY). Children were evaluated at three assessment points: pre-intervention, midpoint, and post-intervention and participated in two observed self-regulation tasks: the Snack Delay and Locked Box tasks. Tasks were designed to assess the children's self-regulation behaviors, including arousal and emotional regulation with each task being modified to align with the developmental ages of the participants.

Results: The repeated measures ANOVA results revealed no significant differences between the two groups. However, negative parental content (affect and responsiveness) was found to decrease from pre-intervention to post-intervention ($M = 2.00$, $SD = 1.00$; $M = 2.33$, $SD = 1.154$; $M = 1.667$, $SD = 1.154$; $M = 2.00$, $SD = 1.000$). One-way ANOVA results for the BITSEA at pre-intervention were statistically significant ($F(1,4) = 9.191$, $p = .039$). Furthermore, the SEAM and ESCS scores exhibited upward trends across all timepoints. Although simple linear regression results did not show significant findings for most tasks, the locked-box self-regulation task yielded notable trends toward significance at both pre- and post-intervention ($R^2 = .356$, $F(1,5) = .552$, $p > .05$).

Conclusions: Understanding the association between maternal content (positive and negative affect and responsiveness) in interactions and toddler self-regulation is critical for gaining insights into how parenting practices shape at risk children's ability to regulate emotions during a targeted intervention. This study highlights the importance of targeting self-regulation trajectories in the context of parent-mediated interventions for toddlers diagnosed with autism and those with autism risk behaviors.

430.180 Social Motivation and Social Skills Program Outcomes for Autistic Youth: PEERS® for Preschoolers

J. L. Martinez¹, Y. Bolourian², K. L. Fisher³ and E. A. Laugeson⁴, (1)UCLA Department of Psychiatry, PEERS lab: UCLA PEERS Clinic, Los Angeles, CA, (2)UCLA Tarjan Center, Los Angeles, CA, (3)UCLA Semel Institute for Neuroscience and Human Behavior, UCLA PEERS Clinic, Los Angeles, CA, (4)UCLA Semel Institute for Neuroscience and Human Behavior, UCLA PEERS® Clinic, Los Angeles, CA

Background: The social motivation hypothesis proposes that the neurobiological differences in attention and reward processes to social and nonsocial stimuli present in autism contribute to reduced opportunities for autistic children to learn and have reduced social motivation, contributing to social deficits, which may impact their ability to develop typical social cognition and behavior through social learning (Chevallier et al., 2012; Clements et al., 2018). The downstream cascading effects of reduced social motivation can therefore result in difficulties forming and maintaining relationships with peers, despite often strongly valuing and desiring such connections (Black et al., 2024). PEERS® for Preschoolers (P4P) is an evidence-based, parent-assisted social skills program for young autistic children and those with other social challenges, teaching age-appropriate skills and promoting positive peer relationships (Park et al., 2022). Previous research has shown that higher social motivation in autistic populations is associated with improved social skills and fewer social challenges (Itskovich et al., 2021; Neuhaus et al., 2021). However, there is limited understanding of how social motivation may impact the treatment response to social skills programming aimed at enhancing positive social skills and increase social competence in autistic children.

Objectives: The purpose of this study is to investigate social motivation as a predictor of program outcomes among autistic youth prior to and following the P4P program.

Methods: Participants included 74 autistic children between 4-6 years (77% male, $M_{age}=4.7$, $SD=0.82$) and their parents who attended P4P. Social motivation was assessed via the Social Responsiveness Scale, 2nd Edition (SRS-2; Constantino & Gruber, 2008), using the social motivation treatment scale T-score. Child outcomes were assessed via parent-reported scores from pre- to post-programming on the Social Skills Improvement System Social Skills (SSiS-SS; Gresham & Elliott, 2008), while social engagement was measured by the number of playdates recorded in the Quality of Play Questionnaire (QPQ; Frankel et al., 2010). The Parenting Stress Index, 4th Edition, Short-Form (PSI-4-SF; Abidin, 2012) was used to measure parenting stress. A multivariate analysis of variance (MANOVA) assessed the impact of baseline social motivation on changes in program outcomes.

Results: Following participation in P4P, results demonstrated significant improvements in SSiS-SS ($M_{change}=5.52$, $SD=12.38$), QPQ ($M_{change}=0.95$, $SD=3.53$), and PSI ($M_{change}=2.29$, $SD=6.71$) scores. However, multivariate tests indicated that baseline social motivation did not significantly predict changes in program outcomes (*Wilk's Λ* =.889, $F(3,38)=1.576$, $p=.211$).

Conclusions: Findings demonstrated that baseline social motivation did not significantly influence degree of change on primary outcomes for autistic children following PEERS® for Preschoolers program. This is encouraging as it suggests young autistic children with varying social motivation profiles may benefit from the program. However, given recent research suggesting that the SRS-2, and in particular the social motivation scale, may be confounded by symptoms of anxiety (South et al., 2017; Capriola-Hall et al., 2021), further research is warranted. Future research should continue to explore moderators of P4P response in the light of heterogeneity in autism presentation to inform clinical care and recommendations.

430.181 Systematic Review on Sibling-Mediated Intervention through an Intersectional Lens

J. Y. Jeong and M. DeMayo, The University of Texas at Austin, Austin, TX

Background: Sibling-mediated interventions (SMIs) represent a growing area of research aimed at leveraging the natural dynamics within sibling relationships to support individuals with intellectual and developmental disabilities (IDD). Siblings often play critical roles in the lives of individuals with IDD, yet their potential contribution as mediators in interventions has been underexplored. SMIs can offer a unique, sustainable, and culturally responsive method to promote social, cognitive, and behavioral outcomes for individuals with IDD, while also potentially benefiting neurotypical siblings. However, the extent to which intersectional factors, such as race/ethnicity, language, and socioeconomic status, are considered in these interventions remains unclear.

Objectives: This systematic review aims to synthesize existing literature on SMIs for individuals with IDD. Specifically, the review will explore: (1) the efficacy of these interventions in improving outcomes for individuals with IDD, (2) the impact of SMIs on the neurotypical sibling, and (3) the extent to which intersectionality is embedded in the development and implementation of SMIs.

Methods: A comprehensive search of peer-reviewed journal articles was conducted across databases, including APA PsychInfo, ERIC, Medline, Academic Search Complete, and Education Source. Independent screening was performed by the first and second authors using the blind function on Rayyan. While the second author's screening is still in progress, the authors expect to complete the screening and develop coding schemes by the end of October, with initial coding finalized by the end of November. Both authors have committed to adhering to PRISMA guidelines throughout the screening and coding process.

Results: Preliminary analysis based on the first author's screening suggests that SMIs show promising outcomes for individuals with IDD, particularly in enhancing social skills and fostering sibling relationships. Early findings also highlight a lack of attention to cultural and intersectional factors within these studies. The final results will offer a comprehensive synthesis of SMI effectiveness, identify recurring themes in intervention design, and assess gaps in research on diverse populations.

Conclusions: Although the final results are pending, this review is anticipated to provide valuable insights into the effectiveness of sibling-mediated interventions for individuals with IDD. It will emphasize the potential of SMIs to support both individuals with IDD and their siblings while underscoring the need for more inclusive research that considers cultural and intersectional dynamics. This review will inform future research, practice, and policy by offering recommendations for developing more equitable and effective SMI programs that address the diverse needs of families.

430.182 Training and Ongoing Feedback Process for Maintaining Discrete Trial Teaching Intervention Fidelity across Multi-Site Randomized Control Trial Studies

C. Hoffkins¹, E. Beach², S. Iadarola² and L. Levato², (1)DBP, University of Rochester Medical Center, Rochester, NY, (2)University of Rochester Medical Center, Rochester, NY

Background: Fidelity, in the context of implementing an intensive, behavioral intervention for autism such as Discrete Trial Teaching (DTT), refers to ensuring the intervention is implemented in the way it was intended. Fidelity checks can be used to ensure treatment adherence and quality. Fidelity is critical because it has a relationship to treatment outcomes, including within studies evaluating autism interventions such as DTT. The general method for DTT is taking a larger skill, breaking it down into smaller parts, and systematically teaching the parts by using a most to least prompting hierarchy (being quickly faded), multiple opportunities for practice (trials), reinforcement, and error correction.

The creation of a treatment reliability process can minimize treatment drift as experts provide consistent training, feedback, and oversight to interventionists. There is limited consensus around how fidelity is conducted for intensive, behavioral interventions such as DTT. Therefore, establishing and evaluating fidelity in these types of interventions is critical.

Objectives: The objective is to explore the frequency of corrective feedback from fidelity data collected across studies in order to assess interventionists' reliability and inform initial, ongoing, and future training.

Methods: We explored DTT interventionist fidelity across two multi-site trials for autistic children with minimal spoken language. Interventionists received training and demonstrated at least 80% fidelity across three practice participants before working with study participants. Interventionists received feedback every one to two weeks.

DTT experts for each study provided interventionists with fidelity ratings based on randomly chosen 10-minute session recordings. A standardized fidelity form included thirteen categories outlining best practices for DTT implementation. Each category used a Likert scale rating (0-5, or not applicable), and included space for written feedback and an overall fidelity score.

An exploratory secondary data analysis was conducted via retrospective manual review of fidelity forms. Excel was used to stratify (by study and site), randomly select fidelity forms across participants, and organize a component analysis of the thirteen fidelity categories. Data elements included: site, case number, session phase, week, date, interventionist and rater initials, overall score, and whether written corrective feedback was provided.

Results: The overall mean score of 70 fidelity forms from across both studies was greater than 90%. Corrective feedback percentages based on feedback opportunity per category ranged from 10% to 51% of the sample (see figure 1).

Conclusions: Overall fidelity ratings were consistent and high across two major intervention trials focused on language development in autistic children. The areas of DTT implementation that showed the most frequent need for more explicit feedback were error correction and prompting procedures. This information can inform future training and help DTT supervisors pinpoint potential treatment drift areas.

Future directions using fidelity data should be expanded to identify feedback needed during different phases of the studies, evaluate Likert scale information by category, and explore correlations between implementation location and outcomes or fidelity scores and participant outcomes.

Future research could include replicating or adjusting the training and feedback process in other settings or applications for DTT fidelity monitoring.

430.183 Treatment Engagement in Tele-PCIT Among Underserved Youth with Neurodevelopmental Disorders: Clinical Presentation and Sociodemographic Factors

S. Gomez Batista¹, R. Ros-DeMarize², L. Carpenter¹ and C. C. Bradley¹, (1)Medical University of South Carolina, Charleston, SC, (2)Department of Pediatrics, Medical University of South Carolina, Charleston, SC

Background: Children with neurodevelopmental disorders (ND), such as autism spectrum disorder (ASD) and ADHD, are more likely to present with elevated disruptive behaviors (e.g., oppositionality, aggression, impulsivity). Parent Child Interaction Therapy (PCIT) is a parent training program that has shown efficacy for children with ND in reducing disruptive behaviors (Bagner et al., 2023). Telehealth delivery of PCIT increases access for families who experience systematic barriers and is deemed comparable in efficacy (Comer et al., 2017). Preliminary work has documented the robust impact of PCIT in achieving comparable post-treatment outcomes for children across diagnostic profiles and with a range of sociodemographic backgrounds when treatment is completed. However, little is known regarding the impact of families' sociodemographic factors and clinical presentations on treatment completion rates and engagement in PCIT.

Objectives: The purpose of this study is to examine the associations between a) sociodemographic factors and b) clinical presentations on treatment completion and engagement.

Methods: This study was conducted with 68 parent-child dyads (Child: $M_{age} = 4.95$, $SD = 1.19$) from underserved backgrounds who completed a time-limited version of PCIT via telehealth. Children had the following diagnoses: ASD (14.7%), ADHD (55.9%), ODD (20.6%), Global Developmental Delay (13.2%), Language Delay (45.6%), and Motor Delay (17.6%), and were predominantly male ($n=51$, 75%). All children had a receptive language age equivalent of at least 2.0 years. Treatment completion was classified as completion (10 sessions) or drop-out. Treatment engagement was measured via the amount of homework completed throughout the course of therapy. Analyses included logistic and linear regressions.

Results: 75% of this sample successfully completed treatment. Child autism diagnosis did not predict treatment engagement or completion. Child diagnosis of ADHD and parent diagnosis of depression were significant positive predictors of treatment completion (See Table 1). Children with ADHD were approximately 4 times more likely to complete therapy compared to children without ADHD ($p = .02$). Parents with a self-reported depressive disorder were approximately 12 times more likely to complete therapy compared to parents without a depressive disorder ($p = .02$). Child language level were also a predictor of treatment completion, with children with higher language abilities being more likely to complete therapy ($OR = 1.09$, $p < .01$). Higher child age ($\beta = -.35$, $p = .040$) was associated with lower treatment engagement (homework completion).

While limited in range, parent age, education, and income were not predictors of treatment engagement or completion (Tables 1 & 2).

Conclusions: PCIT is a highly effective treatment for disruptive behaviors in children with ND, but not all families are successful in engaging in and completing treatment. This study highlights the importance of considering families' clinical presentation (i.e., age, diagnosis, language level) and sociodemographic factors in promoting treatment engagement and completion. Results of this studies also underscore the suitability of telehealth when engaging with parents with history of depression. Future research should consider these variable in matching families to treatment modality such as virtual vs. in person treatment.

430.184 Understanding and Addressing Eating Problems in Autistic Children: A Case-Based Approach to Cause-Specific Interventions

D. Chettri¹ and V. Kanodia², (1)HUMANITIES AND SOCIAL SCIENCE, IIT Kanpur, KANPUR, UTTAR PRADESH, India, (2)Department of Psychology, Pushpa Khanna Memorial Centre, Kanpur, Uttar Pradesh, India

Understanding and Addressing Eating Problems in Autistic Children: A Case-Based Approach to Cause-Specific Interventions

Background: Eating problems at times can be the biggest challenge that we as therapists need to combat while teaching people to cope with autism. Nutrition is an important step in managing ASD specifically and this makes it essential for us to identify the causes of eating problems in children with autism and provide them with the appropriate interventions. Finding the root cause of the eating problem is usually the easiest way to manage it. In India, we seem to have a lack of awareness in regard to nutrition's role in managing Asd.

Objectives: We aim to discuss the different causes of eating problems in autistic children and how to identify the cause(s) specific to each child. We will elaborate through two cases with which we have been working. These cases also illustrate how finding the cause of these problems is most often the way to manage them.

Methods: Case Study1: The child is 4 years 9 month old with moderate autism. On the Indian Scale For Autism Assessment, he presented a score of 120. He was a premature kid with speech regression. Developmental Screening Test and Vineland Social Maturity Scale test, he presented with a score below 60 on both. On assessing his sensory profile, he got a score of 45/50 for his oral sensory score for sensitivity which is very high.

Case Study 2: The child is a four year 2-month-old with moderate autism. On the Indian Scale For Autism Assessment, he presented with moderate Autism. On conducting the Developmental Screening Test and Vineland Social Maturity Scale test, he presented with a score below 60 on both. He is also lactose intolerant. When presented to us, he would eat only certain foods based on his mood and has primarily consumed isom ilk since April 2021.

Results: We found exceptional improvement in the eating problems which our patients faced once we found out their cause.

Case Study 1: As of August 2024, the child has started drinking milk from a glass and selectively eating foods such as Dal (Lentil Soup), Rice, Milkshakes, Idli, Sambar, and Oats with Yogurt.

Case Study 2: As of January 2024, the child has started eating a variety of foods including Roti (flatbread), 2 types of Paratha, Makhana, Bread and Cornflakes at times depending on his mood. He has also started consuming Buffalo milk and has been completely off milk since December 2023.

Conclusions: In India, it is more common to try to force-feed children who do not like to eat food. Often, parents relate such food avoidance to picky eating. This, however, is not the case with a lot of the children on the autism spectrum. Hence, we have found it essential to reach the root cause of the problem to be able to target it.

430.185 An Exploratory Study on Clinical Outcomes of Low-Intensity Early Start Denver Model for Young Children with Autism Spectrum Disorder in Southern Taiwan

S. C. Huang¹ and T. L. Lin², (1)Behavioral Medicine, National Cheng Kung University, Tainan, Taiwan, Taiwan, (2)Institute of Behavioral Medicine, National Cheng Kung University, Tainan City, Taiwan

Background: Young children with autism spectrum disorder (ASD) begin to exhibit communication and social difficulties from the early age, which subsequently affect their cognitive, social-emotional, and language development. Among the various early intervention models for ASD supported by empirical research, the Early Start Denver Model (ESDM) has gained attention for its integration of traditional applied behavioral analysis and developmental approaches, as well as its simultaneous intervention across multiple important developmental domains. Previous studies have established that long-term, moderate to high-intensity, ESDM intervention can positively impact the clinical outcomes of young children with ASD. However, implementing such programs in regions with limited access to early intervention services remains challenging.

Objectives: Given the severe shortage of resources in southern Taiwan, this study aimed to significantly reduce the intensity of ESDM intervention and used a single-subject design to evaluate the efficacy of the lower-intensity ESDM intervention for young children with ASD in southern Taiwan.

Methods: A single-subject experimental design was conducted with multiple probe designs across individuals. Three children aged 26 to 40 months and diagnosed with ASD participated in the low-intensity ESDM intervention, receiving 2 hours of intervention weekly for 24 weeks. Video recordings of child-therapist interactions during the baseline, intervention, and follow-up phases were analyzed using visual analysis to assess the impact on imitation, verbal expression, and social engagement. Various measurements were administered pre- and post-intervention, encompassing joint attention, play, communication, and language ability as proximal outcome indicators, with assessments such as the Taiwan version of Screening Tools for Autism in Two-Year-Olds (T-STAT) and the Mandarin-Chinese Communicative Development Inventory-Taiwan (MCDI-T). The distal outcome indicators entailed cognitive ability, symptom severity, adaptive behaviors, and behavioral problems, with assessments including the Mullen Scales of Early Learning (MSEL), the Autism Diagnostic Observation Schedule-Second Edition (ADOS-2), the Adaptive Behavior Assessment System-Second Edition (ABAS-II), and the Child Behavior Checklist for Ages 1½-5 (CBCL).

Results: Visual analysis of the recorded sessions indicated that the low-intensity ESDM intervention had a range of effects - from minimal to substantial - on imitation, verbal expression, and social engagement performances of three children. The overall effect on verbal expression was the most significant, followed by social engagement, and then imitation. Furthermore, even with only 2 hours of intervention per week, all children demonstrated improvements in nearly all proximal outcome indicators. In terms of distal outcome indicators, two out of the three children's developmental quotients improved in the MSEL (from 44 to 58, 76 to 90), while the other two children showed a decrease in symptom severity in the ADOS-2 (from 11 to 5, 23 to 18). However, there was little to no progress in adaptive behaviors and behavioral problems.

Conclusions: The findings demonstrated that the low-intensity ESDM intervention enhanced various developmental abilities in young children with ASD in southern Taiwan, especially in verbal expression. Future research may include larger sample sizes and utilize a control-group pretest-posttest design to further validate the efficacy of the low-intensity ESDM interventions for children with ASD.

Keywords: autism spectrum disorder, Early Start Denver Model, low intensity

430.186 Coaches' Perspectives on the Barriers and Facilitators to the Social ABCs Caregiver-Mediated Intervention for Toddlers with Autism

E. M. Dowds¹ and J. A. Brian², (1)Autism Research Centre, Holland Bloorview Kids Rehabilitation Hospital-Autism Research Centre, Burlington, ON, Canada, (2)Holland Bloorview Kids Rehab Hospital, Toronto, ON, Canada

Background: Research supports the involvement of caregivers in intervention programs for young children (i.e., caregiver-mediated early intervention - CMEI). CMEIs capitalize on natural caregiver-child interactions and increase the 'dosage' of treatment while also providing support to families (Zwaigenbaum et al., 2015). CMEIs have a substantial evidence-base (e.g., Frost et al., 2021). Among these, the Social ABCs stands as a well-established CMEI, designed for toddlers aged 12 to 36 months with confirmed or suspected autism (Brian et al., 2016; 2017). Nevertheless, certain families encounter challenges in accessing, engaging with, and deriving benefits from the program. While much is known about families' lived experiences, the perspectives of the clinicians delivering the programs are scarcely reported. This perspective has potential to shed light on families who do not complete the program, a key perspective that is usually missed.

Objectives: This study aimed to explore the barriers and facilitators that families experience from the perspective of the coaches delivering the program.

Methods: A mixed-methods exploratory sequential design was employed (Cresswell & Plano Clark, 2011) and using Braun and Clark's six-step reflexive thematic analysis (2006), the study examined barriers and facilitators from the perspectives of 30 coaches. Data were collected via a focus group (n = 6), followed by a survey (n = 30). We explored correlations between coach characteristics (e.g., education, training level) and top-rated survey items (corrected p-value of .0125 was used).

Results: Three key themes were established: (1) **Prioritization of the Social ABCs within family life**, (2) **Relationships among families, coaches, and systems** and (3) **Parental learning, understanding, and goal alignment**. Across themes, intake was a recurrent topic in the focus group discussion:

"[A] big facilitator is having the right questions asked at the intake process, it can really prepare the caregiver for what is to come".

The results from the survey bolster this finding, with coaches strongly endorsing the key role of intake across three organizing categories (access, engagement, and outcomes). Using a 5-point Likert scale, coaches strongly endorsed scheduling options and visit times as playing a key role in both access and outcomes (M=4.10 and 4.33), while and caregivers' upfront understanding of the Social ABCs expectations was strongly endorsed for its role in engagement (M= 4.37).

Finally, the role of coach level factors was explored, revealing that higher education levels of coaches were associated with greater importance attributed to caregiver involvement ($\rho = .47$, $p = .009$); viewing caregivers as decision-makers.

Conclusions: Findings reveal parsimony between quantitative associations (e.g., between coaches' educational level and their perceived importance of *parents as decision-makers*) and qualitative findings about the importance of the coach-parent relationship. A core issue that was woven throughout the coaches' responses was the way in which intake processes can scaffold (or prevent) successful access to and participation in care. In considering practical solutions, bolstering intake processes may be the most immediately actionable strategy to reduce barriers and facilitate positive outcomes. Future research into improving intake processes and studying their impact is a key area for practical application.

Poster Session

431 - Molecular and Cellular Biology I

May 2nd, 2025, 6:00 PM - 7:00 PM - Hall 4A

431.187 A Critical Period Sensitive to Hoxb8 Microglia in Mouse Brain

N. Nagarajan¹ and M. Capecchi², (1)Genetics, Utah School of Medicine, Salt Lake City, UT, (2)Human Genetics, University of Utah, Salt Lake City, KY

Background: *Hoxb8* mutant mice show compulsive behavior similar to the repetitive behaviors in the Autism spectrum disorder in comorbidity with trichotillomania, a human obsessive-compulsive-spectrum disorder. The only *Hoxb8* lineage-labeled cells in the brains of mice are microglia, suggesting that defective *Hoxb8* microglia caused the disorder. We have shown the presence of two microglia subpopulations: canonical, non-*Hoxb8* microglia and *Hoxb8* microglia. Unlike non-*Hoxb8* microglia, *Hoxb8* microglia progenitors appear to be generated during the second wave of yolk sac hematopoiesis, then detected in the aorto-gonad-mesonephros (AGM) and fetal liver, where they are greatly expanded, prior to infiltrating the E12.5 brain.

Objectives: To investigate the effect of sensory deprivation on *Hoxb8* microglia function

Methods: Examination of the canonical, non-*Hoxb8* microglia and *Hoxb8* microglia

Results: Using whisker trimming based sensory deprivation model, our result suggests that the sensory deprivation during critical period reduces *Hoxb8* but not non-*Hoxb8* microglia density in contralateral hemisphere to the deprived hemisphere without affecting the non-*Hoxb8* microglia population. The effect is enhanced significantly in *Hoxb8* mutants. Given the crucial role of *Hoxb8* microglia in synaptic pruning, our current data suggests that *Hoxb8* microglia are highly sensitive to synapse density during critical period. Furthermore, we demonstrate the unique capabilities of *Hoxb8* microglia in synaptic pruning compared to non-*Hoxb8* microglia.

Conclusions: Non-*Hoxb8* microglia significantly outnumber *Hoxb8* microglia, but they cannot compensate for the loss of *Hoxb8* function in *Hoxb8* microglia, suggesting further crucial differences between the two subpopulations during critical period, synaptic development, synaptic pruning and postnatal synaptic maturation.

431.188 Aberrant Hippo Signaling Due to TAOK1 Mutation Leads to Brain Organoid Overgrowth

S. John¹, D. Marciniak², S. E. Ong¹ and S. Yadav¹, (1)Pharmacology, University of Washington, Seattle, WA, (2)University of Washington, Seattle, WA

Background: Mutations in the kinase encoding gene TAOK1 (Thousand and one amino acid kinase 1) cause a syndromic neurodevelopmental disorder (NDD) with developmental delay, macrocephaly and autism. Despite its association with brain development deficit, the precise function of TAOK1 in brain development and how its dysfunction leads to neuropathology remains unknown. To model TAOK1 dysfunction during early brain development, we generated human iPSC lines harboring a TAOK1 NDD and macrocephaly associated mutation, S111F that abolishes a key residue required for catalytic activity.

Objectives: We hypothesize that the kinase dead TAOK1 mutations contribute to pathogenesis of NDDs by affecting proliferation of neural progenitor cells (NPCs). In our study, we aim to investigate how TAOK1 dysfunction contributes to neurodevelopmental disorder using human iPSC derived NPCs and dorsal forebrain cortical organoids. Further, we use comparative phosphoproteomic analysis of control and TAOK1 mutants NPCs to identify pathways dysregulated in the mutant cells and to determine physiological neuronal substrates of TAOK1.

Methods: We generated human WTC11 iPSC lines harboring heterozygous (TAOK1S111F/+) and homozygous S111F mutation (TAOK1S111F/S111F) along with their isogenic control lines. Two distinct clones of each genotype were differentiated into dorsal forebrain neural progenitor cells (PAX6, NESTIN +ive) via two independent differentiations. The NPCs were immunostained with proliferation markers Ki-67 and Cyclin A2 to quantify the number of proliferating cells in each genotype. Cell cycle analyses of control and mutant NPCs were conducted using propidium iodide staining and flowcytometry to quantify the proportion of cells in various cell cycle stages. In addition, dorsal forebrain cortical organoids were derived from these iPSC lines and cryosectioned at DIV 70/90. The cryosections were stained for different layers of the cortex (PAX6, TBR2, SATB2, CTIP2, GFAP) and proliferation markers. Finally, to elucidate mechanisms that underlie increased proliferation in TAOK1 mutant organoids and macrocephaly in TAOK1 syndrome patients, we performed comparative phosphoproteomic analysis of control and TAOK1 mutants NPCs using five replicates for each condition.

Results: Immuno-staining with proliferation markers and flowcytometric analysis revealed a significant increase in the number of proliferative cells in the homozygous S111F mutant NPCs compared to the controls. In addition, cortical organoids generated from TAOK1 mutant iPSC lines showed a dramatically expanded proliferative zone (Pax6+ive) with higher numbers of actively dividing progenitors (CyclinA2 and Ki67 +ive) compared to isogenic control organoids at both DIV70 and 90. Pathway analyses and phosphopeptide analyses revealed differential phosphorylation of YAP/TAZ proteins in TAOK1 mutant NPCs indicating aberrant Hippo signaling. Immunocytochemistry and western blot revealed an increase in the total YAP protein concentration and nuclear enrichment of YAP/TAZ proteins in the mutant NPCs. Additionally, an increase in the expression of the YAP-TEAD target genes including CTGF, CYR61 and ANKRD in the mutant NPCs was confirmed using qPCR.

Conclusions: In summary, this study employs iPSC derived dorsal forebrain NPCs and cortical brain organoids, mass spectrometry and high-resolution imaging to unmask the effects of NDD associated mutants of TAOK1 on neuronal development and function. Our findings reveal aberrant Hippo signaling as a likely and druggable driver of the TAOK1 related neurodevelopmental disorders.

431.189 Altered Synaptic Density and Gene Expression in the Amygdala in Autism Spectrum Disorder

M. Duong¹, E. L. Carlson², H. C. Zakharenkov¹, E. C. Haley², A. Omanska¹, K. L. Hanson³, K. D. Murray⁴ and C. M. Schumann⁵, (1)California National Primate Research Center, Davis, CA, (2)Psychiatry and Behavioral Sciences, University of California Davis School of Medicine, Sacramento, CA, (3)Psychiatry and Behavioral Sciences, UC Davis MIND Institute, Sacramento, CA, (4)Physiology and Membrane Biology, University of California Davis, Davis, CA, (5)UC Davis MIND Institute, Sacramento, CA

Background:

Autism Spectrum Disorder (ASD) is a neurodevelopmental disorder characterized by changes in social interaction and communication. Emerging evidence suggests that an imbalance between excitatory (E) and inhibitory (I) neurotransmission may underlie many of the core symptoms of ASD. The amygdala, a region critical for processing emotions and social behavior, has been implicated in ASD. Studies suggest that altered excitatory/inhibitory (E/I) balance within the amygdala may alter neurotransmission and connectivity within this region. While studies have documented synaptic abnormalities, the spatial relationship between synaptic density and gene expression at the cellular level remains largely unexplored.

Objectives:

This study aims to explore synaptic density and gene expression related to neurotransmission and E/I signaling in the amygdala of individuals with ASD. Specifically, we aim to assess whether synaptic density changes are mirrored by altered gene expression of excitatory and inhibitory synaptic components.

Methods:

To evaluate synaptic density, we identified synapses by staining tissue sections from the mid rostrocaudal amygdala using fluorescent immunolabeling of the proteins GAD65/67, markers of inhibitory GABAergic synapses, and the protein PSD95, a marker of excitatory glutamatergic synapses, in lateral, basal, and accessory basal nuclei. Synapses were quantified using the Synapse Counter module in Fiji. To evaluate gene expression, we performed a multiplex gene expression assay (QuantiGene Plex) from 2mm biopsy punches of fresh frozen tissue of the lateral, basal, and paralamina amygdala. To spatially map gene expression, we used RNAscope (HiPlex v2) to visualize gene expression associated with inhibitory and excitatory neurotransmission in the lateral, basal, and accessory basal nuclei of the amygdala.

Results:

Our analysis revealed an increase in inhibitory synaptic density measured by GAD65/67 immunolabeling in the lateral, basal, and accessory basal nuclei of the amygdala in ASD cases compared to neurotypical (NT) cases while no significant differences were found in excitatory synaptic density measured by PSD95 immunolabeling. At the regional level, QuantiGene analysis showed no significant differences in the expression of *GAD1/GAD2* in the lateral and basal nuclei. However, expression of genes associated with excitatory neurotransmission, (*SLC17A7* and *DLG4*) showed significantly increased expression specifically in the lateral nucleus.

Conclusions:

Our results suggest that lateral amygdala in ASD is characterized by an increase in inhibitory synapse density, measured through protein marker labeling. No corresponding changes in gene expression for these same markers was observed. In contrast, no changes in excitatory synapse density, measured by protein markers, was observed. However, genes associated with these markers (*SLC17A7* and *DLG4*) were increased in expression. These results point toward a potential compensatory mechanism in ASD, wherein altered excitatory gene expression in the absence of changes in excitatory synaptic density may counterbalance heightened inhibitory synapse density. RNAscope analysis provides spatial context to these findings, offering further insight into amygdala synaptic architecture in ASD. This study advances our understanding of the molecular mechanisms underlying synaptic dysregulation in ASD and may point towards novel therapeutic targets for restoring E/I balance.

431.190 Single-Cell Investigation of Telencephalic Development in Mouse Models with Chd8 Haploinsufficiency

N. Seban¹, C. P. Canales², S. Lozano¹, K. Cichewicz¹, D. Rahbarian¹, M. Corea¹, E. Fenton³, N. Chu³, P. Levitt⁴, M. Tabbaa¹ and A. S. Nord², (1)UC Davis Center for Neuroscience, Davis, CA, (2)Department of Psychiatry and Behavioral Sciences, UC Davis Center for Neuroscience, Davis, CA, (3)Center for Neuroscience, University of California Davis, Davis, CA, (4)Children's Hospital Los Angeles, Los Angeles, CA

Background:

Mutations in the chromatin-remodeling factor CHD8 are closely linked to autism spectrum disorder (ASD). Our previous research, along with that of others, indicates that Chd8 haploinsufficient mice exhibit genomic, neuroanatomical, and behavioral abnormalities relevant to ASD. However, reported neurodevelopmental phenotypes have varied across different laboratories, with most studies focusing primarily on the development of the pallium/cortex.

Objectives:

This study aims to elucidate the conserved disruptions in forebrain development caused by Chd8 haploinsufficiency using two distinct loss-of-function mouse models. We seek to identify specific cell type alterations and associated transcriptional and epigenetic changes during early neurogenesis, as well as to assess the variability of these effects across different genetic backgrounds. By employing single-cell multiomic approaches, we aim to provide a comprehensive understanding of the molecular pathology linked to CHD8 mutations in the context of autism spectrum disorder.

Methods:

In this study, we address this variability by employing two distinct loss-of-function mouse models of Chd8 haploinsufficiency to identify conserved disruptions in forebrain development associated with reduced Chd8 dosage. We analyzed both pallial and subpallial cell populations at embryonic (E14.5) and early postnatal stages (P2) with single-cell multiomic approaches. We examined cell-type specific differences in abundance, rate of development, differential expression, and differential accessibility in our dataset. Additionally, we examined bulk RNA-seq transcriptional profiles in multiple genetic backgrounds of one Chd8 mouse model to assess broader variability during neurogenesis.

Results:

Our multiomic single-cell findings reveal small to moderate changes in the proportions of pallial progenitors and early-born neurons at E14.5, transitioning to unexpected decreases in glutamatergic neuron proportions and increases in astroglial populations by P2, with a more pronounced effect on subpallial neurogenesis. Our dataset also identified perturbed transcriptional and epigenetic programs in distinct telencephalic lineages and cell types at E14.5 and P2. E14.5 bulk RNA-seq data demonstrated considerable variation across mouse genetic backgrounds, particularly concerning proliferation and neuronal maturation. Incorporation of multiple models and genetic backgrounds allowed us to identify conserved molecular pathology associated with Chd8 haploinsufficiency during early murine development.

Conclusions:

In conclusion, our approach enabled the identification of cell type-specific developmental programs, both shared and background-specific, that are vulnerable to Chd8 haploinsufficiency during mouse telencephalic neurogenesis and forebrain development.

431.191 Computational Electrophysiological Modeling Identifies Voltage-Gated Potassium Ion Channel Modulators for Autism Therapy

C. Mahapatra, Biomedical Engineering, Indian Institute of Technology Bombay, Mumbai, Maharashtra, India

Background: Autism Spectrum Disorder (ASD) is a neurodevelopmental condition that typically becomes apparent in children by the age of three. It encompasses a variety of symptoms, including challenges in social interaction, communication, cognitive functioning, and repetitive behaviors. The underlying causes of ASD are believed to involve a combination of genetic and environmental factors. Abnormal electrical activity in the brain, often linked to genetic mutations, plays a significant role in the development of ASD. Dysfunction of voltage-gated potassium (Kv) channels can lead to hyperexcitability and neurological disorders such as epilepsy, underscoring their importance in regulating electrical activity in the brain.

Objectives: Computational electrophysiology serves as a valuable alternative to traditional experimental methods by simulating the electrical behavior of ion channels at a molecular level, thereby aiding in the understanding of how mutations impact channel function. This study aims to evaluate how Kv ion channels affect action potential generation in dopamine neurons and to explore potential new drug treatments for ASD.

Methods: We have developed a detailed biophysical in silico model to replicate the electrophysiological behavior of a single isolated mouse dopamine neuron. Our model integrates various ionic currents, including L-type and T-type calcium (Ca^{2+}) currents (I_{CaL} and I_{CaT}), sodium-calcium exchange currents (I_{NaCa}), fast and background sodium (Na^+) currents (I_{Na} and I_{bNa}), sustained inward current (I_{st}), ATP-dependent potassium (K^+) current (I_{KATP}), and multiple components of the delayed rectifying potassium current (I_{Kur} , I_{Kr} , I_{Ks}), among others. These neurons are activated by neurotransmitters such as AMPA and N-methyl-D-aspartate (NMDA) receptors, or by direct electrical stimuli.

Results: The steady-state activation curve, current-voltage curve, and currents under the voltage-clamp protocol are generated for the voltage-gated potassium channel currents (I_{Kv}) under control and mutation conditions. Active currents were induced by applying a series of +10 mV voltage steps ranging from -70 mV to 70 mV, each lasting 50 ms, starting from a holding potential of -100 mV. The Kv model is integrated into a single-compartment model of mouse dopamine neurons to simulate action potential generation. To simulate the Kv mutation, the Kv ion channel's maximum conductance is set to zero. The AMPA conductance and NMDA permeability are maintained at their average levels, while the maximum conductances of the other ion channels remain unchanged throughout the simulation. Figure 1 (A) and (B) display the evoked action potential firing patterns of the mouse dopamine neuron model under normal conditions and with a Kv channel mutation. The results suggest that gating pore currents caused by ASD-related Kv ion channel mutations can significantly disrupt neuronal action potential firing, particularly leading to hyperexcitability.

Conclusions: Autism Spectrum Disorder has significant social, medical, and economic impacts worldwide. These complex challenges emphasize the urgent need for enhanced fundamental research to develop new treatments for individuals with ASD. Studying membrane electrical activities and ion channel currents is essential for understanding the disorder's pathophysiology. Findings from our model indicate that targeting specific potassium channel agonists may improve treatment outcomes for autism.

431.192 To Explore the Association of Heavy Metals and Essential Micronutrients As Environmental Markers in Children with Autism Spectrum Disorder: A Cross Sectional Study.

S. Gulati¹, J. A. Qadri², S. Karmakar³, P. Sisodia⁴, S. Ojha⁵, G. Kamila⁵, S. Pandey⁶ and A. Shariff⁷, (1)Centre of Excellence and Advanced Research for Childhood Neurodevelopmental Disorders, Child Neurology Division, Department of Pediatrics, Ansari Nagar, New Delhi, India, (2)Anatomy, All India Institute of Medical Sciences, New Delhi, New Delhi, India, (3)Department of Biochemistry, AIIMS, New Delhi, New Delhi, Delhi, India, (4)Child Neurology Division, Department of Pediatrics, AIIMS, New Delhi, New Delhi, Delhi, India, (5)Centre of Excellence and Advanced Research for Childhood Neurodevelopmental Disorders, Child Neurology Division, Department of Pediatrics, All India Institute of Medical Sciences, New Delhi, New Delhi, India, (6)Department of Biostatistics, All India Institute of Medical Sciences, New Delhi, India, (7)All India Institute of Medical Sciences, New Delhi, New Delhi, India

Background:

Heavy metals have been suggested to play a role in the etiology of Autism Spectrum Disorder (ASD) through epigenetic mechanisms. Previous research has highlighted the potential link between heavy metal exposure and epigenetic rewiring in ASD. Further, DNA structural variations like CNV, insertions, and deletions also play a decisive role in disease susceptibility and outcome.

Objectives:

To analyze the levels of heavy metals and essential micronutrients in blood, urine, hair and nail of children with Autism Spectrum Disorder (ASD) and their comparison with control population. Genomic and Epigenomic alterations were also interrogated to establish the molecular link between metal toxicity and genomic changes contributing to disease phenotype.

Methods:

In this cross-sectional study, children aged 18 months to 18 years fulfilling Diagnostic and Statistical Manual of Mental Disorders 5th edition criteria for ASD were included. Those with a known micronutrient deficiency, on chelating agents, on exclusion diet or with chronic systemic diseases were excluded. Control group was identified as children with IQ>70 on Malins Intelligence Scale for Indian Children and absence of any behavioral problems. Twenty-one heavy metals and trace elements were assayed using Inductively Coupled Plasma Mass Spectrometry (ICP-MS) in blood, urine, hair and nail. Extraction and isolation of genomic DNA from the ASD samples, followed by bisulfite-mediated conversions, were undertaken to estimate DNA methylation. The modified DNA was then used for the Illumina promoter array. Paired extracted gDNA was used for whole genome SNP analysis to identify the chromosomal variants in ASD using the Illumina Infinium Global Screening Bead ChIP Array harboring 650K SNPs.

Results:

A total of 500 ASD and 100 control subjects were enrolled. Mean age was 5.75 ± 3.19 and 7.31 ± 4.23 years respectively. Analysis of blood (500-ASD, 60-controls) and Urine (250-ASD, 30-controls) for heavy metals was done. Rest of the data is under process and results will be analyzed shortly. The following heavy metals were found significantly in higher levels in blood of ASD vs Control group: **Lead** [49(23.4-75.7) vs 26(11-41) mcg/dl, $P<0.001$], **Arsenic** [2.5(1-4.7) vs 1.5(0.6-1.8) mcg/L, $P<0.001$], **Cadmium** [0.9(0.5-2.2) vs 0.8(0.3-1.4) mcg/L, $P=0.04$], **Manganese** [41.3(13.5-97.7) vs 16(6.9-42.3) mcg/L, $P<0.001$] and **Chromium** [45 (17-92) vs 10 (6-16) mcg/L, $P<0.001$]. **Lead** [$P=0.003$], **Arsenic** [$P<0.001$], **Cadmium** [$P<0.001$] and **Manganese** [$P=0.03$] were also found significantly in different proportions in urine in comparison to controls.

A total 19 ASD subjects underwent methylation study. Results showed 289 hypo and 1132 hyper-methylated promoter CpG in the ASD group. CETNP4, HMGA1, and RPAIN were the most hypermethylation promoters prevalent in ASD. ALOXE3, OXCT1, and GLUD1 were the most hypomethylated promoters. Results also showed significant associations of several SNPs in ASD patients. TAF1 gene (rs9820086) belonging to the Tumour Necrosis Factor Alpha-Induced Protein was significantly associated. It regulates various biological processes, including inflammation, immune response, and neuronal function, thereby indicating a link between heavy metal ions, inflammation, aberrant promoter methylation, and altered gene expression.

Conclusions:

Levels of Lead, Arsenic, Cadmium and Manganese were significantly high in blood of ASD subjects in comparison to controls. Aberrant methylation and specific genomic variants play a role in contributing to ASD.

431.193 Deciphering the Role of High Risk Autism Kinase BRSK2 during Neurodevelopment and Disease.

S. Paul¹ and S. Yadav², (1)Department of Pharmacology, University of Washington, Seattle, WA, (2)Pharmacology, University of Washington, Seattle, WA

Background: Neuronal health heavily relies on protein kinase signaling network which orchestrate the transitions between different stages of neurodevelopment. Aberrant kinase signaling leads to neurodevelopmental disorders, intellectual disability (ID) and autism spectrum disorders (ASD). Brain Selective Kinase 2 (BRSK2) is one such serine/threonine kinase strongly associated with autism. To date 35 de novo mutations have been identified in different regions of BRSK2 genes that cause autism. However, the effect of these mutations remains to be explored. Previous studies in animal models have provided indirect evidence for its functions in cortical development and neuronal polarity. However, BRSK2 remains as a relatively understudied kinase in neuropathogenesis.

Objectives: The goal of this project is to determine the mechanisms through which BRSK2 mediates neurodevelopment and how its ASD-associated mutations contribute to neurodevelopmental disorders.

Methods: To study the effects of ASD mutations on the function of BRSK2, I have generated its expression constructs harboring autism associated mutations through site directed mutagenesis. A combination of in vitro kinase assay and protein structure analysis have been used to check the alteration in catalytic functions of BRSK2 with the mutations. To visualize the localization of BRSK2 and identify the protein domain necessary for its trafficking in the cells, I have performed domain dissection followed by live cell imaging. Currently I am using a chemical-genetics approach to identify the neuronal substrates of BRSK2 during development using IP-mass spectrometry.

Results: My study discovered that all the autism associated point mutations R65Q, E66K, A163V, A158T, G212E, and R258C in the kinase domain of BRSK2 are catalytically deficient. Most of these missense mutations are found to be distorting the conformation of the kinase domain resulting in kinase dead phenotype. Live cell imaging showed that BRSK2 shuttles between a cytoplasmic state and association with the ER under physiological condition. However, depletion of ER Ca^{2+} induces a robust plasma membrane association where BRSK2 is dramatically localized at the ER-PM contact site. Further, domain dissection confirmed that the kinase associated domain has a plasma membrane tether site outlining a critical function of its regulatory domain which modulates signaling pathways in a calcium dependent manner. To discover the neuronal substrates of BRSK2, I have identified that mutating the gatekeeper residue leucine 95 to a smaller amino acid glycine can efficiently utilize bulky ATP analog benzyl ATPyS. This will allow me to covalently capture putative BRSK2 substrates from brain lysate and identify them using mass spectrometry.

Conclusions: With a combination of biochemical, chemical-genetics and molecular biology approaches, this study identifies that loss of catalytic function of BRSK2 due to missense mutations in its kinase domain is the underlying cause for autism in patients. BRSK2 can act as plasma membrane-ER contact site protein with the help of its regulatory domain in a calcium dependent manner. Further, generating CRISPR/Cas9 mediated BRSK2 KO in human induced pluripotent stem cells (iPSC) followed by neuronal differentiation will allow me to investigate the function of BRSK2 during early human neurodevelopment.

431.194 Elucidating the Molecular Function of the Autism-Associated Kinase NUAK1 in Neurodevelopment and Disease

J. Sejd, D. Marciniak, S. E. Ong and S. Yadav, Pharmacology, University of Washington, Seattle, WA

Background: Dysfunction in kinase signaling is associated with several neurodevelopmental disorders, including autism spectrum disorder (ASD). Three *de novo* mutations in *NUAK1*, which encodes the serine-threonine AMPK-related *Nua* kinase 1 (NUAK1), have been associated with ASD. Heterozygous *NUAK1*^{+/−} mice exhibit ASD-like behaviors, including cognitive impairment and decreased social novelty and sensorimotor gating. NUAK1 is highly expressed in the developing brain, where it regulates axon growth by modulating mitochondrial function. The function of NUAK1 in neurodevelopment depends on its catalytic activity, with pharmacological inhibition of NUAK1 kinase activity resulting in defective axonal and dendritic development. Despite the disease association and developmental role of NUAK1, the direct phosphorylation substrates of NUAK1 are unknown, limiting our understanding of how NUAK1 signaling pathways regulate neuronal development.

Objectives: We hypothesize that NUAK1 regulates neuronal development through phosphorylation of key substrates that mediate axonal and/or dendritic development, and perturbation in this pathway contributes to pathogenesis of ASD. In our study we aim to identify phosphorylation substrates of NUAK1 in the brain, and elucidate how they modulate neuronal development. Further, we aimed to test how ASD-associated *NUAK1* mutations impact its molecular function in neurodevelopment.

Methods: To assay the impact of ASD mutations on the molecular function of NUAK1, I have used *in vitro* kinase assays and confocal imaging of HEK293T and cultured primary rat cortical neurons. To identify direct substrates of NUAK1, I have taken a chemical-genetic approach by mutating the gatekeeper residue of NUAK1 to allow the kinase to utilize bulky, N6-substituted ATPyS analogs. This analog sensitive (AS) NUAK1 can preferentially utilize this bulky ATPyS to specifically thiophosphorylate its substrates in mouse brain lysate. These labeled substrates can then be identified by Western blotting or unbiased mass spectrometry.

Results: I discovered that ASD-associated mutations in NUAK1 differentially affect either its kinase activity or localization, with one mutation, Q433*, causing the protein to be mislocalized to the nucleus even in post-mitotic neurons. Future neuronal studies will elucidate the impact of these mutations on neuronal development. To identify the substrates of NUAK1, I combinatorially screened AS NUAK1 mutants with bulky ATPyS analogs to optimize labeling in mouse brain lysate. Using this optimized system followed by LC/MS, I identified 32 novel, high-confidence substrates of NUAK1. Consistent with published functions of NUAK1, these putative substrates have roles in regulation of splicing, cytoskeletal organization, and neurodevelopment. I have experimentally confirmed two putative substrates, both of which have established roles in maturation of dendritic spines and association with ASD.

Conclusions: In this work, I utilized a multifaceted strategy to interrogate the molecular function of the understudied ASD-associated kinase NUAK1 during neuronal development and define the functional consequences of disease mutations in *NUAK1*. Our work shows that autism-associated mutations in *NUAK1* affect either kinase activity or subcellular localization, suggesting diverse mechanisms by which these mutations contribute to ASD. Our work has facilitated identification of over 30 novel, disease-relevant substrates of NUAK1 in the brain, and validated candidate substrates have strong associations with dendritic development and ASD, underscoring the translational value of this work.

431.195 Elucidating the Role of Autism Risk Gene TAOK2 (thousand and one amino acid kinase 2) in Neuronal Lipid Homeostasis

S. Byeon¹, A. Li², D. Marciniak³, L. Xu², S. E. Ong² and S. Yadav¹, (1)Graduate Program in Neuroscience, University of Washington, Seattle, WA, (2)Medicinal Chemistry, University of Washington, Seattle, WA, (3)Pharmacology, University of Washington, Seattle, WA

Background: Thousand-and-one amino acid kinase 2 (TAOK2) is an autism-associated serine-threonine kinase important for several aspects of neurodevelopment, including axon elongation, dendritic growth, and spine formation. TAOK2 consists of two spliced isoforms, α and β , differing in their C-terminal regulatory domains. TAOK2 α localizes to the endoplasmic reticulum (ER) and mediates the tethering of the ER to the microtubule cytoskeleton. While TAOK2 α is enriched in specific subdomains of the ER, the identity and function of these distinct ER subdomains remain unknown. TAOK2 β on the other hand is a cytoplasmic protein.

Objectives: To understand isoform specific functions of TAOK2 in neurodevelopment using iPSC (induced pluripotent stem cell)-derived neural progenitor cells (NPCs) as a model system.

Methods: Further characterization of TAOK2 α at the ER contact sites was done through co-expression and confocal microscopy. A human TAOK2 KO iPSC line was generated and differentiated into NPCs along with a wild type (WT) line. Comparative quantitative lipidomics was performed to assess the changes in lipid profile between WT vs TAOK2 KO NPCs. Immunoprecipitation mass spectrometry (IP-MS) analysis was performed using the α isoform-specific TAOK2 antibody to better understand the molecular and cellular function of TAOK2 in neuronal lipid homeostasis.

Results: Using confocal microscopy, we found no significant enrichment of TAOK2 α in ER contact sites with mitochondria, lysosomes, and endosomes. However, TAOK2 α co-localized within ER-subdomains that were enriched in lipid synthesizing enzymes CEPT1 and PIS1. Through lipidomics, we discovered that the lipidome was significantly altered in TAOK2 KO neural progenitors. Moreover, through IP-MS, we have identified several proteins that regulate lipid synthesis and transfer as potential interactions of TAOK2 α .

Conclusions: Together, our results suggest that TAOK2 α localizes to specific subdomains within the ER with lipid-associated enzymes and may regulate lipid homeostasis during neurodevelopment. These studies suggest that dysregulation of lipid metabolism may contribute to the etiology of neurodevelopmental disorders.

431.196 Uncovering Cell Type-Specific Impacts of Chd8 Haploinsufficiency on the Transcriptional Landscape of Adult Mouse Cortex

S. Lozano¹, K. Cichewicz¹, N. Seban¹, E. Fenton¹, N. Chu¹, C. P. Canales¹ and A. S. Nord³, (1)UC Davis Center for Neuroscience, Davis, CA, (2)Center for Neuroscience, University of California Davis, Davis, CA, (3)Department of Psychiatry and Behavioral Sciences, UC Davis Center for Neuroscience, Davis, CA

Background:

Mutations in the CHD8 gene are strongly implicated in neurodevelopmental disorders, including autism and intellectual disability. Mice carrying a heterozygous *Chd8* mutation exhibit genomic, neuroanatomical, and behavioral abnormalities resembling key features of these disorders.

Objectives:

In this study, we aimed to uncover the cell-specific transcriptomic consequences of *Chd8* haploinsufficiency in the adult mouse cortex to better understand its persistent effects in the mature brain.

Methods:

Using single-nucleus RNA sequencing (snRNA-seq) on cortical tissue from both male and female *Chd8* mutant mice, we applied a pseudo-bulk differential expression approach to capture cell-type specific changes in gene expression. High-definition weighted gene correlation network analysis (hdWGCNA) was employed across individual cell populations to identify co-expressed gene modules associated with *Chd8* genotype. Synaptic and nuclear fractionation methods paired with bulk RNA-sequencing were also used to disentangle transcriptional changes between synapses and nuclei.

Results:

Our results revealed striking cell type-specific alterations in gene expression, with layer-specific excitatory neurons displaying a pronounced upregulation of genes linked to RNA processing, translation, and synaptic function. Glial and microglial cells were also notably affected. Additionally, discordant transcriptional signatures were identified between the synapse and nucleus.

Conclusions:

Chd8 haploinsufficiency triggers widespread, yet highly cell-specific, transcriptomic changes in the adult cortex, particularly within excitatory neurons. These findings provide deeper insights into *Chd8*'s role in the mature brain and its impact on transcriptional regulation across different cellular compartments.

431.197 Impact of Possible Interactions between Beta-Catenin, Axin2 and Zeb1 Signaling in the Cortex of BTBR Mouse Model of ASD

I. Tuncali¹, S. Noriega¹, A. Ikram¹, R. Jagadapillai², E. Gozal² and G. Barnes³, (1)Pediatrics, UL Autism Research Center, Louisville, KY, (2)Department of Pediatrics- Pediatric Research Institute, University of Louisville, Louisville, KY, (3)Pediatrics, Neurology, and Pediatric Research Institute, University of Louisville Autism Research Center, Louisville, KY

Background: Neurovascular development is a growing area of interest in autism spectrum disorder (ASD) research. Wnt signaling has been implicated in dysregulation of developing blood vessel and neuroprogenitor cell (NPC) communications. Canonical Wnt activation requires active beta-catenin nuclear translocation. Axin2, part of the beta-catenin degradation complex in the cytosol, targets it to degradation, preventing its nuclear translocation. Zeb1, a regulator of WNT signaling, has heretofore not been associated with either abnormal neurovascular development or synaptic pruning.

Objectives: Previous studies in Shank3 KO and VPA mice ASD models report that Wnt hyperactivation with increased glycolysis are sufficient to induce ASD behavior. These data showed increased Axin interaction with the glycolytic enzyme enolase 1 (Eno1) in these ASD mice but whether these occur in BTBR mice is unknown. Beta-catenin, Eno1, Axin2 and Zeb1 (a transcription factor regulating Wnt signaling) have all been identified as proteins of interest in ASD.

Methods:

We assessed beta-catenin, Axin2, Eno1 and Zeb1 expression, subcellular localization and protein interaction in 3 m/o male BTBR mice, an inbred ASD mouse model, and in controls C57Bl/6. Subcellular fractionation (SF) and western blot (WB) (n=3/group), Eno1 immunoprecipitation followed by Axin2 WB (n=3/group), were performed on homogenized cortex, developed using a Bio-Rad ChemiDoc imaging system, and quantified with ImageJ software. RT-qPCR (n=3/group) was performed using mRNA isolated from fresh frozen cortex samples. Data were analyzed using unpaired t-tests, with p<0.05 significance.

Results: WB of SF showed increased nuclear and decreased membrane and cytosol beta-catenin expression in BTBR, with increase nuclear Zeb1 and decreased cytosolic Axin2. These data suggest increased Wnt pathway activity. Less cytosolic Axin2 could target beta-catenin to degradation and increased nuclear Zeb1 may regulate beta-catenin transcriptional activity. Axin2 mRNA significantly increased in the BTBR cortex. Eno1 Immunoprecipitation found levels of Eno1/Axin2 association in BTBR cortex and C57Bl/6. This association, similar to that described in Shank3 KO and VPA models, may suggest that Eno1 binding to Axin2 protects beta-catenin from degradation, enhancing Wnt signaling in BTBR.

Conclusions:

The details of this mechanism are currently unknown. The described data suggest a mechanism by which Zeb1 regulation leads to enhanced WNT signaling. Further studies are needed to fully elucidate this signaling pathway, its impact in neural circuitry including synaptic pruning, and determine its developmental timeline and its cell- plus area-specific characteristics.

431.198 Investigating the Molecular Mechanism of Autism-Associated Kinase PAK1

S. Klucas, D. Marciniak, S. E. Ong and S. Yadav, Pharmacology, University of Washington, Seattle, WA

Background: P21-activated kinase 1 (PAK1) is a serine-threonine protein kinase with 12 mutations that are strongly associated with autism spectrum disorder (ASD) and intellectual disability. Patients with PAK1 ASD mutations clinically present with developmental delay, macrocephaly, and seizures. Highly expressed in the brain throughout neurodevelopment, PAK1 regulates cortical development by promoting proliferation and migration of neural progenitor cells through cytoskeletal alterations. PAK1 is catalytically autoinhibited through homodimerization in *trans*-conformation, and the binding of Rho-GTPases RAC1 or CDC42 causes PAK1 activation by dimer dissociation. It is hypothesized that the ASD-associated mutations cause overactivation of PAK1 through dimer destabilization and contributes to the autism phenotype through increased actin protrusions and increased neuronal migration. However, the mechanisms by which PAK1 overactivation gives rise to the autism phenotype is unknown, and direct phosphorylation substrates of PAK1 have not been identified.

Objectives: We hypothesize that PAK1 regulates neuronal development through phosphorylation of key substrates and that overactivation of these pathways contribute to the pathogenesis of autism. In our study, we tested how autism-associated mutations impact PAK1 activity and neurodevelopment. We have also identified the neuronal phosphorylation substrates of PAK1 through chemical genetics. We aim to validate the substrates of interest and investigate how they modulate neurodevelopment.

Methods: I have characterized how autism-associated mutations in PAK1 impact its kinase activity using *in vitro* biochemical assays. In addition, I used high resolution confocal microscopy to determine the impact of disease mutations in PAK1 on its subcellular localization. To identify the direct substrates of PAK1, I have applied a chemical genetic approach by mutating the gatekeeper residue of PAK1 to allow the kinase to utilize bulky N6-substituted ATPγS analogs. This analog sensitive kinase was able to utilize phenyl-ATPγS to specifically thiophosphorylate its substrates in mouse brain lysate that were then identified through unbiased mass spectrometry.

Results: Using *in vitro* kinase assays, I determined that the full-length wild type PAK1 exhibits a low level of kinase activity due to its autoinhibited state. In the full-length PAK1, I then generated selected autism-associated mutations and determined that the mutations increase PAK1 kinase activity compared to wild type, suggesting a trend of PAK1 overactivation. Despite this overactivation of PAK1 with autism-associated mutations, the substrates of PAK1 are not known. To determine the substrates, I used a chemical genetic approach to identify 98 putative PAK1 substrates in the mouse brain. Consistent with published PAK1 functions in actin organization and cellular migration, the putative substrates have roles in cytoskeletal rearrangement and neuronal development. Identified substrates will be tested for phosphorylation by recombinant PAK1 with *in vitro* kinase assays.

Conclusions: In this work, I have utilized a multifaceted strategy to investigate the molecular function of an understudied autism-associated kinase PAK1 and define the functional consequences of disease mutations. These studies have elucidated the trend of overactivation seen in PAK1 autism mutations, further underscoring the importance of identifying phosphorylation substrates of PAK1 in the brain. We will uncover the mechanisms by which PAK1 contributes to neurodevelopment, which will have translational value for neurodevelopmental disorders.

431.199 Investigating the Role of Tbc1 in Rare Neurological Disorder

M. Cornell¹, T. Williams², D. Marciniak¹, J. Mathieu³, S. E. Ong¹ and S. Yadav¹, (1)Pharmacology, University of Washington, Seattle, WA, (2)Biochemistry, University of Washington, SEATTLE, WA, (3)Institute for Stem Cell and Regenerative Medicine, University of Washington, Seattle, WA

Background: TBC domain containing kinase (TBCK) is an understudied protein with three domains: a pseudokinase; Tre-2, Bub2, and Cdc16; and rhodanese, and is highly expressed in the brain. Homozygous mutations in TBCK cause a rare neurodegenerative disorder in children, which clinically presents as syndrome infantile encephalopathy, brain atrophy, cerebellar hypoplasia, and muscle hypotonia. Two mutations in particular, R126Ter and R511H in the pseudokinase and TBC domains respectively, are commonly found among TBCK patients. The progression of the disease is characterized by a global regression in brain development, severe intellectual disability, and premature death in acute cases. The pathogenic mechanism underlying TBCK syndrome is unclear, but past studies show that TBCK patient neurons show abnormal lipofuscin deposits likely resulting from abnormal lysosomal activity.

Objectives: TBCK knockdown has also been shown to decrease mTOR activity and cytoplasmic translation. De novo homozygous and compound heterozygous mutations have been found throughout the protein. We have generated CRISPR-edited Human iPSCs with the aim of investigating how mutations in TBCK impact lysosomal storage and function, neurodevelopment, and the molecular mechanisms of the pseudokinase.

Methods: We used CRISPR site-directed mutagenesis to generate intellectual disability (ID) associated mutations in TBCK in iPSCs. An in vitro kinase assay was used to confirm the pseudokinase status of TBCK and its lack of ATP hydrolase activity. Mass Spectrometry was used to determine the interactors of TBCK, as well as the lysosomal contents of CRISPR-edited TBCK iPSC-derived Neural Progenitor Cells (NPCs).

Results: TBCK lacks critical residues in its kinase domain for catalytic activity. Through in vitro kinase assay, we found and confirmed the inability of TBCK to utilize ATP for phosphorylation. Through immunoprecipitation coupled with mass spectrometry, we pulled down known interactors like PPP1R21 alongside novel interactors.

Conclusions:

We have determined that TBCK is an inactive kinase, and it is known to be critical to proper lysosome function. These novel human TBCK mutant cell models will be utilized moving forward to determine morphological discrepancies in neurons post differentiation as well as analyze changes in lysosomal function and storage.

431.201 Microglia-Astrocyte Crosstalk during Activity-Dependent Synaptic Remodeling

T. Faust¹, Y. H. Lee¹, C. O'Connor¹, M. Boyle¹, V. Duran-Laforet¹, G. Gunner¹, A. Badimon², P. Ayata², A. Schaefer² and D. Schaefer¹, (1)University of Massachusetts Medical School, Worcester, MA, (2)Icahn School of Medicine at Mount Sinai, NY, New York City, NY

Background: Synapses remodel in response to changes in sensory experience and neural activity. Microglia and astrocytes both contribute to activity-dependent synapse remodeling by removing synapses from less active neurons. Yet, how microglia and astrocytes communicate to remodel synapses remains an open question. Previously, our lab showed that microglia engulf and remove synapses in neonate mouse barrel cortex following whisker lesioning and whisker trimming-induced reductions of neural activity. Whisker lesioning-induced synapse removal was dependent on signaling between neuronal fractalkine (CX3CL1) and its cognate microglial fractalkine receptor (CX3CR1).

Objectives: Using this whisker lesioning paradigm, the investigators explored how astrocytes and microglia coordinate to regulate synapse remodeling

Methods: Using translating ribosome affinity purification followed by RNA-seq (TRAP-seq) and MERFISH spatial transcriptomics, the investigators identified novel Wnt-dependent receptor-ligand signaling between microglia and astrocytes that drives synapse remodeling.

Results: Intriguingly, microglia-to-astrocyte Wnt signaling is CX3CR1-CX3CL1 signaling dependent and induces reduced astrocyte-synapse contact prior to synapse engulfment by microglia. Together, these results identify a novel mechanism by which microglia signal to astrocytes to facilitate synapse engulfment and remodeling of cortical synapses in response to changes in sensory experience.

Conclusions:

As changes in astrocyte-synapse contact occur naturally during sleep, as circuits mature, and in an array of neurological disorders, it is proposed that astrocyte-synapse contact could be a general regulator of microglial synapse engulfment and subsequent synapse remodeling. I am now actively exploring this possibility by examining how other manipulations that affect astrocyte-synapse contact impact developmental critical windows.

431.203 Profiling of Metabolites for Autism Spectrum Disorder By Metabolome Analysis

K. Nakamura¹, S. Shimoyama² and Y. Sakamoto³, (1)Department of Neuropsychiatry, Graduate School of Medicine, Hirosaki University, Hirosaki, Aomori, Japan, (2)Neurophysiology, Hirosaki University Graduate School of Medicine, Hirosaki, Japan, (3)Department of Neuropsychiatry, Graduate School of Medicine, Hirosaki University Hospital, Hirosaki, Aomori, Japan

Background: Autism Spectrum Disorder (ASD) is a disorder with a wide variety of symptoms, including impairment of social interaction, repetitive and restricted behaviors. Many omics studies explored genetic and metabolic biomarkers for ASD, but none of them have been put to practical use. Unfortunately, these studies could not discover a definitive, valid, and available biomarker due to various factors depending on individual differences such as symptoms, race, sex, and age.

Objectives: Metabolome analysis was carried out assuming that there must be substances that could be biomarkers under limited conditions in this study. We also hypothesized that there might be some metabolite that is related to some characteristics of ASD.

Methods: Subjects were recruited from the Hirosaki Five-year-old Children Developmental Health Check-up study between 2013 and 2018, with informed consent after approval by the Research Ethics Committee of Hirosaki University (approval number: 2013-293). Blood samples were collected from community-based 5-year-old children in Japan (healthy control: 41 males and 25 females, patients with ASD: 80 males and 38 females) and subjected to target-metabolome analysis. Target-metabolome analysis was performed using AbsoluteIDQ® Kit p180kit (Biocrates Life Sciences AG) in accordance with manufacturer's instructions. The amounts of 188 metabolites including amines, acylcarnitines, and lipids in plasma were measured by mass spectrometry and analyzed using MetaboAnalyst.

Results: Several metabolites were observed to have significant differences in blood concentration. One of the acylcarnitine, dodecanedioylcarnitine (C12-DC), was significantly higher in patients with ASD (120.0 ng/ml, 95% CI: 113.3-126.7 ng/ml) than in healthy subjects (83.1 ng/ml, 95% CI: 78.4-87.8 ng/ml) ($P = 4.2179 \times 10^{-11}$, fold change = 1.42) and have no differences between sex. Receiver operating characteristic (ROC) curve analysis determined that the sensitivity and specificity were 77.2% and 71.2%, respectively (cutoff = 82.8 ng/ml). In addition, although the average concentration of C12-DC was higher than the control group, there was a tendency to be divided into a high group and a low group. A positive correlation was found between the concentration of C12-DC and the Autism-Spectrum Quotient (AQ) score ($r^2 = 0.551$, $P < 0.001$). Especially, the score of local details was the medium correlation ($r^2 = 0.595$, $P < 0.001$). C12-DC is known to be detected in blood at high levels in oxidative stress and mitochondrial damage. Since oxidative stress and mitochondrial damage are also known to occur in patients with ASD, the increased blood levels of C12-DC may be due to these factors.

Conclusions: We showed that the blood concentration of C12-DC was significantly higher in the ASD group. A positive correlation was found between the concentration of C12-DC and the Autism-Spectrum Quotient (AQ) score. Thus, C12-DC may be a potential biomarker for diagnosing ASD.

431.204 Protein Interactions of Chd8 in Mouse Forebrain

E. Smith¹, C. P. Canales², M. Kenaston³, Y. Guo³, D. Perla³, K. Medvedeva³, A. S. Nord³ and P. Shah⁴, (1)Center for Neuroscience, University of California Davis, Davis, CA, (2)Department of Psychiatry and Behavioral Sciences, UC Davis Center for Neuroscience, Davis, CA, (3)University of California Davis, Davis, CA, (4)Microbiology and Molecular Genetics, University of California Davis, Davis, CA

Background: Autism spectrum disorder (ASD) is a neurodevelopmental disorder (NDD) characterized by social and communication difficulties. Genome sequencing has enabled the identification of a growing number of risk genes for NDDs. Among these NDD risk genes, chromatin associated factors have emerged as among the most strongly enriched loci and have been shown to have a strong causal association in humans via *in vitro* and animal studies. Chromatin remodelers canonically regulate chromatin dynamics via modulating nucleosome spacing and cooperating with transcription factors and histone modifiers to allow the transcription of DNA. One such chromatin remodeler, Chromodomain helicase DNA binding protein 8 (*CHD8*), has among the highest observed *de novo* loss-of-function mutations rates in patients with ASD. *CHD8* has been shown to regulate the transcription of other ASD risk factors and *Chd8* mutation or knockdown has broad transcriptional impact.

Objectives: Despite its status as a top risk gene, molecular mechanisms linking *CHD8* haploinsufficiency and ASD are poorly understood. To address this, we aim to identify *Chd8* molecular interactions in developing mouse forebrain.

Methods: Proteins interactors were identified by endogenous co-immunoprecipitation followed by Liquid Chromatography with Tandem Mass Spectrometry (LC-MS/MS). Interactions were verified via proximity ligation analysis and CoIP followed by western blotting. We further used RIP-seq to test for RNA interactions and bulk RNA sequencing to test for transcription differences in *Chd8*^{-/-} mutant mice.

Results: We observed a substantial number of interactions implicating chromatin remodeling and epigenetic factors, transcriptional machinery, and cytoskeletal proteins, with a surprisingly strong enrichment for proteins involved in RNA processing. RIP-seq of *Chd8* provides some support for links between *Chd8* genomic and mRNA targets. Finally, we found perturbations in splicing in perinatal forebrain in *Chd8*^{-/-} mutant mice. Further validation experiments of these *CHD8* molecular interactions are ongoing.

Conclusions: Overall, identifying these *Chd8* interactions will more comprehensively define the roles of *Chd8* in the brain, open new avenues of research, and further understanding of molecular mechanisms in ASD.

431.205 Single-Cell Analysis of B Cell Landscape Underlying Behavioural Heterogeneity in ASD and ADHD

K. Cao¹, S. Cleary², E. Kelley³, J. Jones⁴, M. Ayub⁴, S. Georgiades⁵, J. Crosbie⁶, R. Weksberg⁷, R. Schachar⁸, R. Nicolson⁹, E. Anagnostou¹⁰, J. A. Foster¹¹ and C. Wang¹, (1)Sunnybrook Research Institute, Toronto, ON, Canada, (2)McMaster University, Hamilton, ON, Canada, (3)Department of Psychology, Queen's University, Kingston, ON, Canada, (4)Department of Psychiatry, Queen's University, Kingston, ON, Canada, (5)Offord Centre for Child Studies, McMaster University, Hamilton, ON, Canada, (6)University of Toronto, Toronto, ON, Canada, (7)Institute of Medical Sciences, University of Toronto, Toronto, ON, Canada, (8)Department of Psychiatry, The Hospital for Sick Children, Toronto, ON, Canada, (9)Department of Psychiatry, The University of Western Ontario, London, ON, Canada, (10)Bloorview Research Institute, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (11)UT Southwestern Medical Center, Dallas, TX

Background: An estimated 10% of Canadian children are diagnosed with neurodevelopmental disorders (NDs) such as autism spectrum disorders (ASD) and attention-deficit/hyperactivity disorder (ADHD). Clinical heterogeneity in NDs makes it difficult to match individuals with effective treatments. Within the disorders, heterogeneity in behavioural phenotype (e.g., social communication, anxiety) and gut abnormality (e.g., constipation, diarrhea, reflux) is common and may be related to differences in the underlying biological mechanisms and treatment responses. Immune dysregulation has been widely reported in NDs and may serve as a link between the gut-brain axis, underlying clinical heterogeneity. We leveraged blood samples and clinical data acquired through the Province of Ontario Neurodevelopmental Disorders (POND) network, a multidisciplinary team of scientists, clinicians, and community stakeholders. In agreement with published literature, a nested analysis of 1130 of the total 1727 participants demonstrated that increased GI symptoms was associated with increased severity of behavioural symptoms. Notably, in individuals (20% ADHD, 80% ASD) that presented with behavioural deficits across all domains, half of these individuals had at least one GI symptom with 25% of those having multiple GI symptoms. The POND network has banked biospecimens from 654 participants, including typical developing, ASD and ADHD that were transdiagnostically clustered into behavioral groups with distinct behavioral score and co-occurrence of GI symptoms.

Objectives: Investigate the molecular network underlying the peripheral B cell dysregulation associated with GI dysfunction and behavioural heterogeneity

Methods: A proof-of-concept pilot single cell RNA sequencing analysis was performed to reveal the transcriptome state of immune cells from banked PBMCs of 15 male individuals aged 8 to 17 across behavioral clusters with varying frequency of GI symptoms including 3 typical developing (TD), 6 ASD and 6 ADHD individuals (3 per disease group with severe social communication deficit and increased GI symptoms).

Results: Comparing disease and healthy groups, ASD individuals had higher frequency of B cells than TD. ADHD individuals had more regulatory B cells with upregulation of NR4As and TCL1A as compared to ASD. Within B cell subtypes, both naive and memory B cell levels were lower in ASD and ADHD compared to TD, while frequency of transitional B cells was higher in both disease groups. B cells were more activated in individuals with severe social communication deficit and increased GI symptoms trans-diagnostically, but the activation is heterogenous. In ASD, B cell activation, reflected by more significant MHC class II antigen presentation, was associated with selected HLA subtypes (HLA-DQA2 and HLA-DRB5) in individuals with increased GI symptoms. In contrast in ADHD, individuals with increased GI symptoms were associated with NF- κ B activation.

Conclusions: B cell functional state underlies behavioral heterogeneity trans-diagnostically in ASD and ADHD. We will further validate the preliminary results leveraging more banked PBMCs from POND by scRNA-seq and flow cytometry. The biological mechanisms will enable us to identify blood-based biomarkers that can be used to stratify individuals into clinically relevant subgroups to better inform treatment.

431.206 Children with Autism Spectrum Disorder Have Low Level Neurotransmitter Alterations in Intestinal Enteroendocrine Cells
K. A. Engevik¹, A. M. Tinger¹, Y. Fernandez Figuerero², A. Krigsman³, M. A. Engevik⁴ and S. J. Walker², (1)Department of Regenerative Medicine & Cell Biology, Medical University of South Carolina, Charleston, SC, (2)Wake Forest Institute for Regenerative Medicine, Winston Salem, NC, (3)Pediatric Gastroenterology Resources of New York and Texas, Austin, TX, (4)Department of Microbiology & Immunology, Medical University of South Carolina, Charleston, SC

Background: Emerging evidence supports a strong bidirectional relationship between the gastrointestinal system and the central nervous system, referred to as the gut-brain axis. While neurotransmitter dysregulation and synaptic dysfunction have been well-documented in the brains of individuals with autism spectrum disorder (ASD), less is known about how these molecular changes manifest in the gut. In this study, we analyzed biopsies from the ileum and colon of typically developing (TD) children and individuals with ASD to assess the expression of genes involved in neurotransmission in the gastrointestinal tract.

Objectives: To evaluate differential neurotransmitter-related gene expression in biopsies from the ileum and ascending colon of TD and ASD pediatric patients with or without inflammation.

Methods: Gastrointestinal biopsy tissues from our large tissue repository (N=1400 children with ASD; 250 TD children) were selected for comparative analysis of neurotransmitter-associated gene expression. Biopsies from the terminal ileum (TI) and ascending colon from GI-symptomatic children with (ASD only, n=10), and without (ASD n=9; TD n=9) inflammation were selected for analysis. Total RNA was isolated from each sample using RNeasy kit reagents (Qiagen) following the manufacturer's protocol, and RNA quantity and quality were assessed using an Agilent Bioanalyzer (ThermoFisher). Total RNA (0.5–2.0 μ g; RIN $\geq$ 7) from each sample was assayed on Illumina HT v4 BeadArray whole-genome microarrays (Illumina Inc.) and data were extracted using Genome Studio Software (Illumina Inc.) and prepared for further gene expression analysis. The genes of the enteroendocrine cell lineage and neurotransmitter pathways were identified based on recent published single-cell RNAseq data of the normal human small and large intestine.

Results: Genes associated with serotonin signaling (*HTR1F*, *HTR7*, *SLC6A4*) (**Figure 1**), dopamine synthesis and receptor function (*DDC*, *DRD5*), and glutamatergic pathways (*GRIK3*, *GRIN1*, *SLC1A1*, *SLC1A7*) were significantly altered in ASD children with inflammation, suggesting a broad disruption in neurotransmitter homeostasis in the gut (**Figure 2**). Additionally, neuropeptide Y (NPY), PAX6, and endothelin-2 (EDN2) were also downregulated, further implicating altered neuroimmune interactions and developmental pathways in gut tissues.

Conclusions: We identified several neurotransmitter pathways that are altered in the ASD gut, particularly in the setting of inflammation. These findings highlight the potential role of the gut as a critical modulator of neurodevelopmental processes in ASD and suggest that gut-brain axis dysregulation may contribute to the ASD phenotype. This study provides new insights into the molecular mechanisms in the gastrointestinal tract in individuals with ASD and suggests novel therapeutic targets for restoring gut-brain communication. This research opens new avenues for therapeutic strategies targeting the gut-brain axis in autism.

431.207 Creating a Living Intestinal Organoid Biobank: A Model System for Mechanistic Testing in GI-Symptomatic Children with Autism

Y. Fernandez Figuerero¹, T. Simon¹, J. F. Linden¹, A. Krigsman², M. A. Engevik³ and S. J. Walker¹, (1)Wake Forest Institute for Regenerative Medicine, Winston Salem, NC, (2)Pediatric Gastroenterology Resources of New York and Texas, Austin, TX, (3)Department of Microbiology & Immunology, Medical University of South Carolina, Charleston, SC

Background: Persistent gastrointestinal (GI) symptoms are common in children with autism spectrum disorder (ASD) and despite growing evidence linking gut dysbiosis and chronic gut inflammation in these children, the underlying mechanisms remain incompletely understood. To address this, we propose the creation of a model system that can be used for hypothesis testing and mechanistic studies. We hypothesize that gut organoids generated from individual patient-derived gut tissues will recapitulate important disease-driving characteristics of the host.

Objectives: To establish a robust platform that enables the discovery of ASD patient-specific mechanisms underlying GI dysfunction and supports the design of targeted treatments based on the unique molecular and cellular profiles of individual patients.

Methods: *Biobanking:* Biopsy samples from the distal duodenum, terminal ileum (TI), and right colon were collected from ASD and TD children undergoing clinically indicated endoscopy. Intestinal crypts were isolated through enzymatic digestion, embedded in Matrigel basement membrane extract, and cultured in Intesticult growth medium (StemCell Technologies) supplemented with RHO/ROCK pathway inhibitor (10 uM) and gentamicin (50mg/ml). Organoids were expanded through multiple passaging before being transferred to liquid nitrogen for cryopreservation.

Experimental: To test the organoid exposure response to a proinflammatory stimulus (flagellin), a small pilot study was performed using TI organoids from 4 ASD patients. Cryopreserved organoids were thawed, passaged twice, and cultured in differentiation medium (StemCell Technologies) for 4-5 days prior to stimulation. For the stimulation experiment, 1 µg/ml flagellin was added to media and organoids were incubated at 37°C with 5% CO₂. Following a 20 h incubation, the supernatants were collected and assayed for IL-8 (a proinflammatory marker).

Results: To date, we have successfully generated, expanded, characterized, and banked 52 organoids from individual mucosal biopsy samples; 38 from ASD and 14 from TD children. We were able to expand 70% of the ASD and 78% of the TD organoids. No significant differences were observed between ASD and TD controls in average time for expansion (14 days from primary culture to the first passage and 7 days from passage 1 to passage 2). H&E staining showed that both groups exhibited similar morphologies. Differentiated ASD organoids were positive for key gut cell markers, including lysozyme, villin, MUC2, and chromogranin A, indicating successful differentiation (**Figure 1**). Following stimulation with flagellin, ASD organoids showed increased IL-8 secretion, indicating retention of response to proinflammatory activity under *in vitro* conditions (**Figure 2**).

Conclusions: These results confirm the feasibility of generating and cryopreserving ASD-specific organoids without compromising their viability, demonstrating their suitability for experimental studies. We have shown that ASD organoids develop similarly to TD organoids and can mimic *in vivo* responses to bacterial stimuli. To our knowledge, this biobank is the first to generate ASD patient-specific organoids from distinct regions of the GI tract, providing an important new platform for mechanistic testing and evaluation of personalized treatment approaches in ASD research. Further characterization of this organoid model system is ongoing.

431.208 Gene Expression Analysis in Patient-Derived Gut Organoids from Autistic Children with Chronic Gastrointestinal Symptoms

Y. Fernandez Figueroa¹, T. Simon¹, A. Krigsmann² and S. J. Walker¹, (1)Wake Forest Institute for Regenerative Medicine, Winston Salem, NC, (2)Pediatric Gastroenterology Resources of New York and Texas, Austin, TX

Background: Children with autism spectrum disorders (ASD) experience a range of chronic gastrointestinal (GI) problems for which the underlying etiology and pathophysiology are not well understood. One hypothesis suggests that a damaged gut mucosa, resulting in a 'leaky gut', may be partially responsible. To investigate this hypothesis, we are developing a three-dimensional gut organoid model system that utilizes mucosal biopsy tissues derived from children with ASD and chronic GI inflammation.

Objectives: To analyze differential gene expression in gut organoids generated using biopsy tissue from GI- symptomatic children with ASD compared to typically developing (TD) control organoids (from GI-symptomatic children *without* ASD) with the overall goal of enabling the eventual characterization of intestinal epithelial barrier status and mechanistic hypothesis-testing.

Methods: Two biopsies from the terminal ileum were collected from GI-symptomatic ASD children undergoing a clinically indicated ileocolonoscopy. One biopsy was placed in RNA later (stored at -20°C) and a companion (adjacent) biopsy was used to generate gut organoids. Organoids were cultured, expanded, and banked in liquid nitrogen. Cryopreserved GI organoids from typically developing (TD) children (provided from a collaborator at UC Davis) served as controls. Total RNA from both organoids sets (N=4 ASD; N=4 TD), and biopsy tissue from the original ASD donor (N=4) was isolated using the QIAcube (QIAGEN®) instrument. Following RNA isolation and quality assessment, gene expression was analyzed using a gene expression panel (Nanostring) consisting of 241 inflammation-related genes. Differential expression analysis was performed using NSolver software for the following two comparisons: (1) ASD organoids versus TD organoids, and (2) ASD organoids versus ASD biopsy tissues used in the organoid creation (i.e., matched by donor). The list of differentially expressed transcripts (DET) from each comparison were exported to Ingenuity Pathway Analysis (IPA) software wherein canonical pathways and interaction networks were identified.

Results: In comparison #1 (ASD organoids versus TD organoids) 134 DETs were identified, and pathway analysis included 49 analysis-ready molecules across observations; 42 were downregulated and 7 were upregulated. The transcription regulator NFκB was down regulated in *PPAR* and *Tight Junction Signaling* pathways. DAXX, another transcription regulator was downregulated in the *P38 MAPK signaling* pathway. In comparison #2 (ASD organoids versus donor biopsy tissue) 193 DETs were identified and of the 131 analysis-ready molecules, 6 were downregulated and 125 were upregulated. Transcription regulator NFκB1 was upregulated on PPAR signaling. In P13K/AKT signaling, another pathway implicated in leaky gut, a multifunctional anti-apoptotic protein BCL-XL, involved in epithelial cell proliferation, was downregulated. The highlighted DETs are associated with functions of the activation of protein kinase, apoptosis, transcription regulation, epithelial neoplasia, and inflammation suggesting that these pathways are likely relevant to epithelial barrier integrity (**Table 1, Figure 1**).

Conclusions: These results provide evidence of differences in inflammatory-related gene expression between gut organoids derived from GI-symptomatic children with ASD compared to controls that may contribute to functional alteration of the intestinal epithelial barrier. A more comprehensive characterization of this organoid model system is currently underway.

431.209 Using a Robust Organoid Model System to Analyze Serotonin Signaling in Gastrointestinal (GI) Symptomatic Children with Autism Spectrum Disorder (ASD)

Y. Fernandez Figueroa¹, T. Simon¹, M. A. Engevik², A. Krigsmann³ and S. J. Walker¹, (1)Wake Forest Institute for Regenerative Medicine, Winston Salem, NC, (2)Department of Microbiology & Immunology, Medical University of South Carolina, Charleston, SC, (3)Pediatric Gastroenterology Resources of New York and Texas, Austin, TX

Background: Serotonin signaling plays an important role in homeostasis within the microbiota-gut-brain axis, and dysregulation within this axis has been identified as a potentially important component in the etiology of autism spectrum disorder (ASD) symptoms. Enterochromaffin cells located throughout the intestinal epithelium of the small and large intestines produce intestinal serotonin, yet no study to date has analyzed potential dysregulation of the serotonin signaling pathway across different regions of the GI tract in children with ASD. In this study, we propose to use a robust tissue-derived intestinal organoid model, generated using gut mucosal from ASD and typically developing (TD) GI-symptomatic children, to analyze serotonin signaling pathway dysregulation.

Objectives: To compare the levels of serotonin pathway-related genes and proteins in patient-derived organoids from children with ASD vs. TD control and analyze serotonin expression in ASD organoids generated from the small and large intestines.

Methods: Biopsy samples from the distal duodenum, terminal ileum, and right colon were collected from ASD and TD children undergoing clinically indicated endoscopy and used to create organoids. Briefly, intestinal crypts were isolated through enzymatic digestion, embedded in Matrigel basement membrane extract, and cultured in Intesticult growth medium (StemCell Technologies), supplemented with RHO/ROCK pathway inhibitor (10 uM) and gentamicin (50 mg/ml). Following expansion and passaging, organoids were transferred to liquid nitrogen for cryopreservation. *Experiment 1:* Selecting from the cryopreserved biobank samples, organoids derived from terminal ileum were thawed, passaged twice, and cultured in differentiation medium (StemCell Technologies) for 4-5 days. Next, total RNA (N=6 ASD; N=6 TD) was isolated using the QIA cube (QIAGEN®) instrument and standard protocols. Following RNA isolation and quality assessment, gene expression was analyzed using qPCR. *Experiment 2:* To assess the secretion of serotonin (ASD samples only), monolayers were generated from organoids of the distal duodenum (N=3) and right colon (N=3) and exposed to 1 µg/ml flagellin for 20 hrs. Supernatants were then assayed using serotonin ELISA.

Results: qPCR results revealed no significant differences in serotonin transporter (SERT) expression between ASD and TD control at baseline, however ASD organoids were found to have increased expression of tryptophan hydroxylase 1 (Tph1), the rate-limiting enzyme involved in serotonin biosynthesis, relative to TD controls (**Figure 1**), indicating that serotonin biosynthesis may be upregulated in ASD. Monolayers derived from colon organoids exhibited higher serotonin levels when compared to monolayers derived from the distal duodenum organoids (**Figure 2**), however treatment with flagellin did not change the serotonin levels in either location, suggesting that flagellin does not enhance serotonin production in this organoid model.

Conclusions: These data support the notion that these organoids can serve as a valuable model for investigating serotonin synthesis and signaling in children with ASD. The observed dysregulation of key serotonin-related genes, such as tph1, suggests an increased in serotonin production as a potential pathological mechanism in ASD. The next steps will involve comparative molecular analysis between these organoids and patient biopsy tissue to further validate these findings.

**Poster Session****432 - Sensory, Motor, and Repetitive Behaviors and Interests II**

May 2nd, 2025, 6:00 PM - 7:00 PM - Hall 4A

432.210 Differences in Neurophysiological and Behavioral Habituation and Sensory Reactivity Patterns in Autistic Children

S. Soker-Elimaliah¹, S. Major², H. Bayazit³, H. Riehl⁴, L. DeMoss⁵, E. Glenn⁶, G. Dawson⁷, K. L. Carpenter⁸ and G. T. Baranek⁹, (1)Chan Division of Occupational Science and Occupational Therapy, Chan Division of Occupational Science at the University of Southern California, Los Angeles, CA, (2)Duke Center for Autism and Brain Development, Durham, NC, (3)Harvard Medical School, Boston, MA, (4)University of North Carolina, Carrboro, NC, (5)Brown Center for Children & Families, Women & Infants Hospital, Providence, RI, (6)University of Oregon, Eugene, OR, (7)Department of Psychiatry and Behavioral Sciences, Duke University, Durham, NC, (8)Department of Psychiatry and Behavioral Sciences, Duke University Medical Center, Durham, NC, (9)Chan Division of Occupational Science and Occupational Therapy, University of Southern California, Los Angeles, CA

Background:

Habituation, the reduction in response to a repeated stimulus, has a crucial role in learning and cognitive development (Sicard-Cras et al., 2022). Studies have found reduced neurophysiological habituation in autistic children, and this reduced habituation has been linked to sensory reactivity patterns (Cary et al., 2023; Donkers et al., 2015; Hudac et al., 2018). Differences in behavioral manifestation of habituation have also been examined, with studies suggesting that autistic children orient/respond less to a repeated stimulus compared to non-autistic children (Baranek et al., 2007). However, the relationship between neurophysiological and behavioral habituation and how behavioral habituation is associated with sensory reactivity patterns remains unknown. We hypothesize that autistic children who do not exhibit *behavioral* habituation will also demonstrate diminished *neurophysiological* habituation.

Objectives:

Examine how neurophysiological habituation and sensory reactivity patterns differ as a function of behavioral habituation classifications in autistic children.

Methods:

As part of a larger study, 70 autistic children participated ($M_{age}=4.14$, $SD=.87$). **Neurophysiological habituation** was derived from a 100-trial Paired-Click Electroencephalogram (EEG) paradigm. EEG data was recorded using an EGI 124-electrode system. Data were analyzed using standard ERPLab functions to clean and derive the P50 and N100 components. **Behavioral habituation** was assessed with the habituation task on the Sensory Processing Assessment for Young Children (SPA; Baranek et al., 1999). In the habituation task, a phone rings ten times (with ten seconds between rings) while the child is engaged with another toy. Responses were categorized into three classifications: 1. Habituator-child shows three consecutive nonresponses after a response; 2. Nonresponder-child did not respond to any of the ten trials; 3. Hyper-responder-child responds to at least five of the ten trials. Overall sensory hypo- and hyper-reactivity patterns were also calculated from the SPA. A series of general linear models (GLM) were used to examine the differences in both the P50 and N100 amplitudes, as related to sensory reactivity patterns between the three habituation classifications.

Results:

The GLM revealed a significant main effect of *behavioral* habituation classifications ($F(2,61)=3.83$, $p=.027$), with higher hypo-reactivity scores in the Nonresponders group ($M=2.92$) than in the Habitulators group ($M=2.21$; $t(63)=-2.74$, $p=.008$). Another significant main effect for *behavioral* habituation classification was found ($F(2,61)=3.59$, $p=.033$), with higher seeking scores in the Hyper-responders group ($M=2.91$) than in the Habitulators group ($M=2.26$; $t(63)=-2.21$, $p=.031$). For *neurophysiological* habituation, there was a marginal effect ($F(1,31)=4.13$, $p=.051$), with smaller N100 amplitude in the left hemisphere for Nonresponders ($M=5.17$) compared to Habitulators ($M=-.54$; $t(32)=-2.03$, $p=.051$). No significant differences were found with the P50 component ($ps > .39$).

Conclusions:

Autistic children with increased hypo-reactivity showed differences in both behavioral and neurophysiological habituation, possibly due to impaired sensory stimuli registration—potentially caused by decreased sensory gating. These findings highlight the importance of exploring neurophysiological mechanisms to explain processing differences that result in similar behaviors. Notably, only children who did not show behavioral habituation showed reduced neurophysiological habituation, suggesting the relationship between neurophysiological and behavioral habituation may be influenced by other factors. Future analysis will examine factors such as cognitive functioning and attention.

432.211 Temperamental Sensory Features in the First Years of Life Predict Later Autistic Traits

S. Soker-Elimaliah¹, C. E. Brittenham² and J. B. Wagner³, (1)Chan Division of Occupational Science and Occupational Therapy, Chan Division of Occupational Science at the University of Southern California, Los Angeles, CA, (2)Departments of Pediatrics & Neuroscience, Albert Einstein College of Medicine, Bronx, NY, (3)Department of Psychology, College of Staten Island, CUNY, Staten Island, NY

Background:

Differences in responses to sensory stimuli (i.e., sensory reactivity) are tightly linked to autistic traits, such as restricted and repetitive behaviors (RRB; e.g., Boyd et al., 2010). Prospective studies have shown that differences in sensory responses at ages 6-23 months predict higher levels of autistic traits at 3-7 years (Grzadzinski et al., 2020; Chen et al., 2022). Additionally, sensory reactivity is associated with temperamental features in autistic and non-autistic 2-7 years old children (Keuler et al., 2011; Brock et al., 2010). Studies with infants at increased likelihood for autism show that temperamental negative affect, effortful control, and surgency early in infancy and toddlerhood predict autism outcomes at 3 years of age (Pijl et al., 2019, Garon et al., 2015). The current study will expand on past work and examine whether early temperamental sensory features predict variation in a community sample of infants.

Objectives:

To examine whether sensory features in the first and second year of life, derived from traditional temperament measures, can predict autistic traits at 3 years of age.

Methods:

As part of a longitudinal study, caregivers of 59 infants from a community sample completed questionnaires about their child's temperament at one or more time points between 6 and 24 months and then completed the Social Responsiveness Scale, Second Edition (SRS-2; Constantino & Gruber, 2012) when their child was 36 months. For 6- to 12-month temperament, the Infant Behavior Questionnaire (IBQ; Rothbart, 1981) was used; for 18- to 24-month temperament, the Early Childhood Behavior Questionnaire (ECBQ; Putnam et al., 2006) was used. Standard temperament scores on the IBQ included Activity Level, Distress to Limitations, Approach Distress, Duration of Orienting, and Smiling and Laughter, and on the ECBQ included Negative Affect, Surgency, and Effortful Control. Additional sensory composite scores were derived for both the IBQ and ECBQ, combining items spanning the standard subscales that correspond with sensory items from the Sensory Experience Questionnaire (SEQ; Baranek et al., 2006). For autistic traits, total t-scores as well as Social-Communication Index (SCI) and RRB t-scores were calculated.

Results:

Linear regression models predicting SRS-2 scores from IBQ and ECBQ standard subscales showed that Negative Affect and Effortful control on the ECBQ predicted total ($p < .018$), RRB ($p < .045$), and SCI ($p < .030$) t-scores on the SRS-2. The newly-derived sensory composite from the ECBQ also predicted total ($p = .007$), RRB ($p = .026$), and SCI ($p = .005$) t-scores on the SRS-2. For IBQ, regression showed that none of the IBQ standard subscales predicted autistic traits ($p > .13$); however, the newly-derived IBQ sensory composite score predicted RRB scores ($p = .04$). See Table 1 for a full summary.

Conclusions:

Findings suggest that while standard measures of temperament in the second year of life predict autistic traits at age 3, a novel sensory composite measure in the first year was able to predict restricted and repetitive behaviors (RRB) at age 3. This highlights sensory features as an early behavioral marker of autistic traits. Future analyses will explore the developmental trajectories of these temperamental sensory traits in relation to later autistic features and clinical outcome.

432.212 Patterns of Anxiety and Specific Repetitive Behaviors in Autism Spectrum Disorder and Williams Syndrome

D. Hennelly¹, Y. A. Ahn², **R. Nadal³**, J. Van Herwegen⁴, A. C. Samson⁵, M. Alessandri⁶ and J. S. Durocher³, (1)Psychology, University of Miami, Fort Lauderdale, FL, (2)Psychology, Harvard University, Cambridge, MA, (3)Psychology, University of Miami, Coral Gables, FL, (4)Institute of Education, University College London, London, London, United Kingdom, (5)Institute of Special Education, University of Fribourg, Fribourg, Switzerland; Faculty of Psychology, Unidistance Suisse, Brig, Switzerland, Switzerland, Switzerland, (6)Department of Psychology, University of Miami Center for Autism and Related Disabilities, Coral Gables, FL

Background:

Repetitive behaviors (RRBs) and anxiety are common in both Autism Spectrum Disorder (ASD) and Williams Syndrome (WS) (Rogers et al., 2012; Glod et al. 2019). In ASD, RRBs often function as coping mechanisms for sensory overload, unpredictability, and heightened stress, while anxiety tends to exacerbate and reinforce the need for these behaviors, creating a cycle of dependence (Boulter et al., 2014; Lewis & Kim, 2009; Rodgers et al., 2012). Similarly, individuals with WS also exhibit RRBs that may serve as coping strategies for social challenges and heightened anxiety (Glod et al., 2019). However, there remains a gap in understanding how anxiety differentially relates to RRBs across ASD and WS.

Objectives:

This study aims to compare the frequency and types of repetitive behaviors in children with ASD and WS and how these are associated with anxiety within each group.

Methods:

Our research utilizes a subsample from a larger international data set of individuals with special needs collected during the initial stages of the COVID-19 pandemic (Dukes et al., 2021). The current study uses data from caregivers of children with ASD and with WS within the United States, collected via an investigator created survey, which retrospectively measured parent-rated concerns (on a scale of 1=not at all to 5=extremely) before and during the pandemic.

Our sample includes 249 participants aged 5 to 16, with a mean age of 10.32 years (SD=3.42): ASD (N=189, 83% male) and WS (N=60; 45% male). There was no significant difference in age between the two groups: ASD (M=10.22; SD=3.45) and WS (M=10.63; SD=3.33).

Results:

Independent samples *t*-tests were conducted to compare anxiety and RRB levels between children with ASD and WS (see Table 1). Results suggested that there was no significant difference in anxiety levels between children with ASD and WS. However, children with ASD exhibited significantly higher levels of all repetitive behaviors compared to children with WS.

Spearman's rank order correlations were computed to assess the relationship between anxiety and RRBs in the ASD and the WS (see Table 2) groups. In the ASD group, anxiety was significantly correlated with all repetitive behaviors except Food Selectivity while in the WS group, only Routine Sameness, Perfectionistic Behaviors, and Clothing Rigidity were correlated with anxiety.

Conclusions:

Children with ASD exhibited higher levels of repetitive behaviors than those with WS, although anxiety levels were similar between the two groups. Anxiety was also positively, but differentially, associated with RRBs across both groups. These findings contribute to a growing body of literature that emphasizes the importance of targeting both anxiety and repetitive behaviors in therapeutic interventions; reducing anxiety may have a cascading effect on decreasing the severity or frequency of repetitive behaviors, potentially improving quality of life. Information about differences in the patterns of RRB and their association with anxiety across ASD and WS may also inform the development of more tailored therapies for these two groups.

**432.213 Patterns of Self-Injurious Behavior in a Cohort of Children with Autism: From Preschool to School Age**

A. F. Dimian¹, K. Botteron², S. R. Dager³, A. M. Estes⁴, H. Hazlett⁵, C. M. Lee⁶, R. T. Schultz⁷, M. D. Shen⁸, L. Zwaigenbaum⁹, J. Piven¹⁰ and J. J. Wolff¹¹. (1)University of Minnesota, Minneapolis, MN, (2)Washington University School of Medicine, St. Louis, MO, (3)Radiology, University of Washington, Seattle, WA, (4)Speech and Hearing Sciences, UW Autism Center, Seattle, WA, (5)University of North Carolina, Chapel Hill, NC, (6)Department of Pediatrics, University of Minnesota - Twin Cities, Minneapolis, MN, (7)The Center for Autism Research/CHOP, Philadelphia, PA, (8)University of Alberta, Edmonton, AB, Canada

Background: Self-injurious behavior (SIB) is a relatively common behavior with estimates indicating that approximately half of autistic children will engage in SIB within their lifespan (Duerden et al., 2012). For a subset of children, SIB becomes entrenched, chronic, and poses significant risks to health, safety, and quality of life. Research

indicates that individuals with autism are at higher risk for developing SIB compared to other intellectual and developmental disabilities (Dimian & Symons, 2022). Few longitudinal studies have followed children from preschool into school age and evaluated the emergence and persistence of SIB over time.

Objectives: The purpose of this study was to examine how persistent, frequent, and severe SIB was among a cohort of children with ASD followed from preschool into school age.

Methods: All children included in this study had a clinically confirmed diagnosis of autism (n=21, 17% female). This dataset was part of an ongoing longitudinal study of children who have an older sibling with autism. SIB measurements were collected over time at 36 months of age and at follow up in school age (~10 years) using the Repetitive Behavior Scale, Revised (RBS-R; Bodfish et al. 2000). Adaptive function was assessed in preschool using the Vineland 3 ABC score (VABS; Sparrow et al. 2016) and cognitive ability was evaluated with the Mullen Scales of Early Learning (Mullen, 1995) or Differential Ability Scales 2 (DAS-2; Elliott

2007). We used descriptive analyses, Spearman rank correlations and relative risk to assess the prevalence and severity of school age SIB by previous SIB status at 36 months of age (i.e., persistent SIB, transient SIB, No SIB, Incident SIB) in relation to adaptive and cognitive level in preschool.

Results: SIB point prevalence estimates were 52% at 36 months and 66% at school age. Average severity of SIB was 1.48 (SD= 1.89) at 36 months and 2.48 (SD=2.58) at school age. The most common topographies at 36 months were hits self against surface and hits self with body part. At school age the most common forms of SIB reported were bites self and hits self with body part. Persistence in SIB was positively associated with SIB severity scores at both timepoints ($r_s = .48, p = .03$; $r_s = .68, p < .001$). There were no statistically significant associations between SIB endorsement or severity and measures of adaptive and cognitive functioning. Finally, the relative risk of engaging in SIB at school-age follow up given SIB at preschool age was 1.78.

Conclusions: SIB was highly prevalent at school age follow up, and severity and number of topographies were increased at school age. Those children with stable (i.e. persistent) SIB were characterized by greater severity of SIB at school age than those with transient or incident SIB. Contrary to findings from older individuals, SIB was not statistically significantly associated cognitive or adaptive functioning. More research is warranted to better understand who is at increased risk to engage in chronic SIB so intervention can be leveraged earlier to increase quality of life.

432.214 Perceptual Decision-Making in Autistic and Non-Autistic Adults and Relationship with ADHD-Related Traits

C. Manning^{1,2}, **H. Yusuf**^{2,3}, **L. Thomas**^{2,4}, **G. Scerif**, **A. Cameron**^{5,6}, **J. Greenhalgh**³, **G. Taylor**⁷ and **N. J. Evans**^{7,8}, (1)School of Psychology, University of Birmingham, Birmingham, West Midlands, United Kingdom, (2)University of Reading, Reading, Berkshire, United Kingdom, (3)Birkbeck, London, London, United Kingdom, (4)NHS England, London, London, United Kingdom, (5)Experimental Psychology, University of Oxford, Oxford, Oxfordshire, United Kingdom, (6)University College London, London, London, United Kingdom, (7)University of Queensland, Brisbane, QLD, Australia, (8)University of Liverpool, Liverpool, Merseyside, United Kingdom

Background: Autistic individuals respond to sensory information in perceptual tasks differently than non-autistic individuals. However, previous research has largely neglected the multiple component processes that contribute to these responses, so it is unclear which processing stages are affected in autism (e.g., early sensory processing or later decision-making strategies). The diffusion model allows the decomposition of performance into distinct processing stages (see Figure). Previous studies using this model have suggested that autistic individuals adopt a cautious decision-making style, emphasising accuracy over speed. However, this approach has not been widely applied across tasks, and often the samples used are modest, yielding inconclusive results. Furthermore, the effect of co-occurring ADHD traits on perceptual decisions has also not been established, which is important given the high co-occurrence of autism and ADHD traits, and previous work showing differences in diffusion model parameters between those with and without ADHD.

Objectives: Here we applied the diffusion model to decompose performance in a numerosity discrimination task into distinct processing stages. We aimed to understand which processing stages vary between autistic and non-autistic individuals, and how they correlate with ADHD-related traits. While commonly used to assess perceptual decision-making, the numerosity discrimination task has not yet been applied to autism or ADHD.

Performance in this task may be important for better understanding mathematical cognition in these conditions.

Methods: We conducted a pre-registered study with a rigorous blinded analysis approach. We investigated group differences between diagnosed autistic (n = 100, aged 21-40 years, 47 females, 43 males, 9 non-binary, 1 non-disclosed) and neurotypical (n = 100, aged 22-40 years, 40 females, 59 males, 1 non-disclosed) participants with comparable non-verbal reasoning ability, and assessed relationships with ADHD traits. Participants completed an online numerosity discrimination task (as accurately and quickly as possible) with stringent, pre-registered inclusion/exclusion criteria. Data were fit with hierarchical Bayesian diffusion models.

Results: Models showed good convergence and fit. We found conclusive evidence (Bayes factors > 3) that autistic individuals have shorter non-decision times than neurotypical individuals, reflecting less time taken for sensory encoding and/or response generation, with no group differences in the rate at which participants accumulate sensory evidence and no differences in their response caution. There was also evidence that individuals with higher verbal hyperactivity-impulsivity accumulated sensory evidence more slowly. These results withstood robustness checks.

Conclusions: We show that autistic and non-autistic adults vary in their non-decision times. Future research will need to disentangle the relative contributions of sensory encoding and/or response generation. We found no group differences in response caution (unlike in other studies), which could be due to the emphasis of both speed and accuracy in task instructions. The rate of accumulation of sensory evidence was linked to verbal hyperactivity/impulsivity, showing the importance of considering the contribution of co-occurring ADHD traits. The diffusion model therefore provides a fine-grained approach to reveal how the processing stages contributing to perceptual decisions converge and diverge across different aspects of neurodiversity.

**432.215** Psychometric Properties of the Senses-R

A. M. Huizinga¹, **M. L. Bezemer**² and **E. M. Blijd-Hoogewys**³, (1)INTER-PSY, Groningen, Groningen, Netherlands, (2)INTER-PSY, Groningen, Netherlands, (3)Psychiatrie Noord, Groningen, Netherlands

Background:

Sensory processing difficulties are a core feature of ASD, as described in the DSM-5-TR, and can manifest as hypersensitivity, hyposensitivity, or unusual sensory interests. Despite their clinical significance, no standardized tool previously assessed all three aspects comprehensively. To address this gap, Turkensteen and Blijd-Hoogewys (2020) developed the Senses, a Dutch self-report questionnaire designed to assess sensory processing in adults with ASD. The Senses has shown strong psychometric properties. Based on initial validation, the Senses-R, a shortened version, was created.

Objectives:

To assess the psychometric properties of the Senses-R, including reliability, validity, and factor structure.

Methods:

The clinical group ($n = 862$) comprised adult patients referred to a mental health clinic for ASD assessment, with 63% ($n = 541$) receiving an ASD diagnosis (ASD group versus non-ASD group). Measures administered included the AQ-50, Senses-R, BRIEF-A, and AASP. A subset of participants ($n = 68$) completed a second Senses-R assessment 3–10 weeks later to evaluate test-retest reliability. The control group ($n = 183$) was recruited via social media from the general population, with exclusion criteria of self-reported ASD or an AQ-10 score above 5.

Internal consistency was measured using Cronbach's alpha, while test-retest reliability was assessed with Pearson correlation. Factor analysis was performed using principal component analysis (PCA). ROC analysis assessed the ability of the Senses-R to differentiate ASD patients from controls. Convergent validity was tested through correlations with the AASP, while divergent validity was explored by correlating the Senses-R with two BRIEF-A subscales: Organization of Materials and Task Evaluation.

Results:

The Senses-R showed strong psychometric properties. Internal consistency for the total score was excellent ($\alpha = .904$), with subscales for hypersensitivity ($\alpha = .862$), hyposensitivity ($\alpha = .833$), and unusual sensory interests ($\alpha = .758$). Test-retest reliability was high ($r = .881$, $p < .001$). Convergent validity with the AASP was robust, particularly for hypersensitivity ($r = .795$, $p < .001$). Divergent validity analysis found significant equivalence with the BRIEF-A Organization of Materials scale ($r = .220$, $p = 0.013$), but not with Task Evaluation ($r = .308$, $p = 0.59$).

The three research groups differed significantly in Senses-R total scores ($p < .001$, $\eta^2 = .294$). The Senses-R correlated strongly with autism severity (AQ-50, $r = .568$, $p < .001$) and showed good discriminative ability between clinical and control group (AUC = .918). Gender analysis confirmed these differences. PCA revealed a 3-factor structure corresponding to the three sensory domains in the DSM-5-TR, explaining 38% of the variance.

Conclusions:

The Senses-R is a reliable and valid tool for assessing sensory processing issues in adults with ASD. It demonstrates excellent internal consistency, strong test-retest reliability, and good convergent validity. While divergent validity was mixed, the scale successfully differentiates between ASD and non-ASD individuals, showing promise for use in clinical settings. The Senses-R is well-suited for evaluating sensory complaints aligned with DSM-5-TR's B4 criteria for ASD diagnosis.

432.217 Auditory and Gustatory Sensory Responsivity Are Linked to Anxiety Symptoms in Autistic Preschoolers

K. Sarmukadam¹ and A. L. Hogan², (1)University of South Carolina, Columbia, SC, (2)Department of Communication Sciences and Disorders, University of South Carolina, Columbia, SC

Background: Sensory impairments, such as hyper-responsivity to sensory stimuli, have been shown to contribute to anxiety symptoms in autistic children. However, the impact of modality-specific (e.g., visual, auditory) sensory impairments on anxiety symptoms, particularly in preschool-aged autistic children with co-occurring intellectual disability (ID), is largely unknown. As at least 40% of autistic preschoolers experience significant anxiety symptoms, characterizing the unique contributions of sensory impairments to anxiety symptoms during early development is crucial in identifying factors impairing daily functioning and mitigating later difficulties associated with anxiety in school, social, and home settings.

Objectives: To explore the relationships between modality-specific sensory impairments and anxiety symptoms in autistic and non-autistic (NT) preschoolers using a network estimation model.

Methods: Participants included 46 autistic preschool children [$M(SD)_{age}=3.60(0.50)$ years; 17% female; $M(SD)_{IQ}=59.26(14.50)$]. Thirty-five autistic participants (76%) had co-occurring ID ($IQ < 70$). Thirty-three NT children were included as an age-matched sample [$M(SD)_{age}=3.56(0.86)$ years; 21% female; $M(SD)_{IQ}=101.09(16.70)$]. Measures included the Sensory Experiences Questionnaire – Version 2.1 (SEQ) and Preschool Anxiety Scale-Revised (PAS-R). Network analyses were conducted using undirected graphical least absolute shrinkage and selection operator (gLASSO) as a form of regularization in R to explore how SEQ modalities (auditory, visual, tactile, gustatory, vestibular) interacted with each other and the PAS-R Total Score. All variables were converted to z-scores for standardization. Network centrality measures (i.e., strength, closeness, and betweenness) were obtained.

Results: Groups did not differ on PAS-R scores ($t(77)=1.108$, $p=.271$), but autistic preschoolers exhibited higher scores for all sensory modalities measured by the SEQ, $ts(77)\leq 4.04$, $ps\leq .001$. In autistic preschoolers, gustatory ($r=.32$) and auditory ($r=.38$) responsivity had a moderately strong positive association with anxiety, with tactile responsivity showing a weak negative association with anxiety ($r=-.19$). No other variables contributed to anxiety in the autistic group. Centrality statistics indicated that anxiety, gustatory and tactile modalities were most frequently occurring in the autistic network ($z>1$). For NT preschoolers, anxiety was moderately positively associated with tactile responsivity ($r=.38$) and weakly associated with gustatory responsivity ($r=.28$). All centrality statistics indicated that tactile responsivity was most recurrent in the NT network. Network analysis results are depicted in Figure 1.

Conclusions: Findings demonstrated that gustatory responsivity was central to the network in autistic preschoolers, followed by anxiety and tactile responsivity. Auditory and gustatory responsivity were both moderately associated with anxiety symptoms and modulated relationships with other sensory modalities. In contrast, tactile responsivity was most influential in the network and most associated with anxiety in NT preschoolers. These results suggest that a combination of different sensory stimuli may interact with and influence anxiety symptoms in autistic preschool children as compared to NT preschoolers. Targeted interventions involving increasing habituation to gustatory and auditory stimuli may assist with reducing anxiety symptoms in autistic preschoolers.

432.218 Restricted and Repetitive Behaviors in Toddlers Newly Diagnosed with Autism

E. R. Worthley¹, A. F. Dimian¹, J. J. Wolff¹, A. N. Esler², S. Lee¹, A. Castillo¹ and J. Simacek¹, (1)University of Minnesota, Minneapolis, MN, (2)Department of Pediatrics/Masonic Institute for the Developing Brain, University of Minnesota Medical School, Minneapolis, MN

Background: Restricted and repetitive behaviors (RRBs) are core diagnostic criteria for autism spectrum disorder in the Diagnostic and Statistical Manual of Mental Disorders (5th ed.; DSM-5-TR American Psychiatric Association, 2022). How these core features of autism manifest in young children newly diagnosed with autism is not well characterized, particularly with respect to associations with other child and family characteristics. As RRBs span behaviors that may function as strengths (Klin et al., 2007; Nasr, 2015; Winter-Messiers et al., 2007) or interfering behaviors (Dimian et al., 2023), family empowerment may be an important family characteristic related to the manifestation of RRBs.

Objectives: The objectives of the present study were to 1) characterize RRBs in a group of young children newly diagnosed with autism and 2) examine relations of RRB to other parent-reported child and family variables.

Methods: Data were collected for $n = 44$ young children between 1 and 5 years of age ($M = 2.84$ years, $SD = 1.24$; 27% assigned female at birth; 16% from Spanish-speaking families). Data were collected using the Repetitive Behavior Scale for Early Childhood (RBS-EC; Wolff et al., 2016), Autism Impact Measure (AIM; Mazurek et al., 2020), Vineland Adaptive Behavior Scales, Third Edition (Vineland-3; Sparrow et al., 2016), Family Empowerment Scales (FES; Koren et al., 1993), and Behavior Problems Inventory-Short Form (BPI-S; Rojahn et al., 2012a, 2012b). A three-step hierarchical multiple regression model was built to investigate the relations between biological variables (age, sex assigned at birth), behavioral variables (autism characteristics, adaptive behavior, and problem behaviors), and family variables (family empowerment) to RRBs in toddlers and young children newly diagnosed with autism. Cohen's f^2 was calculated to estimate effect sizes.

Results: Overall, hierarchical regression modeling found biological, behavioral, and family variables to significantly explain variance in RRBs in young children newly diagnosed with autism. The first step of the hierarchical multiple regression model, including biological variables age and sex assigned at birth, did not significantly explain variance in RRBs, $F(2, 34) = 3.11$, $p = .057$, $f^2 = 0.18$. The second step added behavioral variables (autism characteristics, adaptive behavior, and behavior problems), significantly explaining variance in RRBs with a large effect size, $F(5, 30) = 11.65$, $p < .001$, $f^2 = 1.92$. The third step added family empowerment and significantly explained variance in RRBs with a large effect size, $F(6, 29) = 14.19$, $p < .001$, $f^2 = 2.94$. A greater level of autism characteristics and behavior problems were associated with more frequent RRBs. Younger age and lower adaptive behavior scores were also associated with more frequent RRBs. Notably, after biological and behavioral variables were accounted for, families with greater levels of empowerment had children with less frequent RRBs, on average.

Conclusions: Overall, a variety of factors, including biological, behavioral, and family variables, explained the variance in the frequency of RRBs in young children newly diagnosed with autism. A limitation of this study was that all measures were parent-report. Future analyses should include direct measures of child development and autism symptomatology, including RRBs.

**432.220** Retrospective Review of Children's Diagnostic Assessments for Autism Spectrum Disorder in BC: Are We Identifying Co-Occurring Motor Deficits?

J. G. Zwicker^{1,2,3}, A. Christiansen¹, I. Fishman¹, **S. M. Hutchison¹** and E. Mickelson¹, (1)Occupational Science & Occupational Therapy, University of British Columbia, Vancouver, BC, Canada, (2)Brain, Behaviour, & Development Theme, BC Children's Hospital Research Institute, Vancouver, BC, Canada, (3)Pediatrics, University of British Columbia, Vancouver, BC, Canada, (4)Elizabeth Mickelson, Vancouver, BC, Canada

Background: Motor impairments are highly prevalent in children with Autism Spectrum Disorder (ASD). Current data suggest that 50–88% of autistic children experience difficulties in performing gross- and fine-motor skills, with motor performance that is usually slower, less accurate, and more variable than that of neurotypical children [1]. These motor challenges can have a negative cascading effect on a child's quality of life, limiting their ability to interact with peers and participate in social and physical environments (e.g., school, playground, community). Interestingly, the nature of motor impairments in ASD often meets the criteria for Developmental Coordination Disorder (DCD), a distinct neuromotor disability marked by significant difficulty in learning and performing motor skills at an age-appropriate level. Since the publication of DSM-5 in 2013, a dual diagnosis of ASD and DCD has been permitted. However, DCD is under-recognized and under-diagnosed in this population, with less than 15.1% of children with ASD receiving a dual diagnosis of DCD [2]. Delayed diagnosis of motor challenges or DCD can limit opportunities for early, targeted interventions and inhibit timely referral to support services.

Objectives: The purpose of this study is to: (1) determine the prevalence of motor problems in children diagnosed with ASD before (2000-2013) and after the publication (2014-2019) of DSM-5; and (2) determine how many of these children received a co-occurring diagnosis of DCD.

Methods: Data from medical records of 19,307 children (15,090 males; 4,207 females; 10 unreported) ages 2-18 years [mean (SD) age: 7.5 (4.2) years: assessed for ASD in British Columbia from 2000–2019 have been extracted. Between 2000-2013, 4,358/7,779 (56%) children received an ASD diagnosis, compared to 7,689/11,528 (67%) from 2014-2019. We did not include data from 2020 given the change in practice during the COVID-19 pandemic. We are in the process of coding motor concerns consistent with DCD and DCD diagnosis; children with intellectual disabilities and other conditions affecting movement will be excluded. We will determine the prevalence of fine and/or gross motor difficulties that were reported as part of the ASD assessment and determine the number of children who were given the diagnosis of DCD after 2013.

Results: We expect that motor concerns and DCD diagnosis will be under-reported in children with ASD.

Conclusions: Identification of DCD in children with ASD is critically important as there is an effective, evidence-based intervention to improve the motor skills of children with ASD (without intellectual disability) [3]. Screening for DCD should become routine clinical care when assessing children for ASD.

432.221 Reward-Associated Changes in Oculomotor Control Are Associated with Executive Function in Adolescents with Autism Spectrum Disorder

K. E. Unruh¹, P. Arafi² and M. W. Mosconi³, (1)Kansas Center for Autism Research and Training (K-CART), University of Kansas Life Span Institute, Lawrence, KS, (2)University of Kansas, Lawrence, KS, (3)Clinical Child Psychology Program, Schiefelbusch Institute for Life Span Studies, University of Kansas, Lawrence, KS

Background: Atypical processing of reward has been implicated in both core social-communication and repetitive behavior symptoms of autism spectrum disorder (ASD), as well as commonly co-occurring diagnoses (e.g., attention-deficit/hyper-active disorder, ADHD); however, studies have yielded inconsistent findings. Studies of non-human primates have identified the oculomotor system as a powerful tool for measuring reward-facilitated changes in behavior with a high degree of sensitivity. Specifically, expectation of reward produces faster, more accurate eye movements; these changes are facilitated via increases in dopaminergic transmission within the basal ganglia.

Objectives: The purpose of the current study was to adapt a visually-guided saccade task to measure the effects of reward expectation on oculomotor behavior in ASD and measure associations with core and co-occurring features of ASD. We hypothesized that reward contingencies would lead to faster saccades in both autistic and age-matched neurotypical (NT) control participants, but that autistic participant would show attenuated changes that were more variable across individuals.

Methods: We studied N=19 autistic adolescents and N=23 age- and sex-matched NT controls. Participants were instructed to look to the peripheral target as quickly as possible (saccade). Participants could earn points for looking to the target quickly (indicated by a green circle preceding the block of trials). Points were later converted to money; participants did not know the conversion rate. Trials were blocked into no-reward (2) and reward (2). Reward criteria: During the first block of trials (no-reward), saccade latencies were collected. On subsequent reward trials, points would be awarded (green checkmark) if the saccade latency was shorter than the median latencies collected during the first block. We estimated this would allow for participants to earn reward roughly 50% of the time.

Results: Across groups, saccade latency and latency variability were reduced during reward vs. no-reward trials. Autistic participants showed greater changes in saccade velocity (controlling for amplitude) during reward vs. no-reward trials, relative to NT controls. Among autistic participants, increased saccade velocity during reward relative to no-reward trials was associated with greater executive function difficulties. Similarly, greater improvements in latency variability on reward relative to no-reward trials were associated with greater executive function difficulties and reduced cognitive flexibility.

Conclusions: Reward expectation yielded similar changes in oculomotor behavior across ASD and control groups, suggesting that reward-motor integration is intact in autism. Changes in saccade velocity have been linked directly to changes in dopaminergic transmission, reflecting enhanced response to reward cues. Consistent with dopaminergic hypotheses of ADHD-type symptoms, we found that greater impairments in executive function (i.e., initiating, planning, and completing tasks) were associated with greater response to reward contingencies (increased saccade velocity), suggesting that extrinsic reward cues may be effective for modifying behaviors. Reductions in latency variability during rewarded conditions likely arise from increased attention to task-relevant information, resulting in more consistent initiation of saccades. Similarly, our finding that reward-associated latency variability changes were greater in autistic individuals who exhibited more difficulties with executive function and reduced cognitive flexibility suggests that reward may help these individuals inhibit attention to task-irrelevant information to improve task performance.

432.222 Self-Perceptions of the Impacts of Selective Eating in Young Adults**R. A. Rivera** and **L. Bennetto**, *Psychology, University of Rochester, Rochester, NY*

Background: Young adulthood presents a crucial time in development to study eating experiences, as many emerging adults begin to transition to greater independence and become more autonomous in making decisions about their health and well-being. In particular, young adults who live away from home have less mealtime influence from parents and greater influence from peers, personal preference, sensitivities, or other behavioral factors. Additionally, research has shown that selective eating can generally confer additional risk for mental health concerns and well-being among the general population. Finally, autistic adult self-advocates have highlighted eating concerns and sensory sensitivities as important areas of research.

Objectives: This study aimed to examine the nuances of eating experiences amongst autistic and non-autistic young adults by assessing (1) group differences on four aspects of selective eating (i.e., food neophobia, individual food selectivity, food quality selectivity, and Avoidant/Restrictive Food Intake Disorder [ARFID] symptoms) and (2) self-perceptions of the impacts of food preferences and eating behaviors on four domains of daily life (e.g., social life, physical health, mental health, logistics/financial well-being).

Methods: The sample comprised 416 autistic and non-autistic young adults aged 18-27 ($M = 20.2$), who were recruited through a variety of sources including community-based groups, online research databases, social media, and university undergraduates. All participants completed included a series of online questionnaires and standardized measures assessing multiple domains: food preferences and eating experiences, autistic traits, mental health (e.g., anxiety and depressive symptoms), BMI, and their perceptions on how their eating experiences positively and/or negatively impacted different domains of their life.

Results: ANOVAs on food selectivity showed that autistic young adults reported greater food selectivity across all four measures compared to non-autistic young adults (all $ps < .001$). Notably, 42% of the autistic group endorsed clinically significant restrictive eating the compared to 9% of the non-autistic sample. Autistic young adults also reported greater depressive symptoms, anxiety symptoms, and higher body mass index (all $p < .001$) compared to non-autistic participants. Of note, increased food selectivity (across all four measures) was significantly correlated with higher anxiety and depressive symptoms (all $ps < .001$), but not with BMI. Chi-square tests suggested that autistic young adults were more likely to report that their food preferences and eating behaviors impacted their social life ($p < .001$) and meal planning and financial well-being ($p < .001$). For those who reported an impact of their eating experiences, over half of the autistic young adults reported at least "somewhat" negative impacts across all four domains.

Conclusions: This study expands our understanding of eating experiences among autistic and non-autistic young adults by assessing outcomes and perceived impacts related to food preferences and eating behavior. This is a critical first step in identifying who may be at risk for more significant outcomes related to eating concerns beyond childhood. Moreover, this can help educate providers on the importance of proactively addressing concerns related to food selectivity in young adulthood.

432.223 Sensory Atypicality, Internalizing and Externalizing Problems in Children with ASD**M. W. A. Lam¹**, **P. W. Leung²** and **O. Wong³**, *(1)Department of Psychology, Department of Psychology, The Chinese University of Hong Kong, Hong Kong, Hong Kong, Hong Kong, (2)Department of Psychology, The Chinese University of Hong Kong, Hong Kong, Hong Kong, Hong Kong, (3)Department of Psychiatry, Department of Psychiatry, The Chinese University of Hong Kong, Hong Kong, Hong Kong (China)*

Background: Since the incorporation of sensory atypicality as a core symptom of Autism Spectrum Disorder (ASD), there has been an increasing interest in their associations with other ASD symptomology, and co-occurring emotional and behavioural problems. However, the interplay among these factors remains inconclusive. Additionally, . Yet, the broader range of internalising and externalising problems is seldom examined. The understanding of how these factors interact would be crucial for informing treatment development and support for ASD children and their caregivers.

Objectives: This study aimed to elucidate the relationships between sensory atypicality, emotional and behavioural problems in children with ASD.

Methods: Data from 749 children with ASD of normal intelligence (male:female ratio = 6.88:1; mean age = 7.89 years) were analysed. Participants were recruited from the Children and Adolescent Psychiatry Clinic of a university teaching hospital. Caregivers completed three instruments: the Social Responsiveness Scale (SRS-2), the Sensory Experience Questionnaire (SEQ), and the Child Behaviour Checklist (CBCL). Path analysis was conducted to examine the mediated relationships between sensory response patterns, ASD symptoms, and internalizing and externalizing problems. **Results:** Our final model demonstrated good fit ($\chi^2(8) = 24.220$, $p = .002$; CFI = .992, SRMR = .030, RMSEA = .053). Results revealed that sensory hyper-responsiveness and hypo-responsiveness indirectly affected internalizing and externalizing problems through social communication impairment and restricted/repetitive behaviours. Specifically, both hypo- and hyper-responsiveness exhibited similar patterns of indirectly influencing internalizing problems through both social communication ($p < .001$), and externalizing problems through restricted/repetitive behaviours ($p < .001$). In contrast, sensory seeking directly influenced externalizing problems ($p < .001$), with restricted/repetitive behaviours also serving as an indirect pathway ($p < .001$).

Conclusions: Given the interlinkage between sensory atypicality, core ASD symptoms, and co-occurring psychopathology in ASD children, our findings suggested a potential shared mechanisms underpin these clinical symptoms. While hypo- and hyper-responsiveness exerted a generalised impact on both internalizing and externalizing problems, sensory seeking behaviours specifically linked to externalizing problems. Our study highlights the importance of addressing sensory issues in ASD interventions. Thus, tailored, integrated intervention approaches combining social skills training, behavioural therapy, and strategies to manage sensory atypicality may effectively mitigate common co-occurring psychopathology in children with ASD.

**432.224 Sensory Differences and Their Consequences: Relating Neural Signals of Auditory Habituation to Behavior in Autism****K. A. McNair¹**, **Y. Braverman²**, **D. Senturk³** and **A. R. Levin⁴**, *(1)Boston Children's Hospital, Boston, MA, (2)Neurology, Boston Children's Hospital, Brookline, MA, (3)UCLA, Los Angeles, CA, (4)Neurology, Boston Children's Hospital / Harvard Medical School, Brookline, MA*

Background: Up to 70% of autistic people will experience auditory processing (AP) difficulties in their lifetime (Williams et al., 2021). Differences in AP have been linked to many common behavioral and social challenges, such as sound tolerance and speech affect recognition. These differences are largely recognised to have a neurobiological basis, specifically, atypical cortical processing following sound.

Electroencephalography (EEG) offers precise insight into cortical AP over time. EEG measures of AP in autism, however, are characteristically heterogeneous, with hyper- and hypo-sensitivity reported. Similarly, sensory behaviors exhibited by autistic people are diverse. In the pursuit of biomarkers for autism which reliably predict behavior, work is needed to investigate individual differences in EEG measures and how they relate to behavioral outcomes.

Objectives: We pair a novel auditory habituation paradigm with electroencephalography (EEG) to investigate (a) event-related potential (ERP) habituation in the P100 component in autistic and typically developing (TD) children, and (b) how individual differences in P100 habituation relate to behavior.

Methods: 44 3- to 4-year-old children (24 TD, 20 autistic children) were presented with 50 groups of five 50ms 1000Hz tones, separated by 700ms of silence. EEG was continuously recorded with a 128-channel EGI Geodesics net. Data were pre-processed using EEGLAB functions. P100 amplitudes following each tone were computed from Cz and two neighboring electrodes. A linear regression was conducted for each participant with P100 amplitude as the dependent and tone number (1-5) as the independent variable, and standardized β coefficients (slopes) were extracted. We interpreted negative slopes as habituation. Each participant was also administered a Sensory Assessment for Neurodevelopmental Disorders (SAND). Data collection is ongoing (target N = 60). 19 TD children and 11 autistic children have validated SAND scores which were used for the reported analyses, with remaining scores to be validated.

Results: Preliminary analyses reveal smaller slopes in TD children ($M = -0.14$, $SD = 0.42$) relative to autistic children ($M = 0.23$, $SD = 0.51$), $t(37.06) = -2.58$, $p = .014$. 30% of autistic children (6) and 62.5% of TD children (15) demonstrated negative slopes, and were classified as 'habitutors'. An exploratory ANOVA revealed that, in the autism group, sensory seeking scores were higher in 'habitutors' ($M = 7.25$, $SD = 2.22$) compared to 'non-habitutors' ($M = 3.71$, $SD = 3.20$), with a trend toward significance $F(1,9) = 3.76$, $p = .084$, $\eta^2 = 0.29$. This relation was insignificant for TD children ($p = .743$).

Conclusions: Our results demonstrate P100 habituation in TD children, with no consistent habituation and a positive average slope (i.e., facilitation), in autistic children. Efforts to link individual differences in P100 slopes to behavioral measures are continuing, with promising early evidence that P100 habituation slopes are uniquely linked to sensory seeking behaviors in autism. Our findings offer exciting opportunities for both forward translation, by connecting EEG measures to meaningful outcomes for families and clinicians, and back translation, by connecting to animal-model habituation studies examining underlying brain mechanisms such as excitatory/inhibitory balance in short term synaptic plasticity (Seay et al., 2020).

432.225 Sensory Processing and Emotional Dysregulation in Autistic and Nonautistic Students: Preliminary Insights on the Potential Role of Classroom Environment

C. Parks¹, N. J. Sparapani², A. Dimachkie Nunnally³ and S. L. Birkeneder¹, (1)School of Education, University of California, Davis, Davis, CA, (2)UC Davis MIND Institute, University of California, Davis, Sacramento, CA, (3)UC Davis MIND Institute, M.I.N.D. Institute, UC Davis, Sacramento, CA

Background: While sensory processing difficulties are associated with emotional dysregulation among autistic students (e.g., Little et al., 2017), less is known about the role of classroom environments in shaping this relationship. Emotional dysregulation, a mismatch between students' physiological arousal and the environment, can negatively impact classroom learning and engagement (Howe & Staggs, 2016; Sparapani et al., 2016).

Objectives: This study examined group differences between autistic and nonautistic students in the associations between sensory processing as measured by the individual domains of the Sensory Profile-2 (SP2; Parham et al., 2021), emotional dysregulation as measured by the *Classroom Measure of Active Engagement* (Sparapani et al., 2016), and the quality of the classroom environment as measured by the *Quality of Classroom Learning Environment* (QCLE; Connor et al., 2014).

Methods: 82 students (41 autistic, 41 non-autistic) were recruited from a 4-year exploration study examining inclusion of neurodivergent students within general education classrooms (R324A210288). Students ($M = 6.46$, $SD = 1.29$) ranged between TK and 5th grade and were from diverse ethnic, racial, and linguistic backgrounds. Teachers completed a battery of questionnaires, and video observations of academic lessons were collected. Trained observers coded emotion regulation using the *CMAE* and three dimensions of the classroom environment (differentiation, organization, responsiveness) using the *Q-CLE* within a 20-minute video sample. Interrater agreement between observers was above 80% for all dimensions. Spearman's correlations were used to examine associations between sensory processing and emotion dysregulation.

Results: Preliminary findings from a sample of 48 students (21 autistic, 27 non-autistic) are reported. Scores on the Q-CLE ($M = 9.67$) ranged between 5 and 16, with higher scores indicative of higher quality learning opportunities. On average, autistic students spent 28% ($M = 5.57$ mins; $SD = 4.41$) of the sampled time in a dysregulated state; non-autistic students spent 14% ($M = 2.83$ mins; $SD = 2.51$) of the time in a dysregulated state. These findings were significantly different ($p < 0.05$). We observed differences in sensory processing skills between autistic and non-autistic students, with autistic students exhibiting more sensory processing difficulties. See Table 1. Finally, we observed moderate, positive correlations between dysregulation with auditory sensitivity ($r = 0.370$, $p = 0.021$), visual sensitivity ($r = 0.320$, $p = 0.047$), and touch sensitivity ($r = 0.359$, $p = 0.025$). See Table 2.

Conclusions: This study provides a preliminary look at emotion regulation and sensory processing within general education classrooms, outlining significant differences between autistic learners and their non-autistic peers. The nonsignificant associations between emotion dysregulation and sensory processing by group may be due to the small sample size, warranting further analysis. Future analyses will include a larger sample to examine the moderating effect of classroom environment on the relationship between sensory processing and emotional dysregulation, with the hypothesis that sensory-friendly, structured classrooms can buffer against sensory-induced dysregulation in autistic students.

432.226 Sensory Profiles in Children with Neurogenetic Syndromes and Their Relation to Social Impairment

E. McLaughlin and B. L. Kelleher, Psychological Sciences, Purdue University, West Lafayette, IN

Background:

Sensory profiles are measured through processing patterns including hyporesponsiveness and hyperresponsiveness. Sensory processing difficulties, present in 74% of children with autism spectrum disorder (ASD), are a diagnostic feature of ASD, present as early as 6-months of age, and may predict later social communication deficits (Kirby et al., 2022). Children with neurogenetic syndromes (NGS) often show ASD symptoms, including sensory and social communication deficits. However, while children with NGS have social and sensory profiles similar to children with ASD, the similarities and differences in the neurodevelopmental pathways of sensory processing and social communication between ASD and NGS groups has yet to be examined in early childhood.

Objectives:

This study aims to identify the proportion of atypical sensory profiles in children with NGS, and how they differ from those of typically developing (TD) children. Secondarily, we aim to examine the extent to which sensory profiles relate to social impairment within NGS groups.

Methods:

Data from caregivers of three-year-old ($M=41.59$, $sd=3.33$) children with NGS ($n=139$) and TD children ($n=46$) were subselected from a longitudinal study of early phenotypes. NGS groups included Angelman Syndrome (AS; $n=36$), Williams Syndrome (WS; $n=33$), Fragile X Syndrome (FXS; $n=21$), Down Syndrome (DS; $n=23$), and Prader Willi Syndrome (PWS; $n=26$). Here, we examine cross-sectional sensory and social profiles through the Sensory Experiences Questionnaire (SEQ; Baranek, 2006) and the Social Responsiveness Scale (SRS; Constantino & Gruber, 2012).

Results:

Depicted in Figure 1, atypical sensory profiles were present across all groups, including TD controls (AS=52.8%, WS=48.5%, FXS=33.3%, DS=21.7%, PWS=11.5%, TD=13%), at rates statistically greater than 0 ($p's<.001$). Significant differences of sensory profiles from TD children presented in AS, FXS, and WS. For Total SEQ scores, AS ($M=75.67$, $sd=14.93$), FXS ($M=70.52$, $sd=14.27$), and WS ($M=73.27$, $sd=13.56$) were higher than TD ($M=57.76$, $sd=11.85$) ($p's<.001$). Similarly, hyporesponsive SEQ scores in AS ($M=12.03$, $sd=4.16$) and WS ($M=9.723$, $sd=2.32$) were higher than TD ($M=7.96$, $sd=2.23$) ($p's<.001$). Hyperresponsive SEQ scores in WS ($M=31.12$, $sd=6.76$) were higher than TD ($M=25.63$, $sd=5.78$) ($p=0.001$). A chi-squared analysis (Table 1) of SRS and SEQ scores revealed significant associations between categorically elevated SRS and total ($X^2(1)=27.98$, $p<.001$), hyperresponsive ($X^2(1)=8.57$, $p=0.003$), and hyporesponsive ($X^2(1)=22.42$, $p<.001$) SEQ scores.

Conclusions:

Sensory processing difficulties are common in children with AS, WS, and FXS, although at lower rates than in ASD according to the literature. This study examined the degree to which these atypical profiles present in early childhood across NGS. While atypical profiles were present in DS and PWS, groups did not differ from TD children on this measure. This indicates that either (1) the SEQ may not capture sensory difficulties across all NGS groups, or (2) temporal emergence of sensory processing difficulties occurs non-linearly across NGS, with some groups appearing typical in early childhood. We also found that sensory processing difficulties in NGS were associated with ASD symptomology across total, hyperresponsive, and hyporesponsive SEQ scores, indicating potentially similar developmental associations between sensory processing and social communication. Future research may identify whether interventions developed for ASD are appropriate and effective for NGS groups, given potentially unique early developmental trajectories.

**432.227 Sensory Response Pattern Trajectories in Children 2-12 Years with and without Autism**

Y. Tang, A. Flores, J. Lisle, K. Hayes, J. Sideris and G. T. Baranek, Chan Division of Occupational Science and Occupational Therapy, University of Southern California, Los Angeles, CA

Background: Four sensory response patterns are commonly reported by caregivers of autistic children ages 2-12 years: Hyperresponsiveness (HYPER) involves aversive or avoidant responses to stimuli; Hyporesponsiveness (HYPO) involves delayed or absent responses to stimuli; Sensory Interests, Repetitions, and Seeking Behaviors (SIRS) are characterized by an intense fascination or interest in specific sensory stimuli; and Enhanced Perception (EP) involves heightened discrimination or finer acuity in perceiving sensory stimuli (Ausderau et al., 2014; Baranek et al., 2014). The Sensory Experiences Questionnaire Version 3.0 (SEQ-3; Baranek, 2009) assesses these patterns, validated in the autistic sample, and demonstrated stability over three years (Baranek et al., 2019). Despite the strong construct and discriminant validity studies in the literature, age-related developmental changes in each sensory pattern remain unclear. Further, developmental trajectories need to be tested more definitively across autistic and non-autistic groups to establish whether differences exist in the rate or shape of change across the four sensory response patterns. We hypothesize that the four sensory response patterns may follow distinct trajectories in the two groups. Mapping developmental trajectories has important clinical implications for assessment and intervention planning.

Objectives: To examine how sensory response patterns change across age, and test group differences between autistic and typically-developing (TD) children ages 2-12 years in a large national sample.

Methods: Participants ages 2-12 years (N=2087) were pooled from three studies that collected caregiver-reported SEQ-3 data as part of their larger battery. A total of 1,271 autistic children (mean age: 7.4 years) and 816 TD children (mean age: 7.0 years) were aggregated. The final analysis included 2,099 SEQ-3.0 measurement points for autistic children and 840 for TD children; each child had at least one, and no more than four, SEQ-3 measurements. SAS PROC MIXED models tested linear (age), quadratic (age²), and cubic (age³) models of age, as well as tests of group interactions for each of the four sensory response patterns. Model-estimated scores for each sensory response pattern from ages 2 to 12 were generated and graphed for models that were significant ($p < .05$).

Results: As compared to TD, autistic children had significantly higher scores across all four sensory response patterns (see Table 1). The group X age interaction was significant for SIRS ($p=0.03$), HYPO ($p < 0.01$) and EP ($p=0.03$), indicating that the slope and the shape of these three patterns differed between the two groups over age (see Figure 1). However, slopes and shapes for the groups followed a similar trajectory for HYPER. All four main effects of age (linear) were significant; the quadratic effect was significant for EP.

Conclusions: These findings from a large pooled sample illustrate differences in the expected development across each of the four sensory response patterns from 2-12 years of age, and further, highlight how autistic and non-autistic children differ in their level and rate of change on some, but not all, variables. Longitudinal studies that systematically collect more timepoints across groups, and minimize potential cohort effects, are needed for replication; such research is critical to inform guideposts for clinical assessment and intervention efficacy.

432.228 Sensory Responses of Autistic Children to Environmental and Food-Related Stimuli in a Restaurant Setting

L. Rockers¹, K. Luu² and H. S. Seo¹, (1)Food Science, University of Arkansas, Fayetteville, AR, (2)Electrical Engineering & Computer Science, University of Arkansas, Fayetteville, AR

Background: Autistic children often face challenges in processing sensory inputs, which can significantly impact their daily experiences. In particular, food-related activities, such as dining out or grocery shopping, may pose significant difficulties due to over- or under-stimulation in public settings. There is a critical need for research to better understand how environmental sensory inputs (e.g., background sounds) affect autistic children in everyday public environments, such as grocery stores and restaurants.

Objectives: This study aimed to examine how autistic children respond to various environmental and food-related stimuli, specifically within the immersive context of a restaurant setting.

Methods: The sensory responses of autistic children (ASD) were compared with those of neurotypical children (NT) in an immersive restaurant environment. The study focused on their reactions to both auditory comfort and discomfort conditions. Thirty children, aged 7 to 14 years (15 ASD and 15 NT), participated in this study. They rated their liking of different food stimuli and used emojis to express their emotional responses to various samples and conditions.

Results: The ASD group rated their liking for a cocoa solution significantly lower than NT children under the comfort sound condition. In the discomfort sound condition, autistic children perceived the cocoa solution as significantly more intense compared to their neurotypical counterparts. Additionally, differences were observed between the groups in the use of emojis to express their feelings about the samples and conditions.

Conclusions: This study confirms that environmental factors, particularly background sound levels, can significantly influence the sensory responses of autistic children. The findings highlight the importance of creating sensory-friendly environments, especially in public spaces such as restaurants. These insights can guide foodservice businesses in designing more inclusive, comfortable experiences for autistic individuals.

432.229 Sex and Autism Diagnosis Moderate the Relationship between Anxiety and Repetitive Behaviors in School-Age Children

M. McAllister¹, J. Parish-Morris², J. F. Strang³ and C. Harrop⁴, (1)University of North Carolina Chapel Hill, Durham, NC, (2)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (3)Gender and Autism Program, Children's National Health System, Washington, DC, (4)Department of Allied Health Sciences, University of North Carolina - Chapel Hill, Chapel Hill, NC

Background:

Restricted and Repetitive Behaviors (RRBs) are a core feature of autism. They have also been found to consistently associate with anxiety in both autistic and non-autistic children (Keating et al., 2023; Sellick et al., 2021). Despite sex differences in both RRBs (Knutsen et al., 2019) and anxiety (Horwitz et al., 2023), the majority of prior research characterizing the relationship between RRBs and anxiety has been conducted with primarily male samples. It has been theorized that RRBs serve as an early manifestation of anxiety, but the moderating role of sex has not been sufficiently explored (Bird et al., 2024).

Objectives:

(1) evaluate sex differences in anxiety and RRBs cross-sectionally in autistic and non-autistic children, and (2) assess the moderating role of sex and autism diagnosis in the relationship between anxiety and RRBs.

Methods:

Data were collected for 105 autistic (ASD) and 104 non-autistic (NA) children aged 4-8 years ($M=6.5$, $SD=1.5$) enrolled in an accelerated longitudinal design observational study (estimated N by Spring 2025 = 280). The sample includes roughly equal representation by assigned sex in both autistic (ASD; $M=57$, $F=48$) and non-autistic (NA; $M=48$, $F=56$) groups. RRBs and anxiety were assessed through parent-report on the Repetitive Behavior Scales-Revised (RBS-R; Lam & Aman, 2007) and the Parent-Rated Anxiety Scale for Youth with Autism Spectrum Disorder (PRAS-ASD; Scahill et al., 2019).

Results:

There was a main effect of diagnosis, with autistic children having higher rates of anxiety, $F(3,205)=81$, $p<.001$, and RRBs, $F(3,205)=204$, $p<.001$. There was a main effect of sex on RRBs, with males having higher parent rated RRBs, $F(3,205)=6.5$, $p<.05$. There was no main effect of sex for anxiety, although females had a non-significant trend towards higher anxiety, $F(3,205)=1.9$, $p=.17$. The interactions between sex and diagnosis were not significant for anxiety, $F(3,205)=2.3$, $p=.13$, nor RRBs, $F(3,205)=.93$, $p=.34$.

A three-step hierarchical linear regression was conducted to evaluate how sex and diagnosis moderate the relationship between anxiety and RRBs. In step one, anxiety significantly predicted RRBs (Table 1). In step two, adding sex and diagnosis as predictors significantly improved the model fit, $\Delta R^2=.19$, $F(2,207)=57$, $p<.001$, with both sex and diagnosis showing a significant effect (Table 1). In step three, interaction terms between anxiety and sex, $b=-.3$, $t(204)=-2.7$, $p<.01$, and anxiety and diagnosis, $b=-.27$, $t(204)=-1.8$, $p<.1$, were included, further improving the model fit $\Delta R^2=.014$, $F(2,207)=5.2$, $p<.05$, and indicating that the relationship between anxiety and RRBs was moderated by sex and diagnosis (Figure 1).

Conclusions:

Replicating prior research, we found that RRBs are more prominent in autistic males than autistic females. Moderation analyses indicate that the association between anxiety and RRBs is moderated by both sex and diagnosis, such that autistic males with high anxiety also have more RRBs than autistic females with equivalent levels of anxiety. Taken together, these results indicate that RRBs may not serve the same function in autistic females, or that anxiety manifests differentially in females, and less through observable behaviors such as RRBs, potentially indicative of camouflaging in autistic females.

432.230 Special Interests in Autistic Adults Are Wide-Ranging and Intellectually Oriented

C. L. Caldwell-Harris, *Psychological and Brain Sciences, Boston University, Boston, MA*

Background:

Special interests are referred to as circumscribed, narrow, and intense. Intense interests among children disrupt family life, interfere with socialization, and impair classroom learning. Yet, why do autistic individuals have intense interests? Current theories mention demand avoidance, self-regulation, and providing a foundation for careers.

Objectives:

How autistic adults describe their intense interests when communicating with other autistic adults was pursued by analyzing online discussion forums.

Methods:

A corpus of 300 posts from 8 discussion forums was compiled by undergraduate research interns, blind to hypotheses of the study, in a systematic manner which disallowed cherry-picking of posts. Forum users posted and responded to broad questions such as "What are your special interests?" and "What is your current hyperfixation?"

Content analysis was guided by four questions.

- What are the types of interests, their range, and their frequencies?
- Did special interests serve the purpose of self-regulation or escaping demands?
- Did interests provide opportunities for systemizing and knowledge acquisition?

Were interests restricted, intense, or idiosyncratic?

Results:

A striking result was the unexpectedly high preponderance of academic topics in posters' special interests, amounting to 40% of all interests. Word counts did not support self-regulation and escape as salient functions (see Table).

Posters frequently described a broad topic and a more specific interest within that, as is characteristic of academic scientists, as illustrated in this quote: "I can spend hours reading about cell biology, endlessly fascinated. My latest hyper fixation, however, was about a protein called focal adhesion kinase, and I spent hours learning everything I could about it and figuring out how it would look like in a cell visually, so I drew lots of diagrams."

It was natural to divide the academic interests into the conventional categories of Social Sciences, Humanities, and Natural Sciences; however, topics related to Psychology and Sociology dominated. Posters mentioned the appeal of studying people's lives without engaging with them, of learning about the psychology behind narcissists, and of researching late diagnoses of autistic women. Some posters were explicit that reading psychology research helped them understand others and how to fit in.

Among history, culture, and literature, posters frequently mentioned highly specific topics, such as Gothic Literature, Queer Women's History, and Recipes from the Depression Era. Even for the 60% of interests that were categorized as non-academic topics, posters described using their interest in ways that support knowledge seeking and systemizing. For example, one poster pursued entertainment media like an academic topic, as in "I asked for a book with all the episodes and summaries and quotes..." One-quarter of posts were coded as demonstrating a wide-ranging intellectual appetite. This code indicated the presence of four or more knowledge-heavy interests from different intellectual domains. Several posters labeled "learning itself" as their special interest.

Conclusions:

More than merely having talents in circumscribed areas, autistic adults demonstrated a preoccupation with knowledge-seeking, similar to that of scientists and academics. Technological changes will mandate life-long learning, positioning autistic adults to be able to make substantial contributions to society.

432.231 Speed-Accuracy Trade-Offs in Motion Coherence Processing in Autistic and Non-Autistic Children

L. J. Thomas¹, M. Laird¹, H. Yusuf^{1,2}, G. Scerif³, G. Taylor⁴, N. J. Evans^{4,5} and C. Manning^{1,6,7}, (1)University of Reading, Reading, Berkshire, United Kingdom, (2)Birkbeck, London, London, United Kingdom, (3)Experimental Psychology, University of Oxford, Oxford, Oxfordshire, United Kingdom, (4)University of Queensland, Brisbane, QLD, Australia, (5)University of Liverpool, Liverpool, Merseyside, United Kingdom, (6)Department of Experimental Psychology, University of Oxford, Oxford, Oxfordshire, UNITED KINGDOM, (7)School of Psychology, University of Birmingham, Birmingham, West Midlands, United Kingdom

Background: Multiple previous studies have found reduced sensitivity in motion coherence tasks in autistic relative to typically developing participants. Previous research using other perceptual decision-making tasks has also found differences in speed-accuracy trade-offs, with autistic individuals emphasising accuracy over speed. However, we recently applied a drift-diffusion model to motion coherence task data to examine the processes underlying task decisions, and did not find conclusive evidence for differences in speed-accuracy trade-offs between autistic and non-autistic children, as measured by the boundary separation parameter. Boundary separation reflects how much evidence needs to be accumulated before making a decision, with wider boundary separation indicative of prioritising accuracy over speed. These differences in findings between studies may, in part, be due to differences in task instruction.

Objectives: We aimed to determine whether there was a difference in autistic and non-autistic children's ability to adjust their speed-accuracy trade-offs based on instruction, and to examine differences in boundary separation between groups.

Methods: We conducted a pre-registered study with a rigorous blinded analysis approach and have completed data collection, with 50 autistic and 50 non-autistic participants aged 6 to 14 years in the final sample. We applied hierarchical Bayesian drift-diffusion models to examine differences across versions of a child-friendly motion coherence task: with children asked to either emphasise speed, or accuracy. Here, we are reporting preliminary analyses based on a subset of diagnosed autistic ($n = 22$, male = 14, female = 8) children, matched as closely as possible on age and full-scale IQ with children with no diagnosed developmental conditions ($n = 22$, male = 14, female = 8). For these preliminary analyses, posterior mean estimates for boundary separation, and the posterior mean difference in boundary separation between speed and accuracy conditions were extracted from the fitted data for each participant. Differences were examined using one-way ANCOVAs, controlling for full-scale IQ.

Results: Models showed good convergence and fit. Preliminary analyses revealed no significant group differences in posterior means for drift rate, boundary separation, or non-decision time. Posterior mean differences in parameters between the speed and accuracy conditions were also not significantly different between groups. This indicates that autistic and non-autistic children were able to modulate speed and accuracy when explicitly instructed, in a similar manner.

Conclusions: We show preliminary evidence of no difference in the ability of autistic and non-autistic children to modulate speed-accuracy trade-offs based on instructions. This indicates that the potential tendency of autistic children to respond cautiously can be modulated with explicit task instruction, which could explain previous mixed findings. Analyses on the full dataset will be used to confirm these results using Bayesian statistics to assess the strength of evidence. Further analyses will also consider the contribution of co-occurring ADHD traits on decision-making, and the ability to modulate responses. This is due to both the high degree of overlap between autism and ADHD, and previous research indicating differences in response caution in ADHD.

432.232 Tactile Hypo-Responsivity As a Potential Diagnostic Marker for Autism

G. Kadlaskar¹, R. McNally Keehn², R. N. Rozniarek³, N. P. Fujii³ and B. Keehn⁴, (1)Psychiatry & Behavioral Sciences, University of Nevada, Reno, Sacramento, CA, (2)Pediatrics, Indiana University School of Medicine, Indianapolis, IN, (3)Purdue University, West Lafayette, IN, (4)Speech, Language, and Hearing Sciences, Purdue University, West Lafayette, IN

Background: Differences in tactile reactivity are observed in autism and to some extent in children with other developmental concerns. Additionally, research has shown that differences in responding to touch are associated with autism symptom severity and adaptive skills. However, it is unknown whether differences in responding to touch may serve as a diagnostic marker of autism in children referred for developmental evaluation.

Objectives: To examine the utility of a tactile reactivity assessment in differentiating autistic children from those with other neurodevelopmental concerns, and to investigate the association between tactile responsivity, autism symptomatology, developmental level, and adaptive skills.

Methods: Participants included 151 children (108 autism [mean age 31 months], 43 non-autism [mean age 29 months]). Children were referred by community pediatricians for evaluation due to positive autism screening or concerns raised during developmental surveillance. Autism diagnoses were confirmed using the Autism Diagnostic Observation Schedule-2, Vineland Adaptive Behaviors Scale-3, DSM-5 caregiver interview, and expert clinical judgement. Children were administered the tactile portion of the Sensory Processing Assessment (SPA) designed to identify patterns of hypo-responsivity. The task included presenting children with social (shoulder tap) and non-social (air-puff) tactile stimulation while they played with a distractor toy until a clear behavioral response was observed or up to a maximum of three trials for each stimulus. Location (right/left) and order of stimuli was counterbalanced across participants. Possible orienting scores for each stimulus were 1, 2, 3 (consistent with the trial during which the child oriented), or 4 (no response). Measures of autism symptoms, developmental level, and adaptive behavior were also collected. Finally, exploratory analysis was conducted to examine whether engaging in sensory seeking behaviors during play could be associated with tactile responsiveness.

Results: Autistic children showed decreased orienting to both social and non-social touches compared to children in the non-autism group. The social touch responsivity had a sensitivity of 0.62 and a specificity of 0.76. The non-social touch responsivity had a sensitivity of 0.21 and a specificity of 0.93. The sensitivity for overall responsivity was 0.14 and the specificity was 1. For all children, reduced tactile responsivity was associated with greater autism symptomatology, adaptive functioning difficulties and lower developmental levels (all p -values < 0.01). Autistic children who engaged in sensory seeking behaviors showed reduced orienting tactile input.

Conclusions: Autistic children showed reduced orienting to both social and non-social touches compared to children with other developmental disabilities within the context of a brief tactile assessment. Children who did not respond to *both* social and non-social touches were more likely to be in the autism group. Additionally, reduced orienting to tactile stimuli was associated with higher autism symptomatology, and reduced verbal, non-verbal, and adaptive skills in all children. Finally, tendencies of seeking behaviors impacted orienting to external tactile cues within the autism group. These findings highlight the significance of considering touch as a potential biomarker of autism in young children referred for developmental evaluations.

432.233 Tactile Perception and Sensory Differences in Autistic Preschoolers

O. Ollari¹, Z. Gulbahce², J. Begum Ali³, L. I. Silva Abello⁴, K. L. Carpenter⁵, E. Loth⁶, T. Tavassoli⁷, E. Jones⁸ and N. A. Puts⁹, (1)Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology, and Neuroscience, King's College London, London, London, United Kingdom, (2)School of Psychology, University of Reading, Reading, reading, United Kingdom, (3)Centre for Brain and Cognitive Development, Birkbeck, University of London, London, United Kingdom, (4)Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology, and Neuroscience, King's College London, London, London, United Kingdom, (5)Department of Psychiatry and Behavioral Sciences, Duke University Medical Center, Durham, NC, (6)Department of Forensic and Neurodevelopmental Sciences, Flat 2, 116, South Hill Park, London, London, United Kingdom, (7)Centre for Autism, School of Psychology & Clinical Language Sciences, University of Reading, Reading, United Kingdom, (8)Centre for Brain and Cognitive Development, Birkbeck University of London, London, United Kingdom, (9)Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology & Neuroscience, King's College London, London, United Kingdom

Background:

Altered sensory reactivity is common in autism and can significantly affect daily life, often resulting in heightened distress and anxiety. Touch is the first sense to develop, shaping our understanding of the environment and form social bonds. Previous psychophysical studies have demonstrated that differences in low-level tactile perception are correlated with other clinical features of autism such as anxiety. Most prior work focused on older children or adults. However, sensory difficulties in early development can have tremendous cascading effects on higher-order behaviours.

Objectives:

Using highly novel tablet-based psychophysical assessments to measure perception in preschool children and questionnaire-based approaches, we test the relation between sensory measures and anxiety and autistic features. Based on preliminary findings, we determine whether objective measures of sensory processing in toddlers provide sufficient information to characterize individual sensory features and connect them to the severity of core and associated autism outcomes.

Methods:

Eight autistic and 18 non-autistic (12M, 14F; age = 56 ± 14 months) took part. Measures of low-level tactile perception were obtained through a novel tablet-based psychophysical detection task (as measured through reaction time, reflecting sensory gating; Figure A). Sensory differences were evaluated using the Sensory Assessment for Neurodevelopmental Disorders (SAND) reporting observed and parent-report ratings of hyper/hypo-reactivity and sensory seeking. Anxiety was measured gathered through The Spence Children's Anxiety Scale (SCAS). All children underwent standardized observation of autistic traits (ADOS).

Results:

Increased reaction times (RT) to tactile stimuli are associated with hypo-reactivity, ($\beta = 2.6$; $p = 0.01$), which in turn correlates with higher autistic traits (ADOS; $\beta = 0.5$; $p = 0.04$) and elevated anxiety ($\beta = 0.1$ $p = 0.007$) (Figure B). Additionally, significant group differences were observed across all measures (all $p < 0.05$), supporting the use of the current assessment tools for sensory stratification. Specifically, autistic children exhibited greater hyper- ($\beta = 7.5$; $p = 0.001$) and hypo-reactivity ($\beta = 10.6$; $p = 0.001$), as well as heightened sensory-seeking behaviours ($\beta = 12.1$; $p < 0.001$), compared to their non-diagnosed peers. Parents also reported higher anxiety levels in autistic children relative to the others ($\beta = 19.0$; $p = 0.001$). Furthermore, while females demonstrated less sensory-seeking behaviour than males ($\beta = -4.5$; $p = 0.03$), they exhibited higher anxiety levels ($\beta = 8.0$; $p = 0.03$), which appeared to be linked to hypo-reactivity to sensory stimuli ($\beta = 2.0$; $p = 0.04$).

Conclusions:

Overall, our preliminary results indicate that notable sensory differences can be detected using the sensory battery developed in this study, and in particular, that psychophysical tablet-based approaches are both applicable and meaningful in preschool children. This work highlights the potential for stratifying autistic phenotypes based on sensory profiles and the contribution of bottom-up differences in sensory gating to sensory reactivity, and potential cascading impact on anxiety. These insights will enhance our understanding of the individual variations in the expression of autistic behaviours and facilitate tailored support to improve mental health outcomes and develop novel experimental approaches for young children with neurodevelopmental approaches.

**432.234 Task-Specific Upper Extremity Movements in Autistic Children during Feeding Activities**

M. Shabani¹, H. L. Miller² and N. E. Fears¹, (1)School of Kinesiology, Louisiana State University, Baton Rouge, LA, (2)School of Kinesiology, University of Michigan, Ann Arbor, MI

Background: Clinically-significant motor difficulties are highly prevalent in autistic children, affecting over 80% of individuals. These motor difficulties significantly impact activities of daily living, including self-feeding, dressing, and handwriting. Previous research has shown motor differences between autistic and neurotypical individuals in motor planning (e.g., reaction time) and motor execution (e.g., movement time, spatial efficiency, movement smoothness). Although this lab-based research has provided rich information on motor planning and execution, this work has been used in restricted tasks with simple movements (e.g., gripping, pointing, pressing a button) that are difficult to translate to clinical settings.

Objectives: We explored the differences in motor planning and motor execution of complex hand movements during feeding tasks between autistic and neurotypical children.

Methods: We examined hand movements in 17 autistic (Male=15, Female=2, $M_{age}=10.2$ yrs, $SD_{age}=2.9$, $Range_{age}=5-14$) and 25 neurotypical (Male=14, Female=11, $M_{age}=8.76$ yrs, $SD_{age}=3.36$, $Range_{age}=4-14$) children during feeding-related tasks. Participants wore form-fitting suits with 30 reflective markers placed on anatomical landmarks of the head, torso, and upper extremities. We used a 3D motion capture system (120Hz) to track and analyze hand movement using a marker placed on the second metacarpal during two tasks: drinking from a cup and feeding with a spoon. We assessed reaction time (i.e. latency before movement initiation), movement time (i.e., time from movement start to until stopping at the mouth), path length (i.e., spatial efficiency of movement), and jerk cost (i.e., smoothness of movement).

Results:

Reaction Time. Preliminary results revealed a main effect of task ($\chi^2=5.46$, $p=.019$) qualified by an interaction of task and age ($\chi^2=8.25$, $p=.004$) such that participant's reaction times decreased as age increased for the cup task ($b=-0.015$, $SE=0.005$, Figure 1A).

Movement Time. Preliminary results revealed a main effect of task ($\chi^2=653.03$, $p<.001$) such that the cup task was shorter than the spoon-to-mouth task ($b=-0.333$, $SE=0.013$, Figure 1B). There was also a main effect of age ($\chi^2=653.03$, $p=.017$) such that movement time increased as age increased ($b=0.027$, $SE=0.0111$, Figure 1B).

Path length. Preliminary results revealed a main effect of age ($\chi^2=20.70$, $p<.001$) such that path length increased as age increased ($b=32.205$, $SE=7.078$, Figure 1C). There was also a main effect of task ($\chi^2=209.80$, $p<.001$) such that participants used shorter path lengths for the cup task compared to the spoon-to-mouth task ($b=-169.790$, $SE=11.722$, Figure 1C).

Movement Smoothness. Preliminary results revealed a main effect of task ($\chi^2=346.99$, $p<.001$) such that participants had lower jerk cost in the cup task compared to the spoon-to-mouth task ($b=-1.212$, $SE=0.065$, Figure 1D). There was also a main effect of age ($\chi^2=7.41$, $p=.032$) qualified by an interaction ($\chi^2=4.59$, $p<.032$) between group and age such that autistic participants jerk cost increased as age increased ($b=0.068$, $SE=0.032$, Figure 1D).

Conclusions: Autistic children exhibit unique motor planning and coordination challenges during everyday feeding tasks, potentially hindering their capacity to perform activities of daily living independently. These findings indicate that motor challenges in autism may vary depending on the specific task demands. Future research should further examine the role of jerk cost on autistic children's motor execution in ecologically-valid tasks.

432.235 Neurophysiology of Perceptual Closure Abilities in Autistic and Neurotypical Control Children

E. K. Bojanek, E. G. Freedman and J. J. Foxe, *The Ernest J. Del Monte Institute for Neuroscience, University of Rochester Medical Center, Rochester, NY*

Background: Visual perceptual differences are well documented in autism spectrum disorder (ASD); however, gaps remain in our understanding of the neurobiological mechanisms underlying these observable sensory behaviors. In this study, we examined how the visual system fills in missing information during incomplete viewing conditions. Autistic individuals tend to focus on local object features at the expense of the global picture, which may result in visual perception difficulties during incomplete viewing conditions. We examined this process using a perceptual closure paradigm during electroencephalography (EEG) recording. Using this paradigm, our group previously identified a specific event-related potential (ERP) component, the closure negativity (N_{cl}), which reflects the process by which fragmented elements of complex objects are gradually filled-in, thus indexing the perceptual closure process.

Objectives: This study aims to define the neurophysiological underpinnings of the perceptual closure process in neurotypical development and examine whether there are global visual perception disruptions in autistic children.

Methods: Data collection is ongoing. Currently 11 autistic children and 14 neurotypical (NT) control children, ages 7-17 years have completed the perceptual closure paradigm during EEG recording. Participants are shown a series of image sets consisting of 8 images of progressively greater fragmentation. Images are presented from least complete (image 8) to most complete (image 1). Participants indicate whether they can identify the image; following identification, the image set is terminated. We examined the amplitude of the closure negativity (N_{cl}) and the P1 component at the level of the image identification (ID) and 3 levels prior. We also examined the accuracy of image identification and the mean level of image identification.

Results: Preliminary results show that there is an emerging N_{cl} in both groups, particularly in older participants. Autistic participants showed a greater P1 amplitude than NT controls across the ID and 3 prior levels. Regarding behavioral performance, NT controls were significantly more accurate in their image identification than autistic participants. However, ASD and NT control participants did not differ in their mean ID level for correct trials (level 3).

Conclusions: Overall, we found that neurotypical children are more accurate in their identification of fragmented images compared to autistic children. However, autistic and neurotypical children show no differences in the identification level suggesting a similar level of information is required to "close" or accurately perceive the object. Our preliminary results show an emerging N_{cl} in both the autistic and neurotypical children suggesting that perceptual closure abilities may reach adult levels later in development. We also found that both groups show greater modulation within the P1 component, which has not previously been observed in adults. However, the autistic participants showed a greater modulation of P1 and a greater P1 amplitude than NT controls across all levels examined. This finding may suggest a different process of object identification for children than adults and may suggest that autistic children interpret each fragmented image as different objects rather than interpreting the image set as a perceptual whole. Further examination is necessary to understand the development of local-global object perception in autistic children.

432.236 The Hotter the Better: A Large-Scale, Cross-Sectional Study of Associations between Body Temperature and Language, Nonverbal IQ, and Stereotyped Behaviors in Autistic Children Beyond the Fever Effect

W. S. Neo and E. Neuhaus, *Department of Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA*

Background: Some autistic children exhibit transient behavioral improvements during fever. Children who reportedly improve with fever are significantly more likely to be minimally verbal, have lower nonverbal IQ (NVIQ), and show more stereotyped behaviors. The behavioral benefits of fever are postulated to result from two mechanistic pathways: immune response and increased body temperature itself. However, it remains unclear whether temperature in the non-fever range is associated with previously identified child characteristics. Additionally, studies have yet to identify which and how long stereotyped behaviors are related to temperature.

Objectives: Modeled after Grzadzinski et al. (2018), we examined associations between body temperature and language level, NVIQ, and stereotyped behaviors; we broadly expected positive effects of higher temperatures. We further explored relationships between temperature and two stereotyped behaviors (unusual sensory interests; hand/finger/complex mannerisms) across three timeframes (concurrent; recent; lifetime).

Methods: Participants were 1,213 autistic children from the Simons Simplex Collection (86.5% male; mean age: 9.05 years) who completed cognitive testing and the ADOS-2. They also completed a temperature protocol on the day of the ADOS-2, involving three separate measurements (30 seconds apart) of body temperature; for each participant, we calculated mean body temperature. To explore how temperature may be related to stereotyped behaviors measured at different timescales, we leveraged individual items universally measured on the ADOS-2 (concurrent), RBS-R (recent), and ADI-R (lifetime): unusual sensory interests and hand/finger/complex mannerisms. Participants' parents completed the RBS-R, which contained a Stereotyped Behavior subscale that assessed behaviors they observed in the past month, and ADI-R, which included codes to represent various stereotyped behaviors that had ever occurred. Individual items were dichotomized to indicate the absence or presence of the stereotyped behavior.

Results: ADOS-2 modules 1, 2, 3/4 were administered to 22.9%, 21.0%, and 56.1% of participants, respectively. Across the sample, participants varied in NVIQ ($M=81.9$, $SD=27.6$). Stereotyped Behavior subscale scores spanned the entire possible range (0-18; $M=4.77$, $SD=3.51$). Consistent with predictions, temperature differed across ADOS-2 modules ($F=3.73$, $p=.024$), with participants using fluent speech ($M=98.55^{\circ}\text{F}$) having significantly higher temperatures than minimally verbal participants ($M=98.43^{\circ}\text{F}$; $p=.020$). As expected, temperature and NVIQ were positively correlated ($r=.09$, $p=.002$). While in the predicted direction, temperature was negatively but not significantly related to Stereotyped Behavior subscale score ($r=-.03$, $p=.296$). Exploratory analyses revealed that temperature was significantly higher in children without ($M=98.60^{\circ}\text{F}$) than with ($M=98.49^{\circ}\text{F}$) recent unusual sensory interests ($t=2.42$, $p=.016$); temperature did not differ between children with or without concurrent ($t=0.09$, $p=.927$) or lifetime ($t=0.07$, $p=.942$) unusual sensory interests. In contrast, temperature did not differ significantly on the basis of concurrent ($t=1.33$, $p=.185$), recent ($t<1.45$, $ps>.149$), or lifetime ($t<0.17$, $ps>.868$) use of hand/finger/complex mannerisms.

Conclusions: This study highlights that body temperature in the non-fever range is significantly related to language level, NVIQ, and recent unusual sensory interests, extending prior work that documented behavioral improvements during fever in some autistic children. Future work may adopt longitudinal study designs (e.g., repeated temperature measurements and stereotyped behavior occurrences) to determine individual-specific associations, potentially laying the foundation for personalized, temperature-informed supports of challenging behaviors in autism.

432.237 The Impact of Gender on the Relationship between Autism Diagnostic Status and Selective Eating

N. N. Soогоor, R. A. Rivera and L. Bennetto, Psychology, University of Rochester, Rochester, NY

Background: Selective eating is a common occurrence that can lead to consequences such as obesity, mental health concerns, and eating disorders. Research has shown that selective eating is more prevalent in autistic children than non-autistic children; however, few studies have investigated this pattern in young adults. Young adult eating concerns often center around eating disorders, such as anorexia nervosa, bulimia nervosa, and a new DSM-5 disorder, avoidant/restrictive food intake disorder (ARFID). Emerging research has examined these eating disorders as well as broader eating behaviors, like selective eating, in young adults. There are some established gender differences in eating disorders with the greatest evidence supporting that women and girls have increased disordered eating in relation to body image. Less work has examined gender differences in ARFID or selective eating more broadly. The available research with children and adolescents suggests a higher rate of ARFID among boys compared to girls. Additionally, there may be gender-specific patterns of characteristics in ARFID, with girls being more likely to experience nutritional insufficiencies due to food selectivity, and boys more likely to refuse eating due to sensory sensitivities. Importantly, no studies have assessed gender-based differences in young adulthood. Furthermore, studies have yet to look at specific gender differences in selective eating behaviors in autistic and non-autistic young adults.

Objectives: Our study assessed gender-based differences in selective eating patterns in autistic and non-autistic young adults.

Methods: A sample of 425 autistic and non-autistic young adults (76.2% female identifying) ranging from 18-27 years old was recruited using an undergraduate student sample, social media, and Research Match. Participants completed multiple self-report measures to evaluate different aspects of selective eating, including food neophobia, individual food preference, food quality preferences, and ARFID symptoms.

Results: Autistic young adults reported greater individual food selectivity ($F = 191.70$, $p < .001$), food quality selectivity ($F = 145.37$, $p < .001$), food neophobia ($F = 88.46$, $p < .001$), and ARFID symptoms ($F = 161.83$, $p < .001$). In contrast, there were no significant differences between men and women's reports of selective eating across the four measures: individual food selectivity ($F = .91$, $p = .34$), food quality selectivity ($F = .004$, $p = .95$), food neophobia ($F = 2.69$, $p = .10$), and ARFID symptoms ($F = .21$, $p = .65$). Only individual food selectivity yielded a significant interaction effect of gender and diagnostic status ($F = 17.45$, $p < .001$).

Conclusions: Autistic young adults reported higher rates of selective eating than non-autistic young adults; however, there were no gender differences in selective eating patterns across all four measures. When assessing the interaction of gender and diagnostic status, there was only an effect on individual food selectivity which warrants further investigation. Future directions include assessing other factors that may influence the relationship between autism diagnostic status and selective eating.

432.238 The Impact of Sensory Reactivity on Anxiety in Autistic and Non-Autistic Young Adults: A Follow-up Study

C. Layton¹, J. M. Keith² and L. Bennetto¹, (1)Psychology, University of Rochester, Rochester, NY, (2)Department of Psychiatry, University of Rochester Medical Center, Rochester, NY

Background: Sensory reactivity differences and anxiety symptoms are highly prevalent and meaningful in the lives of autistic people, leading to profound impacts on daily functioning and well-being. While sensory reactivity differences have been implicated as a potential risk factor for the development of anxiety in autistic children, research has yet to explore the predictive relationship of sensory symptoms on internalizing pathology in autistic adolescents and adults.

Objectives: The present study sought to examine the developmental trajectories of sensory reactivity and anxiety in autistic and non-autistic people, and their relationships over time, to better understand the impact of sensory experiences and internalizing symptoms on autistic youth as they transition into adulthood.

Methods: This study followed up 12 autistic adults (Mean IQ = 108) and 13 non-autistic adults (Mean IQ = 115), between the ages of 20-26, who participated in a previous study on sensory reactivity at 12-17 years old. Participants completed the same self-report measures at both time points. The Adolescent/Adult Sensory Profile (AASP) and the Brain Body Center Sensory Scales (BBCSS) assessed sensory hyperreactivity, hyporeactivity, and seeking behavior. Anxiety was measured at each time point using the Screen for Anxiety Related Disorders (child or adult version).

Results: ANOVAs demonstrated that autistic adults experience greater sensory hyperreactivity (BBCSS: $F = 22.94, p < .001$; AASP: $F = 8.24, p = .009$) and hyporeactivity (AASP: $F = 12.62, p = .002$) compared to non-autistic adults. Looking over time, repeated measures ANOVAs revealed that for both autistic and non-autistic groups, sensory hyperreactivity and sensory-seeking behaviors remained stable into emerging adulthood (time main effects all *ns*), while sensory hyporeactivity decreased over time ($F = 64.8, p < .001$). None of the group x time interactions were significant. Autistic adults endorsed marginally higher levels of anxiety than non-autistic adults ($F = 4.01, p = .058$). Both groups demonstrated an increase in anxiety symptoms from adolescence to adulthood ($F = 21.0, p < .001$; group x time interaction, *ns*). Looking at the relationships between domains, both measures of sensory hyperreactivity were significantly correlated with anxiety in autistic adults (BBCSS: $r = .60, p = .05$, AASP: $r = .63, p = .04$). Pearson correlations were used to examine the influence of sensory reactivity and anxiety symptoms on each other over time. Sensory hyperreactivity in adolescence, as measured by the BBCSS Hypersensitivity composite, accounted for 44% of the variance in adult anxiety in the autistic group ($r = .66, p = .03$). Conversely, adolescent anxiety did not predict sensory hyperreactivity in autistic adults (BBCSS: $r = .35, p = .29$; AASP: $r = .06, p = .86$).

Conclusions: Results indicate that autistic young adults continue to experience elevated rates of sensory reactivity differences and anxiety symptoms. Importantly, sensory hyperreactivity in adolescence was identified as a significant unidirectional predictor of the development of anxiety symptoms in autistic adults. This suggests working with autistic teens to identify their specific sensory needs and develop personalized strategies may help reduce the impact of sensory hyperreactivity on their mental health over time.

432.239 The Intersection of Food Selectivity and Obesity in Autism Spectrum Disorder: Insights for Treatment

E. S. Kuschner^{1,2,3}, B. B. Maddox⁴, L. Young³, S. Watson³ and G. L. Wallace⁵, (1)Department of Child and Adolescent Psychiatry and Behavioral Sciences, Children's Hospital of Philadelphia, Philadelphia, PA, (2)Psychiatry, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, (3)Department of Radiology, Children's Hospital of Philadelphia, Philadelphia, PA, (4)TEACCH Autism Program, University of North Carolina at Chapel Hill, Carrboro, NC, (5)The George Washington University, Washington, DC

Background: For autistic people, obesity prevalence is concerning relative to non-autistic peers, exacerbating already elevated risk for negative health sequelae and chronic health conditions (e.g., diabetes, stroke). Autism-specific obesity treatment guidance and interventions exist. However, unique eating phenotypes observed in autism—particularly a high prevalence of food selectivity—have not been clearly integrated into treatment. Food selectivity in the presence of obesity in autism may be a “double hit” and significant barrier to treatment success. A critical next step is the integration of existing food selectivity treatment programs tailored for autistic youth, such as the Building Up Food Flexibility and Exposure Treatment (BUFFET) Program, into obesity treatment programs.

Objectives: (1) Examine caregiver and youth perspectives on the role of food selectivity in treatment for obesity in autistic youth. (2) Characterize the theoretical underpinnings (behavioral flexibility, anxiety, and sensory differences that underlie food selectivity) of BUFFET in autistic youth with obesity.

Methods: Caregivers of 69 autistic youth 6-17 years (mean=12.5, SD=3.1; 34M:13F, 2 not-disclosed) with BMI percentile in the range of overweight (N=4) or obesity (N=65), described as ‘with obesity,’ completed a survey to examine the influence of food selectivity on engagement with treatment for obesity in autism. A subset of autistic youth (N=44) self-reported on survey questions. Caregivers completed assessments to characterize their child’s presentation on constructs theoretically foundational to BUFFET, including the Flexibility Scale-Revised (behavioral flexibility), Parent-Rated Anxiety Scale for Youth with Autism Spectrum Disorder (anxiety), and questions on anxiety in eating contexts (eating-specific anxiety) and sensitivity to taste, smell, and food texture in eating contexts (sensory differences that underlie food selectivity).

Results: 72% of caregivers described their autistic child with obesity as a picky eater. 75% of self-reporting autistic youth with obesity described themselves as a picky eater, with 86% caregiver-youth agreement on food selectivity status. A high proportion of caregivers reported that food selectivity impacts their child’s health (88%) and weight (90%). Youth themselves also report that food selectivity impacts their health (64%) and weight (86%). Many (81%) caregivers described food selectivity as a barrier to their child making positive eating changes, despite most (88%) having doctors who discussed food selectivity in conversations about weight management.

A series of ANOVAs revealed that relative to autistic youth with obesity *without* food selectivity, autistic youth with obesity *with* food selectivity showed higher eating-specific anxiety, $F(1,66)=10.3, p=0.002, h_p^2=0.14$ and greater sensory differences that underlie food selectivity, $F(1,64)=17.6, p<0.001, h_p^2=0.22$, as well as trends toward higher overall anxiety, $F(1,46)=3.7, p=0.06, h_p^2=0.07$, and greater difficulty with behavioral flexibility in everyday life, $F(1,45)=3.6, p=0.06, h_p^2=0.08$, and in the context of rituals and routines, $F(1,48)=3.2, p=0.08, h_p^2=0.06$.

Conclusions: Results suggest that autistic youth with obesity and food selectivity demonstrate a profile of eating-related anxiety, sensory differences underlying food selectivity, and perhaps behavioral flexibility that aligns with constructs and treatment targets of food selectivity treatment for autistic youth. Integration of a treatment like BUFFET with existing obesity treatments could address an unmet need identified by caregivers and autistic youth with obesity in this study.

432.240 The Relationship between Sensory Processing and Anxiety in Autistic Adults: A Systematic Review

S. Pelluru¹, K. Garibian¹, M. Rader¹, C. Horan¹, A. Watson-Grace¹ and J. E. Crasta², (1)The Ohio State University, Columbus, OH, (2)Physical Medicine and Rehabilitation, The Ohio State University, Baltimore, MD

Background: Sensory processing differences are prevalent among autistic adults and can profoundly influence other behaviors, such as anxiety, and overall quality of life. While numerous studies have explored the relationship between sensory processing differences and anxiety in children on the autism spectrum, there remains a critical need to examine this relationship within the adult population.

Objectives: This systematic review synthesizes existing research on the association between sensory processing and anxiety in adults on the autism spectrum. Additionally, it identifies commonly utilized measures of sensory processing and anxiety in this population.

Methods: A comprehensive literature search was conducted following the Preferred Reporting Items for Systematic Reviews (PRISMA) guidelines. Databases searched included PubMed, PsychINFO, Embase, CINAHL, Scopus, and Web of Science. Results were imported into Covidence for further screening. Two independent reviewers screened titles, abstracts, and full-text articles based on the following inclusion criteria: (1) participants aged 18 and older with a formal diagnosis of autism, (2) use of outcome measures for sensory processing and anxiety, and (3) statistical analyses examining correlations between sensory processing and anxiety.

Results: Of the 3,076 articles screened, 13 peer-reviewed studies met the inclusion criteria, examining the relationship between sensory processing differences and anxiety in autistic adults. Generalized anxiety was assessed in 11 articles (85%), while two studies (15%) focused on specific anxiety types, including pain anxiety and social anxiety. The most frequently used anxiety measures were the Penn State Worry Questionnaire (PSWQ), Hospital Anxiety and Depression Scale (HADS), Beck Anxiety Inventory (BAI), and Spielberger State/Trait Anxiety Inventory (STAI). The Adolescent/Adult Sensory Profile (AASP) was the most common tool for assessing sensory processing, used in six articles (46%). A significant relationship between sensory processing differences and anxiety was found in 12 studies (92%), with six studies (46%) reporting that heightened sensory sensitivities were associated with increased anxiety levels. Two studies (15%) demonstrated a positive correlation between sensory avoidance and anxiety. While evidence linking sensory seeking and low registration to anxiety was limited, one study (8%) suggested that anxiety might drive sensory-seeking behaviors. Additionally, two studies (15%) identified anxiety as a mediator between sensory processing and other behaviors, such as restrictive and repetitive behaviors (RRBs) and problem behaviors.

Conclusions: The studies suggest a strong association between sensory processing and anxiety in autistic adults. Future longitudinal research is needed to clarify the causal relationship between various sensory processing profiles and anxiety. Sensory sensitivity, in particular, warrants closer examination regarding its influence on anxiety. Additionally, future research should focus on the impact of sensory processing on specific anxiety types to better inform the development of targeted therapeutic interventions that address the underlying causes of anxiety-related behaviors.

432.241 Theta-Gamma and Alpha-Gamma Coupling in Response to Auditory Stimuli in Rett Syndrome

K. N. Sabol¹, D. Kranz², G. Correa¹, D. Lieberman³, M. Fagiolini³ and A. R. Levin⁴, (1)Boston Children's Hospital, Boston, MA, (2)Boston Children's Hospital/Harvard Medical School, Boston, MA, (3)Children's Hospital Boston, Boston, MA, (4)Neurology, Boston Children's Hospital / Harvard Medical School, Brookline, MA

Background: Rett syndrome (RTT) is a neurodevelopmental disorder that shares a number of features with autism, including altered sensory processing in both the visual and auditory domains. RTT may therefore serve as a useful model to gain insight into atypical sensory processing in autism. In particular, electroencephalography (EEG) based measures of phase-amplitude coupling can reflect how the brain integrates and segregates incoming sensory information. Our previous work in electroencephalography (EEG) at rest has shown increased theta-gamma and alpha-gamma phase-amplitude coupling in RTT, but this has not previously been studied in response to sensory stimuli.

Objectives: This study is a preliminary analysis to determine whether there is altered coupling in theta-gamma and alpha-gamma frequencies in response to auditory stimuli in participants with RTT compared to typically developing (TD) controls.

Methods: This experiment involved 26 RTT and 27 TD participants between the ages of 1-50. All RTT participants had a clinical diagnosis of classic or atypical RTT and a pathogenic variant in the MECP2 gene, and TD participants were approximately age and sex matched to RTT participants. EEG data were collected while participants underwent an auditory evoked potential paradigm, during which they listened to 250 500-Hz tones at 60 dB with jittered interstimulus intervals between 1-3 seconds. EEG data were preprocessed through the Harvard Automated Processing Pipeline for EEG (HAPPE) in the Batch Electroencephalography Automated Processing Platform (BEAPP). 200 trials from each participant were randomly selected for analysis. PAC using the Tort method was applied to the data, with the analysis intervals for each trial beginning at stimulus onset and ending at 800 ms post-stimulus. The average raw modulation indices (MI) in the fronto-central channels were averaged across RTT participants and TD participants separately, and the differences between the RTT and TD groups were calculated.

Results: The RTT group exhibited its highest coupling at the theta/high-gamma frequency pairs. The TD group exhibited its highest coupling at the low-theta frequencies across the gamma spectrum. When comparing group MI differences, we observe that PAC across most frequency pairs is higher in the RTT group than the TD group, except for the low-theta/low-gamma pairs. The greatest increase in PAC between the RTT and TD groups occurs in the theta/high-gamma frequency pairs.

Conclusions: We observed increased theta-gamma PAC at high-gamma frequencies in response to sensory stimuli in RTT. Future work using computational modeling will help to understand the circuitry underlying this response. If this altered pattern is due to shared underlying mechanisms (e.g., alterations in function of specific subtypes of inhibitory interneurons), we would expect to see the same altered pattern of theta-gamma coupling in patients with autism who also experience dampened activity in these neurons. Abnormally high theta-gamma coupling in the high-gamma frequencies could therefore serve as a biomarker in autism of this particular type of altered sensory processing.

432.242 Toe Walking Is Associated with Greater Motor, Cognitive, Language, and Sensory Impairment in Autism: Results from a Neural Network Analysis

L. Asta¹, M. Camia¹, R. Sacco², F. Cucinotta³, L. Turriziani⁴, A. Ricciardello⁵, M. Boncoddò⁶, F. Bellomo⁷, A. M. Persico¹ and E. Grossi⁸, (1)Dept. of Biomedical, Metabolic and Neural Sciences, University of Modena and Reggio Emilia, Modena, MO, Italy, (2)Service for Neurodevelopmental Disorders, "Campus Bio-Medico" University Hospital, Rome, RM, Italy, (3)IRCCS Centro Neurolesi Bonino Pulejo, Messina, Italy, (4)Center for Autism "Dopo di noi", Barcellona P.G., Messina, Italy, (5)Cantonal Psychiatric Clinic, Cantonal Socio-psychiatric Organization (O.S.C.), Mendrisio, Repubblica e Cantone Ticino, Switzerland, (6)Institute for Biomedical Research and Innovation (I.R.I.B.), National Research Council of Italy (C.N.R.), Messina, ME, Italy, (7)Child Neuropsychiatry Unit, "G. Martino" University Hospital, Messina, ME, Italy, (8)Autism Research Unit, Villa S. Maria Foundation, Tavernerio, CO, Italy

Background: Autistic children and adolescents frequently exhibit motor abnormalities, including toe walking (TW). Previous research has found persistent TW (i.e., TW that would not resolve spontaneously by 3-7 years of age) associated with greater cognitive impairment, language delay, and orthopedic complications, while evidence of abnormal sensory processing is less consistent.

Objectives: The goal of this study is to outline the overall schema of natural relationships between clinical variables and Short Sensory Profile (SSP) scores in a sample of autistic children and adolescents with and without TW, by applying artificial neural networks

Methods: 256 clinical variables across four domains (prenatal-perinatal issues, medical and neurological features, developmental characteristics, family history) were retrieved for analysis from a cohort of 112 autistic children and adolescents assessed for TW (see Camia et al., 2024, doi: 10.1016/j.rasd.2024.102457). Each domain was processed using Auto-CM, a fourth-generation auto-associative neural network. After training, this system developed weights that reflect the strength of associations between all variables. A minimum spanning tree filter was then applied to the resulting weight matrix, allowing for a graphical representation of the strongest connections between variables, in other words their semantic connectivity map. Preliminary analyses performed on each domain identified 31 clinical variables with up to one degree of separation from "TW-present"/"TW-absent". Six variables were then dichotomized yielding a total of 41 clinical variables. Final analyses were then performed on complete data sets applying Auto-CM: (a) to these 41 clinical variables on a sample of 79 patients (N=46 with and 33 without TW), and (b) by adding also 24 variables, three for each SSP domain (clinical vs borderline vs normal) and for its total score, available for 61 patients (36 with TW and 25 without TW).

Results: The semantic connectivity map generated by Auto-CM revealed a clear separation between presence/absence of TW: (a) Analyzing only clinical variables, "TW-present" was identified as a hub node, linked to motor coordination disorder, abnormal cranial conformation, dysmorphisms, reduced pain sensitivity, hypersensitivity of other senses, sensory self-stimulation, hyperactivity, stereotypic behaviors, and severe autism. TW-absence was linked to presence of imitation/pretend play, mild autism severity, and better language skills, both receptive and expressive. (b) Including also SSP variables, auto-CM generated a map also connecting TW with a string of SSP scores in the clinical range (hyporeactivity, auditory filtering, tactile sensitivity, etc), counteracted by normal SSP scores linked to "TW-absent".

Conclusions: These results confirm the greater severity of motor, cognitive, social, and verbal impairment associated with TW. Sensory abnormalities, linked to TW here but not in our prior study, are likely part of a constellation of signs and symptoms expressing a more pervasive and profound derangement of neurodevelopmental processes, rather than a direct cause of TW. More research will be necessary to understand the neural substrates of TW in autism. Advanced computational tools, like Auto-CM, are indeed helpful in overviewing and partitioning complex behavioral phenotypes.

432.243 Transdiagnostic Investigation of the Link between Anxiety, Insistence on Sameness Behaviours, and Compulsions

E. Spackman¹, L. Chetcuti², E. K. Baker³, A. Y. Hardan³ and M. Uljarevic³, (1)Psychiatry and Behavioral Sciences, Department of Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA, (2)Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA, Australia, (3)Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA

Background: Although insistence on sameness (IS) and compulsions occur across a wide range of clinical conditions, they are typically only examined within the confines of specific disorders. Commonly described differences in these behaviours across diagnoses likely oversimplify complexities and do not address well-established heterogeneity and/or high co-occurrence. For example, compulsions in obsessive-compulsive disorder (OCD) are said to differ from compulsions in autism in that they are performed to relieve distress. However, many autistic individuals describe performing ritualised behaviours precisely for this function and/or report considerable distress caused by interruptions to behaviours. Indeed, theoretical accounts of IS and compulsions across different diagnostic groups bear many similarities, consistently identifying anxiety as a key mechanism. However, as transdiagnostic investigations of these behaviours have been limited to date, it remains unclear whether anxiety shows a similar pattern of association with IS and compulsions within and across diagnostic groups.

Objectives: To examine the endorsement IS and compulsions across diagnostic groups and explore whether anxiety shows different patterns of associations with IS or compulsions within and across diagnostic categories.

Methods: Data obtained from the Healthy Brain Network database comprised a transdiagnostic sample of 1852 youth ($M_{age}=10.36(3.40)$; 591 females) diagnosed with autism ($N=387$), oppositional defiant/conduct disorder (ODD/CD; $N=267$), attention-deficit hyperactivity disorder (ADHD; $N=931$), OCD ($N=59$), or internalizing disorders ($N=208$). IS and compulsions were assessed using the Repetitive Behaviour Scale-Revised (RBS-R) and anxiety using the Screen for Child Anxiety Related Disorders – Parent Version (SCARED-P). Fisher's r to z comparison was used to compare the strength of correlations.

Results: As hypothesised, anxiety, IS, and compulsion levels differed significantly across diagnostic groups, despite all features being commonly endorsed across each clinical condition. The autism group scored the highest on IS ($F=57.12$; $p<.001$) and the autism and OCD/Tic groups scored the highest on compulsions ($F=37.92$; $p<.001$). The autism, ODD/CD and internalizing groups showed significantly higher anxiety than the ADHD group ($F=7.91$; $p<.001$).

Within-group comparisons revealed that anxiety showed a slightly stronger correlation with IS than compulsions in the ASD ($r=.50$ vs $.44$), ADHD ($r=.42$ vs $.36$), and OCD/Tic groups ($r=.58$ vs $.40$), but not the ODD/CD ($r=.43$ vs $.40$), or internalizing groups ($r=.42$ vs $.50$). Despite differences being significant, Cohen's q suggested only a small effect for the OCD/Tic group ($q=.24$) and no effect for other groups ($q<.10$). Between group comparisons found that the strength of association between anxiety and IS ($r=.42$ to $.58$) did not differ between groups, nor did the association between anxiety and compulsions ($r=.36$ to $.50$).

Conclusions: High endorsement of IS, compulsions and anxiety across all diagnostic groups affirms the transdiagnostic nature of these phenomena. Although further research is needed, anxiety showing comparable strength of associations with IS and compulsions within and across diagnostic groups, adds to a growing body of evidence suggesting that IS and compulsions are transdiagnostic features that may have shared aetiologies across diagnostic conditions.

432.244 Understanding Sensory Processing and Pain in Children with Autism Spectrum Disorder

R. M. Mankaryous¹, L. Jones², S. R. Rogers¹, M. Shao³, C. Serianni¹, K. Dunham-Carr³, A. Thurm¹, S. Holmes¹ and A. R. Levin³, (1)Boston Children's Hospital, Boston, MA, (2)Boston Children's Hospital/Harvard University, Boston, MA, (3)Boston Children's Hospital / Harvard Medical, Boston, MA, (4)Office of the Clinical Director, National Institutes of Health - National Institute of Mental Health, Bethesda, MD, (5)Neurology, Boston Children's Hospital / Harvard Medical School, Brookline, MA

Background: There is currently a critical gap in understanding pain perception in children with Autism Spectrum Disorder (ASD). While sensory processing differences are increasingly recognized as a core feature of ASD and also occur in children with Sensory Processing Concerns (SPC) who do not meet criteria for ASD, there remains a limited understanding of how these differences contribute the sensory perception of pain.

Underrecognition of pain experiences may result in insufficient pain relief, compromised quality of life, and preservation of the cycle of sensory challenges and pain experiences. In young or minimally verbal children, behavioral reactions to pain provide clues to the child's pain experience and thus a springboard for linking biology and behavior of pain response. Understanding relations between pain reactivity, sensory sensitivity to different stimuli, social communication, and cognition is crucial for informing tailored interventions to optimize pain management strategies for children with ASD and SPC.

Objectives: We aim to investigate how pain reactivity correlates with other measures of sensory processing, social communication, and cognition by collecting a series of clinician observation and parent report measures.

Methods: Data collection for this study is ongoing, with a current sample size of 48 3- to 4-year-old children, 14 typically developing (TD), 13 SPC, and 21 ASD (total target $N=75$). We derived an approximation of pain reactivity using elements of the Sensory Assessment for Neurodevelopmental Disorders (SAND; a clinical observation and parent report that measures sensory hyperreactivity, hyporeactivity, and seeking behaviors in response to various sensory stimuli) and the Sensory Profile 2 (SP-2; a parent report of a child's sensory processing abilities and their impact on daily functioning). We calculated a pain reactivity aggregate score using the SAND hyperreactivity total score, SAND total tactile score, and response on the "seems unaware of pain" item of the SP-2, following z score transformation, as these metrics were sufficiently intercorrelated to warrant aggregation. Participants' social communication and broader cognitive skills were evaluated using the Autism Diagnostic Observation Schedule 2 (ADOS-2), Social Communication Questionnaire (SCQ), and the Mullen Scales of Early Learning. We ran an ANOVA to determine if our groups differed in pain reactivity and a series of regression and correlation analyses on sensory measures, cognition, and social communication. **Results:** There were no significant group differences in pain reactivity as measured by the pain aggregate score $F=1.98$, $p=0.166$, $\eta^2=0.04$. Pain aggregate scores were significantly positively correlated with the ADOS social affect calibrated severity score, $r=0.31$, $p=0.02$, such that higher pain reactivity corresponded with higher social affect severity scores.

Conclusions: These findings suggest a relation between social communication skills and pain reactivity in children with and without autism and/or sensory processing concerns. This research has the potential to enhance our understanding of pain perception in children with ASD and SPC, paving the way for the development of validated questionnaires and targeted interventions. Further characterization of pain reactivity with a Nociceptive Behavior Response parent questionnaire is currently ongoing and will also be discussed.

432.245 Validation of Markerless Video-Based Gait Analysis Using Pose Estimation in Toddlers with and without Neurodevelopmental Disorders

J. Anderson¹, J. Stenum², R. Roemmich¹ and R. B. Wilson¹, (1)Education, University of California, Los Angeles, Los Angeles, CA, (2)Department of Physical Medicine and Rehabilitation, Johns Hopkins University School of Medicine, Baltimore, MD, (3)Semel Institute for Neuroscience and Human Behavior, UCLA Medical Center, Los Angeles, CA

Background: The onset of locomotion is a critical motor milestone and increases engagement with the environment. Toddlers with neurodevelopmental disabilities often have atypical motor development in the form of delayed motor milestones, atypical gait, and poor coordination or balance. These motor impairments can impact the development of later fundamental motor skills, adaptive functioning, language, and social communication. Standardized motor assessments are limited for measuring motor development as they are subjective and can be difficult to ascertain in children with neurodevelopmental disabilities due to the cognition and attention required to complete the tasks. Video-based gait analysis using pose estimation offers an alternative that is objective, scalable, and easier for children to complete, yet very little work has been done to determine its accuracy in pediatric populations.

Objectives: The goal of this study is to (1) demonstrate the feasibility of using pose estimation to perform gait analysis in children with and without neurodevelopmental disabilities and (2) assess the validity of OpenPose, a markerless movement analysis software, for accomplishing this task. Specifically, we focus on toddlers with a diagnosis of autism, non-autism developmental concerns, a genetic neurodevelopmental syndrome, or typical development. We hypothesized that OpenPose analysis would yield spatiotemporal gait videos that were significantly correlated with those calculated using an instrumented gait mat.

Methods: We analyzed the overground gait of 112 toddlers (M: 30 months, SD: 8 months) with and without developmental disabilities using the ProtoKinetics Zeno Walkway system. Simultaneously recorded videos were processed in OpenPose to perform pose estimation and a custom MATLAB workflow to calculate average spatiotemporal gait parameters. Pearson correlations were used to compare OpenPose with the Zeno Walkway for velocity, step length, and step time. A Bland-Altman analysis (difference vs. average) was used to assess the agreement between methodologies and determine the difference of means. Developmental levels were assessed using the Mullen Scales of Early Learning.

Results: Our analysis included children with autism ($n = 77$), non-autism developmental concerns ($n = 6$), Tuberous sclerosis complex ($n = 13$), 22q deletion ($n = 1$), and typical development ($n = 15$). Mullen early learning composite scores ranged from 49 to 95 ($m = 80.91$, $sd = 26.68$). Velocity ($r = 0.87$, $p < 0.0001$), step length ($r = 0.79$, $p < 0.0001$), and step time ($r = 0.96$, $p < 0.0001$) were all highly correlated between OpenPose and the Zeno Walkway, with an absolute difference of means of 0.04 m/s, 0.03 m, and 0.01 s, respectively.

Conclusions: Our results suggest that video-based gait analysis using pose estimation is accurate in toddlers with a range of developmental levels. Video-based gait analysis shows promising qualities for making motor research more widely available, as it is low cost and can be implemented for remote data collection in natural environments such as a participant's home. These advantages open possibilities for using repeated measures to increase our knowledge of how gait ability changes over time in pediatric populations and improve clinical screening tools, particularly in those with neurodevelopmental disabilities who exhibit motor impairments.

432.247 What Do Autistic Children Who Are Interested in Letters and Numbers Do with Them?

A. Ostrolenk^{1,2}, **L. Mottron**, **M.D.**^{3,4} and **M. Boisvert**^{2,4}, (1)St. Michael's hospital, Unity Health Toronto, Toronto, ON, Canada, (2)Centre de Recherche, Évaluation et Intervention en Autisme (CRÉIA), CIUSSS du Nord-de-l'Île-de-Montréal, Montréal, QC, Canada, (3)CIUSSS NIM, Montréal, QC, Canada, (4)Department of Psychiatry and Addictology, Université de Montréal, Montréal, QC, Canada

Background:

A recent study showed that 37% of autistic children exhibit an intense or exclusive interest in letters at the time of diagnosis (Ostrolenk et al., 2024). This interest is manifested mainly through non-social behaviours in autistic children, such as reading alone, and through social behaviours in typically developing (TD) children. Other findings highlighted that language development in autistic children diverges from neurotypical patterns, with joint attention levels prior to oral language development not predicting outcomes in autism (Kissine et al., 2023). Despite these differences, most autistic children develop functional oral language, pointing to alternative pathways of language acquisition, which may be through their early interest in written language.

Objectives:

This study aimed to qualitatively investigate the atypical manifestations of this interest in autistic compared to TD children. We were particularly interested in determining if and how this interest can benefit children and their families, and understanding the relationship between written and oral language development.

Methods:

The participants were the parents of 138 autistic children (77% male, $M_{age}=51.31$ months, $SD=11.72$, range=24-80) and 76 TD children (53% male, $M_{age}=47.54$ months, $SD=15.74$, range=24-83) between 2 and 6 years old. Most of the autistic children (84%) were non-speaking or minimally speaking. Families were recruited from an autism assessment clinic (autistic group) and daycares in the same geographical area (TD group). Parents participated in a 45-minute semi-structured interview on their child's interest in letters and numbers, the manifestations of these interests, the parental attitude towards it, and the child's oral language. We used the notes and audio recording taken by the interviewers during the questionnaire to transcribe the parents' answers. An inductive thematic analysis (Braun & Clarke, 2006) was performed on the qualitative data by two of the authors to establish recurring themes. To further investigate non-speaking autistic children, we created a subgroup whose parents reported that they did not communicate using spoken words at all.

Results:

Eight themes were identified: atypical behaviors related to written material, emotional attachment to letters and numbers, language acquisition, use of screens, solitary behavior, reduction of the interest over time, parental attitudes, and other special abilities. Thirty-three autistic children were identified as non-speaking. Of them, 18% had an intense or exclusive interest in letters and numbers, 27% could count, 18% would sing the alphabet song, and 24% would name letters. Three non-speaking children could write letters and numbers, two could recognize some written words and one could read.

Conclusions:

This study reveals that the interest in written material manifests itself in atypical ways in autism and is not comparable to the development of an interest in reading in a typically developing context. It also appears that this interest, when present, can be a source of well-being and lead to the acquisition of new skills, potentially developing into hyperlexia. Surprising observations in otherwise non-speaking children suggest that written material may represent an alternative pathway for language acquisition in autistic children. This calls for further investigation of these intense interests and the development of tools to better identify them.

432.248 What Is the Developmental Trajectory of Each Repetitive Behavior and Intense Interest? Do They Vary According to Nviiq? a Longitudinal Account of Repetitive Behaviors and Object Exploration during a Stimulating and Adapted Play Situation.

A. Bastien^{1,2}, **C. Lacelle**^{1,2}, **A. Ethier**^{1,2}, **C. Jacques**^{1,2} and **V. Courchesne**^{2,3}, (1)Université du Québec en Outaouais, Gatineau, QC, Canada, (2)Centre de Recherche, Évaluation et Intervention en Autisme (CRÉIA), Montreal, QC, Canada, (3)Université de Montréal, Montreal, QC, Canada

Background:

A growing body of literature supports the positive value of intense interests (II; Wood, 2023). Similarly, studies have shown that repetitive behaviors (RB) do not interfere with exploration nor learning opportunities (Jacques et al., 2018). However, little is known about their trajectory throughout development. Moreover, RB and II are often studied together, primarily through parent report questionnaires. Using a natural context tailored to autistic characteristics, such as the Montreal Stimulating Play Situation (MSPS), could better capture RB and II throughout the developmental trajectory of autistic children.

Objectives:

Document the developmental trajectory of RB and II in autistic children. More precisely, we aim to 1- document each RB and object explored (referring to II) by autistic children during the preschool and school versions of the MSPS; 2- determine whether this trajectory is modulated by nonverbal IQ (NVIQ).

Methods:

Data were collected from 23 autistic children exposed to the MSPS preschool version (M=50.09 months) and school version (M=130.52 months), recruited through the Autism clinic at Rivière-des-Prairies hospital in Montreal. Exploration of 40 objects of interest, and 48 behaviors were coded by two naive raters using Observer XT© through a systematic inter-rater agreement process. RB and object exploration were analysed in frequency, duration and proportion, with all three used to determine the significance. Wilcoxon Signed-Rank and McNemar tests were used to compare RB and object exploration across measurement times. Mixed longitudinal regressions were used to determine how NVIQ (Raven's 2) predicts changes in RB and object exploration across measurement times. Holm-Bonferroni corrections led to an adjusted alpha level of 0.001.

Results:

Regarding RB, *lateral glances*, *pressing*, and *rolling* objects significantly decreased from preschool- to school-age. While not significant throughout measurement times, other RB showed a general decrease, with the exception of *grouping objects according to their perceptual properties*, *throwing*, and *turning objects*, which remained prevalent and stable. Mixed longitudinal regressions show that higher NVIQ scores were linked to a significant decrease of several RB. Results also suggest that higher cognitive abilities moderated the effect of time on RB, reducing variations.

Regarding object exploration, a significant decrease was observed for *sound embedding objects*. *Letters and numbers*, *boat* (hammer and balls), *big abacus*, and *tactile balls* remained highly explored across measurement times. Mixed longitudinal regressions revealed contradictory patterns, with higher NVIQ scores leading to both increases and decreases in exploration, depending on object type. The findings also suggest that higher cognitive abilities attenuated the impact of time on the exploration of different objects.

Conclusions:

This study suggests that despite a general decline in RB from preschool to school age, distinct patterns are observed when RB are analyzed individually, and when NVIQ is considered. It also underlines that interests in literacy and sensory objects are stable throughout time, and more importantly, that NVIQ modulates object exploration. These findings highlight the importance of studying each RB's trajectory individually. It also suggests that RB and II trajectories are linked to other characteristics such as intelligence, language and motor skills.

432.249 Why Do I Feel Overwhelmed? Integrating Neural and Subjective Responses to Commonly Employed Visual and Haptic Stimuli with Anxiety in Autistic Individuals

G. J. Siegle¹, K. B. Beck², Y. Takarae³, A. Johnston⁴, S. Parsons⁵, M. V. Strege¹ and C. A. Mazefsky², (1)University of Pittsburgh, Pittsburgh, PA, (2)Department of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, PA, (3)Department of Psychiatry and Behavioral Sciences, UC Davis, Sacramento, CA, (4)Psychiatry, University of Pittsburgh Medical Center, Pittsburgh, PA, (5)Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, PA

Background: Autistic people often describe feeling overwhelmed in response to common sensory stimuli. As this experience is unusual, and brain imaging studies of sensory stimulation rarely describe pathways from simple visual, auditory, or tactile stimulation to intense recruitment of emotional and cognitive resources, autistic people's experiences are often between misunderstood and not believed.

Objectives: Greg Siegle, an autistic neuroscientist, will use neuroimaging data from the Pittsburgh Autism Center of Excellence, to relate how autistic people respond subjectively to neural reactions in response to common sensory stimuli at a group and individual, clinical, and narrative level.

Methods: Participants included N=59 study-diagnosed autistic and N=21 verified non-autistic individuals (22 Male (14 autistic), 33 female (23 autistic), 11 non-binary (10 autistic), 13 other (12 autistic), age mean = 33 range = 19-61, N=57 white (47 autistic), 11 Black (6 autistic), 4 Asian (2 autistic), 8 other (5 autistic)). Functional magnetic resonance imaging (fMRI; 3T Siemens Prisma) was completed during a block design using flashing checkerboards and haptic vibration, which are common in cognitive neuroscience, alone and together. Data were processed using HalfPipe (Waller et al, 2022; slice timing, motion correction, cross registration to the MNI152NLin2009cAsym template, 125s fWHM high pass filter, grand mean scaling, ICA-AROMA outlier removal, motion, white matter, csf confound regressors). Block-regressors were convolved with a double gamma hemodynamic response to produce single subject condition-related regressor contrasts, which were averaged across 12 a priori meta-analytically derived (Neurosynth; Yarakoni et al, 2012) functionally homogeneous networks ("task", "social", "sensation", "self", "salience", "pain", "motor", "memory", "interoceptive", "executive", "emotion", "default", "attention", and "arousal"). Means, standard deviations, and distribution shapes (via Siegel-Tukey test) were compared across groups. After the MRI assessment, participants were shown their brain reactions as bar graphs for the a priori networks, and were given the opportunity to interpret the emergent pattern of brain responses narratively. Individual differences in neural reactivity were correlated with self-reported anxiety severity (Generalized Anxiety Disorder (GAD)-7; Spitzer et al, 2006).

Results: Compared to non-autistic participants, autistic participants' responses to sensory stimuli had a long-tailed distributions in many networks. There were disproportionate numbers of autistic participants with both higher and lower-than expected reactivity to sensory stimuli in multiple not-conventionally-sensory-processing-related brain networks, e.g., self, memory. Lower anxiety autistic participants were more reactive than non-autistic participants. Higher anxiety autistic individuals were less reactive than non-autistic participants. This variation was consistent with how participants saw their own reactions at an individual level.

Conclusions: Our data suggest that autistic individuals have diffuse variable, but unique neural reactivity, consistent with emotional and personally relevant reactions to nominally sensory stimuli. Their reactions varied with anxiety severity. Lower anxiety individuals were more reactive; higher anxiety individuals may be more prone to shutting down. Autistic individuals' brain reactions largely reflect their narratives. As autistic individuals may have either very high or low neural reactivity to sensory stimuli, and have insight into these reactions suggests the utility of asking autistic people about their unique sensory experiences and accounting for their anxiety in tailoring sensory-friendly environments and interventions.

432.250 "I Was Told It Wouldn't Hurt at All": A Qualitative Study on Pain Experiences and Pain-Related Anxiety in Autistic Adults.

A. Watson-Grace¹, A. Patel¹, J. Shapiro¹, K. Kuhlman¹, N. W. Haid¹, A. Sturm², C. J. Cascio³ and M. D. Failla⁴, (1)The Ohio State University, Columbus, OH, (2)Loyola Marymount University, Los Angeles, CA, (3)Department of Psychiatry and Behavioral Science, Vanderbilt University Medical Center, Nashville, TN, (4)College of Nursing, The Ohio State University, Columbus, OH

Background:

Sensory processing differences are well-documented in autistic individuals, but we know little about how autistic individuals experience pain specifically. In experimental studies, autistic adults show increased pain sensitivity and endorse more pain-related anxiety symptoms. Anxiety disorders are common co-occurring conditions for autistic people. Qualitative studies of medical interactions in autistic adults have reported that autistic people find it hard to describe their pain to medical professionals, putting them at risk for pain mismanagement. There are no existing qualitative studies specifically addressing how autistic adults experience and reflect on their pain.

Objectives:

In the current study, we aimed to (1) characterize pain experiences and (2) describe the influence of anxiety on pain for autistic adults.

Methods:

We report preliminary data from a sub-sample of autistic adult participants (N=10, 6 Female, Ages 20-44 years old) that were given a semi-structured interview following their participation in a sensory and pain psychophysics study. Interview questions probed pain experiences, medical visits for pain, and experiences of autistic adults participating in pain research. Using thematic analysis, we iteratively developed a coding framework based on engagement with the data.

Results:

Participants reported that their pain experiences seemed to differ from others' reported or expected pain experience ("I was told it wouldn't hurt at all and it was very painful.") which led to diminished trust in others' descriptions of pain and reduced ability to anticipate pain ("I really don't know how much pain you're supposed to be in on a daily basis"). Many stated that anticipation of pain increased their pain intensity. However, when pain was unexpected, many noted that they may not even notice the pain ("I barely felt that"). In anticipation of painful events in medical settings, the anticipation and experience of "sensory overload" contributed to increased anxiety around potentially painful events. For some, pain increased worries about undiagnosed conditions ("what if it's something bigger... cancer?").

Conclusions:

Given high rates of chronic pain conditions and anxiety disorders in autistic individuals, this work highlights the need to understand the relationship of pain and anxiety for autistic adults and to develop targeted treatments for pain-related anxiety.

432.252 Relationship between Postural Control and Vision in Children and Adolescents with Autism Spectrum Disorder. a Scoping Review

G. Valagussa^{1,2,3}, A. Mari¹, E. Redaelli², E. Grossi¹, C. Perin² and G. Purpura², (1)Autism Research Unit, Villa Santa Maria Institute, Tavernerio, Como, Italy, (2)School of Medicine and Surgery, University of Milano-Bicocca, Milano, Milano, Italy, (3)PhD Program in Neuroscience, University of Milano-Bicocca, Milano, Milano, Italy, (4)Autism Research Unit, Villa Santa Maria SCS, Tavernerio, Como, Italy

Background: Motor impairments are frequently observed in individuals with autism spectrum disorder (ASD). Among motor issues, postural control can be found impaired and may also be influenced by visual stimuli. To our knowledge, the results of the studies that assessed the influence of vision on postural control in children and adolescents with ASD were not systematically searched and summarized.

Objectives: We conducted a scoping review to provide a comprehensive picture of the relationship between vision and postural control.

Methods: The scoping review was performed using the Preferred Reporting Items for Systematic Reviews and Meta-analysis Protocol Extension for Scoping Reviews, and the review protocol was registered a priori on the Open Science Framework. The literature search was performed in PubMed, Scopus, Web of Sciences, Cinhal, Embase and Psycinfo databases, searching for publications that assessed the influence of vision on postural control in individuals with ASD from 0 to 18 years of age in any setting. Primary studies with any study design were included; no study design, language or time limitation restrictions were applied. Two reviewers independently read each search result's title and abstract to identify records that potentially met the inclusion criteria and then read the full text of the eligible studies to confirm their inclusion. Afterwards, two reviewers independently extracted the data from the included studies using previously standardised data extraction tables. When appropriate, data extraction was summarised numerically. We also conducted a descriptive analysis of relevant themes related to the research questions.

Results: The database searches identified 646 studies, and fourteen were included after the selection process (see Figure 1). All studies had a case-control study design and considered 482 participants. We found that the relationship between postural control and vision was assessed using several experimental methodologies, summarised as follows: 1) comparison between postural control test results in closed-eye vs open-eye conditions; 2) assessment of postural control in closed-eye condition; 3) effect of a visual stimulus on postural control. The findings reveal that studies on the relationship between vision and posture in ASD children and adolescents are scarce, and their results are contrasting (see Table 1). The sample characteristics and the methodology used to study the influence of vision on postural control were highly variable. The significant heterogeneity in the methods could explain the contrasting results.

Conclusions: Clear and generalizable conclusions about the relationship between vision and posture in children and adolescents with ASD are not possible. Further research might use rigorous study methods and objective outcome measures tailored explicitly to the considered population.

432.253 Quantitative Assessment of Toe Walking in Autistic Individuals with Intellectual Disability: Comparison between Human Visual Extraction and Automated Markerless Gait Analysis

G. Valagussa^{1,2,3}, L. E. Molteni⁴, G. Purpura⁵, M. Boccotti⁶, C. Perin², A. Crippa⁴, G. Andreoni^{1,6} and E. Grossi³, (1)Autism Research Unit, Villa Santa Maria Institute, Tavernerio, Como, Italy, (2)School of Medicine and Surgery, University of Milano-Bicocca, Milano, Milano, Italy, (3)PhD Program in Neuroscience, University of Milano-Bicocca, Milano, Milano, Italy, (4)Scientific Institute IRCCS "E.Medea", Bosisio Parini, Lecco, Italy, (5)Autism Research Unit, Villa Santa Maria SCS, Tavernerio, Como, Italy, (6)Department of Design, Politecnico di Milano, Milan, Italy

Background: Toe-walking (TW) is present in about 20-30% of individuals with autism spectrum disorder (ASD). In some individuals, TW can completely disappear over time without any intervention; in others, it can persist and cause physical problems. TW quantification tools can provide insights into TW trajectories and aid in planning possible interventions. Recently, a video-based coding protocol based on standardized video recordings was proposed to quantify TW in an ecological setting: an operator reviews the videos and computes the parameters. The gold-standard to analyse gait is optoelectronic or wearable motion capture. This is difficult to use in individuals with ASD and cognitive disability because of their non-acceptance. An automated markerless gait analysis system (MGAS) approach could overcome these limitations.

Objectives: This study aims: 1) to implement an MGAS approach to quantify TW and 2) to validate the MGAS approach by comparing it with the reference video-recording approach.

Methods: We conducted a preliminary study on 5 individuals with ASD diagnosed according to DSM-5 criteria. The diagnosis was confirmed through the Childhood Autism Rating Scale (CARS-2), and the intellectual disability was assessed through the Vineland-2. TW was quantified using a modified version of a validated TW structured video-based coding protocol based on standardized video recordings. The test was conducted without shoes, albeit with socks. It consists of transporting 1 object (e.g. puzzle piece, Lego®) from the therapist to the playing table situated 3 meters away and back again 10 times. The assessment was repeated in three days for each individual. Thus, 15 tests were available for analysis. Observing the video, a therapist calculated the percentage of toe steps with respect to the total number of performed steps. OpenPose is the automated MGAS used to analyze the video-recorded tests. A previous study demonstrated its validity. The intraclass correlation coefficient (ICC) was used to assess the reliability between the therapist's visual assessment and MGAS approaches in quantifying percent of toe steps. Also, the Bland-Altman method checks for systematic distortion of measurement values. The 95% Limits of Agreement (LOA) was calculated as 1.96 times the standard deviation (SD) of the difference between the two methods. A narrow LOA range confirms that the methods could be used interchangeably.

Results: The 5 individuals with ASD had a mean age of 9.62 years (SD 2.46) (age range: 7.5-13.2 years; male: 4/5). The mean CARS-2 total score was 37.3 (SD 7.84). The mean Vineland-2 total quotient score was 27.2 (SD 11.35). Two individuals with ASD out of 5 presented TW. The normal data distribution was confirmed (Shapiro-Wilk test $p > 0.05$). The ICC value of the two approaches was 0.975 (excellent). The result of Bland-Altman analysis was shown in Figure 1: an upper LOA below 18.28 and a lower LOA above 29.11 were obtained.

Conclusions: The MGAS OpenPose used for the quantitative assessment of TW in individuals with ASD and intellectual disability showed excellent reliability compared to the reference therapist's visual assessment. Bland-Altman analysis suggests the possibility of clinical application. Further research is required to confirm the results of this preliminary study.

Poster Session

433 - Service Delivery/Systems of Care II

May 2nd, 2025, 6:00 PM - 7:00 PM - Hall 4A

433.255 Implementation of an Autism Screener through Early Intervention: Successes in Implementation but Struggles to Refer and Further Evaluate for Autism

A. J. Schwartz¹, M. J. Morrier², S. Griswell³, R. Eloy⁴ and C. Rice⁵, (1)Department of Psychiatry & Behavioral Sciences, Emory University School of Medicine, Decatur, GA, (2)Department of Psychiatry & Behavioral Sciences, Morrier Consulting LLC, Decatur, GA, (3)Division of Women, Children, & Nursing Services, Department of Public Health, Atlanta, GA, (4)Emory University, Atlanta, GA, (5)Division of Human Development and Disability, Centers for Disease Control and Prevention, Atlanta, GA

Background: Though autism spectrum disorder (ASD) symptoms can often be detected by age 2, the average diagnosis occurs around age 4. Developmental screenings play a crucial role in helping identify children at-risk for autism at a young age, yet ASD-specific screenings are underutilized by pediatricians due to barriers like time constraints, training, and resources. Part C of the Individuals with Disabilities Education Act mandates children under the age of 3 with developmental delays receive early intervention (EI) through state programs. EI has been suggested as a complementary or "back-up" system to pediatrician screenings for ASD, with the potential to reduce missed diagnoses in an already developmentally delayed population. Further, EI providers already assess children across multiple developmental domains during intake and have regular interactions with families, making them well-positioned to conduct ASD-screenings. Studies show EI providers are willing to take on this role, though many express the need for additional training.

Objectives: To evaluate ASD screening within EI by looking at the number of children assessed on and failed an ASD screener, referred for additional testing, and diagnosed with ASD each year post-training of EI providers on the ASD screener.

Methods: As part of a contract between Emory University and the Department of Public Health, EI providers across the state were trained in early 2018 through one of two telehealth trainings on how to administer, score, and record the *M-CHAT-R/F* ASD screener. Public health unidentified data was analyzed using SPSS for each year since the training (i.e., starting June 1, 2018, to May 31, 2023). Data analyzed for all children enrolled in EI services included: district, sex, race, date of birth, eligibility date for EI, eligibility domain(s), *M-CHAT-R/F* score at 18- and 24-months, 18- and 24-month screen date, 18- and 24-month personnel that screened, 18- and 24-month screen pass/fail, 18- and 24-month screen outcome, and autism evaluation outcome.

Results: Each year about half the children eligible received an ASD screening in EI (2018, 23.83%; 2019, 49.29%; 2020, 58.49%; 2021, 58.98%; 2022, 58.04%). These screenings were primarily completed by EI providers (86%) and then pediatricians (13%). Out of the total screenings, almost half each year were fails (2018, 37%; 2019, 39%; 2020, 42%; 2021, 46%; 2022, 52%). The majority outcome of a failed score was to Monitor/Rescreen (2018, 61%; 2019, 62%; 2020, 65%; 2021, 66%; 2022, 64%) and then Refer for further evaluation (2018, 15%; 2019, 16%; 2020, 17%; 2021, 19%; 2022, 23%), with only 10% (except 14% in 2022) being evaluated per year. Further data will be requested and analyzed to look at possible significant differences between health districts, demographics, and EI eligibility areas with ASD screenings and evaluations.

Conclusions: EI providers can successfully implement ASD screeners; however, only about half the children eligible were screened. Further, those that fail the screener rarely are referred for or received an autism assessment. Though an improvement, more research is needed to understand why not more young children are not being referred and then evaluated even when identified in EI.

433.256 Implementation of the World Health Organization Program, Caregivers Skills Training (CST), in Brazil: Feasibility, Acceptability and Effectiveness.

C. C. Rauen¹, G. M. S. Doria², E. Matos³, K. H. Nogara⁴, C. Geyer⁵, R. Massuda², M. D. F. J. Minetto⁵ and L. P. Santos², (1)health, CHC UFPR, Curitiba, Brazil, (2)Psychiatry, Federal University of Paraná, Curitiba, Brazil, (3)Founder, Ico Project Foundation, Curitiba, Brazil, (4)Autism Research and Service, Ico Project Foundation, Curitiba, Brazil, (5)Education, Federal University of Paraná, Curitiba, Brazil

Background: The CST parental training program was implemented in Brazil, pioneering in a southern capital through a partnership between the public health service, NGO, university, and the WHO/Autism Speaks. This caregiver-mediated program has been tested, adapted, and applied across various sociocultural contexts worldwide, aiming to meet the growing demand for interventions for children with ASD and their families.

Objectives: This study aimed to assess the acceptability, feasibility, and effectiveness of the CST program pilot in Brazil.

Methods: Five simultaneous training groups were conducted by facilitators, supervised by Master Trainers (MTs), in a virtual format due to COVID-19 restrictions. A triangulation approach was employed, combining: 1) Quantitative data: non-randomized, open pre- and post-intervention study; 2) Qualitative data: observational, descriptive study. The analysis focused on: 1) The impact on autism symptoms and caregivers' quality of life; 2) Professionals' perceptions of the program's feasibility, acceptability, and effectiveness, and caregivers' perspectives on participation barriers and facilitators. Data collection involved standardized scales (Table 1) and seven post-intervention focus groups (FGs), with content analyzed using Bardin's thematic categorical analysis, supported by IRaMuTeQ® software.

Results: Of the 50 families recruited, 37 began, and 28 completed the program. Among the children, 83.2% were boys, with an average age of 5.22 years and an ASD diagnosis at an average age of 3.34 years. The average adaptive behavior score was 73.7. The ATEC (75.1 to 63.9; $p < 0.01$) and CGI-S (4.42 to 3.89; $p < 0.01$) scores decreased significantly. 75% of TBs improved and CGI-scores increased (0.789 to 1.526; $p < 0.01$). Among caregivers, 91.9% were women (88% mothers), with an average age of 35.2 years. Most (64%) were not formally employed, and 44% reported psychiatric disorders (depression or anxiety). No significant differences were found in the median total scores of the WHOQOL ($p = 1.00$) and PedsQL ($p = 0.66$) between pre- and post-intervention. However, participants without psychiatric illness showed a significant increase in PedsQL scores ($p = 0.02$), and post-intervention differences emerged between those with and without psychiatric illness ($p = 0.02$). The thematic analysis identified 6 categories in the content of the caregivers' FGs, 5 categories in the content of the facilitators' FG, and 6 categories in the content of the MT's FG (Table 2).

Conclusions: Participants appreciated the training content and resources, suggesting minimal adjustments. However, the virtual format and pandemic context presented challenges, such as technological difficulties, caregiver overload (multitasking mothers), and limited bonding among caregivers. Engagement varied according to participants' profiles, influenced by psychosocial and economic vulnerabilities. While synchronous sessions were more effective, some caregivers expressed a preference for direct child-focused care. Facilitator training, which lacked practical interaction with children, was deemed insufficient, making supervision essential. The value of peer exchanges among families and professional support was highlighted. There was also a change in caregivers' understanding of their children's difficulties, better parenting strategies and a reduction in ASD symptoms.

433.257 Implementing a Training Program on Autism Screening for Non-Specialist Healthcare Workers in Sri Lanka: Preliminary Feasibility and Impact

S. Mayadunne¹, A. M. Jayawickrama², B. Fernando³, J. Barbaro⁴, S. Garg⁵, A. Hewamalage⁶ and D. V. Vipulaguna⁷, (1)*Sri Lanka College of Paediatricians, Colombo, Western, Sri Lanka*, (2)*NAMASTE, Sri Lanka, Colombo, Western Province, Sri Lanka*, (3)*Namaste Sri Lanka, Colombo, Western Province, Sri Lanka*, (4)*Olga Tennison Autism Research Centre, La Trobe University, Melbourne, VIC, Australia*, (5)*School of Health Sciences, University of Manchester, Manchester, United Kingdom*, (6)*Namaste Sri Lanka, Colombo, Western, Sri Lanka*, (7)*Ministry of Health, Sri Lanka, Colombo, Western, Sri Lanka*

Background: Research highlights that non-specialist frontline healthcare workers (HCWs) can play a pivotal role in early screening for autism and neurodevelopmental disorders in low-resource settings. In Sri Lanka, Public Health Midwives (PHMs) are ideally positioned for this task as they are the first contact for families of children <5 years old. Training these HCWs on autism and early screening for autism marks the first step in integrating autism screening into the Sri Lankan primary healthcare (PHC) system.

Objectives: The Social Attention and Communication Surveillance (SACS) checklist is a brief play-based autism screening tool developed in Australia (Barbaro & Dissanayake, 2010). This study describes the cultural adaptation of the training program on the SACS checklist for PHMs in Sri Lanka, and evaluates its preliminary feasibility (assessed as suitability and acceptability) and impact.

Methods: Cultural adaptation of the SACS training program followed Barrera and Castro's (2006) framework. In the initial phase, training materials were translated and adapted through consultations with an expert panel and community stakeholders. This study describes the subsequent phase of refining the training to increase suitability to the PHMs' context. The pilot sample for this comprised 108 PHMs from the Colombo District of Sri Lanka, trained from May – October, 2024. Semi-structured focus group discussions were held after the training sessions to inform refinements to the training content. Recordings were transcribed, translated, and analysed using reflexive thematic analysis. Acceptability and confidence in screening were assessed using a five-point Likert scale questionnaire adapted from Gilbert and colleagues (2023). A pretest-posttest autism knowledge questionnaire, adapted from Shrestha and colleagues (2022), was used to evaluate preliminary impact. Quantitative data is analysed using descriptive statistics.

Results: 20 focus groups (n = 108) were conducted in total. Suggestions from PHMs to increase feasibility propelled iterations made to the training curriculum, including: i) retaining original English words for autism-specific terms (e.g., “echolalia”), as the Sinhala equivalent was not widely known, ii) providing a script on how to “convince” parents on the importance of screening, framing it as an “advanced” milestone tracking method where PHMs directly observe the child's development via play (not saying it is for “autism”), iii) using more videos that show screening of Sri Lankan children using the SACS checklist, as Sri Lankan children were typically said to be shy and require more encouragement to engage in play with clinicians, iv) providing a “guide” to help PHMs quickly and efficiently administer screening, recognizing their heavy workload at the PHC setting. Pretest-posttest evaluations over the workshops (n = 108) showed an 18.4% increase in autism knowledge, and a 75.9% increase in confidence in screening for autism. Most PHMs “strongly agreed” that the training was useful (91.6%) and suitable to their context (83.8%), and adequately covered their expected role and responsibilities (83.3%).

Conclusions: These refinements can be considered in similar contexts where an autism screening training program is being integrated into an already busy PHC system. The implementation phase of this study will provide further insights into the program's feasibility and impact.

433.258 Improving Healthcare Provider Confidence and Holistic Care for Autistic Adults through an Echo Autism Intervention

N. C. Cheak-Zamora^{1,2}, B. A. Malow³, M. O. Mazurek⁴, M. Howard⁵, J. V. Smith⁶ and K. Sohl⁷, (1)*Public Health, University of Texas at San Antonio, San Antonio, TX*, (2)*Public health, University of Texas at San Antonio, San Antonio, TX*, (3)*Sleep Disorders Division, Department of Neurology, Vanderbilt University Medical Center, Nashville, TN*, (4)*University of Virginia, Charlottesville, VA*, (5)*Department of Human Services, University of Virginia, Charlottesville, VA*, (6)*Children's National Hospital, Rockville, MD*, (7)*ECHO Autism Communities, University of Missouri School of Medicine, Columbia, MO*

Background: Autistic adults describe significant difficulties accessing services, specifically high-quality primary care services. While primary care practitioners (PCPs) can provide preventative and coordinated care, they often report lack of confidence and knowledge in working with autistic adults. The Extension for Community Healthcare Outcomes (ECHO) model is a longitudinal clinician education program developed to improve patient care across the care continuum. Utilizing a “hub and spoke” model, community-building strategies, and peer case-based learning make this intervention particularly effective for improving the care of autistic patients and others with medical complexity.

Objectives: The present study utilized the ECHO model (“ECHO Autism Adult Healthcare”) to train PCPs in how to best care for autistic adults. Previous quantitative findings from this program suggest that the ECHO Autism Adult Healthcare training bolstered providers' self-efficacy in working with autistic adults (Malow et al., 2023). The present study utilized a qualitative investigative approach to examine the PCPs' subjective experiences of participating in the ECHO training.

Methods: A qualitative descriptive framework was used to explore the experiences of 22 clinicians with autistic patients who completed the ECHO Autism Adult Healthcare program. Semi-structured interviews, conducted through Zoom, were used to examine the support and education needed to care for patients with medical complexity, the benefits and challenges of the ECHO Autism program, and comparisons to other educational support. Three research team members worked collaboratively to code all transcripts, testing inter-rater reliability utilizing Dedoose analytical software to establish reliability and coding consistency.

Results: Four themes were identified: (1) the benefits of hearing from a wide range of perspectives, (2) establishing and supporting an interactive and engaging climate (3) building a sense of community, and (4) the meaningfulness and usability of resources and information. Overall, participants expressed appreciation for the multidisciplinary hub team members' expertise and experiences. Several participants enjoyed the format of ECHO, as it encourages active discussion and engagement. PCPs indicated that they felt a connection with the hub team members and other participants during the ECHO Autism sessions. They also remarked on the usefulness of the tangible resources and information that was shared during each session and how it could be applied to their own practice.

Conclusions: The current study results highlight the benefits of participating in the ECHO Autism Adult Healthcare program and can guide the development and implementation of future training programs using this model. The ECHO model has the potential to become a best practice for delivering medical education. Broad implementation of the ECHO model for clinicians shows significant benefits for clinicians and patients with medical complexity compared to more traditional forms of CME.

INSAR 2025 Annual Meeting Abstracts

433.259 Increasing Professional's Self-Efficacy to Serve Children with Behavioral Health Conditions and Developmental Disabilities through Dual Diagnosis Echo

A. Stockreef and K. Sohl, (1)Department of Mental Health-Children's Office, 51635c157211014a8d010304ba015103, Jefferson City, MO, (2)ECHO Autism Communities, University of Missouri School of Medicine, Columbia, MO

Background:

One in three individuals with developmental disabilities also experiences mental illness, yet clinicians often lack proper training for this demographic, leading to reduced self-efficacy in meeting their needs (Brookman-Frazee et al., 2018; Pinals et al., 2022; Graduate, 2020; Maddox et al., 2020). The Accreditation Council for Graduate Medical Education does not provide the necessary competencies for such cases (Graduate, 2020). To address this, Missouri has initiated the MOADD ECHO program to improve treatment outcomes and enhance community health providers' knowledge of evidence-based practices. The program focuses on virtual sessions with professionals who support children with dual diagnoses and collects data to inform the state government about service gaps and educational needs.

Objectives:

Increase the following learning outcomes for community professionals:

1. Understand best practices for treating/managing dual diagnosis, developmental disabilities, and behavioral health conditions in children.
2. Support children with a dual diagnosis, developmental disabilities, and behavioral health conditions using best practice standards.
3. Explain the Missouri systems available for children with a dual diagnosis, developmental disabilities, and behavioral health conditions.
4. Collaborate/communicate within the Missouri systems that support children with a dual diagnosis, developmental disabilities, and behavioral health conditions.

Methods:

The MOADD ECHO initiative collects data from clinicians via pre- and post-surveys to assess their understanding of best practices and self-efficacy in working with youth with dual developmental and mental health diagnoses.

- Pre-survey: Sent after registration.
- Post-survey: Administered after the program in February.
- Both surveys include demographic questions and self-efficacy assessments focused on autism and mental illness.

Survey questions are informed by the Autism ECHO Communities program, collecting data on educational backgrounds, credentials, age, and experience with autistic youth. This approach evaluates clinician growth and program impact.

The lead facilitator organizes recommendations into categories like care coordination and barriers to care, recorded for clarity.

Results:

Self-Efficacy Data

Results from a subset of participants within the group were based on the change in self-efficacy at the end of the 3rd year series. The average percent change for the whole group of learning outcomes is 24% and the response rate for complete self-efficacy data was 16% (n=19/118). Data for 4th year was collected at mid-series, so it was collected at a different time than cohort 3. The average for cohort 4 is 29% change with the response rate for mid-series 4 being 17% (n=12/72).

Case Recommendations after 3 Cycles

Percentage of Recommendations from 70 cases presented in 3 years.

Category	Percentage of 70 cases
Medication Review	95%
Medical Assessment(Genetic testing and diagnostic evaluations)	87%
FBA and Behavioral Services	64%
Psychotherapy	54%
Family Peer Support Services	46%
Specific Training	41%

Conclusions:

Conclusions show a notable service gap for children with autism and mental health issues in the areas of medication, medical assessment, and applied behavior analysis services. The MOADD ECHO model could aid pediatricians, general practitioners, psychiatrists, and behavior analysts in Missouri by improving their self-efficacy for this population. Surveys from a subset of participants indicated a 24% increase in self-

efficacy at the program's start.

433.260 Individual Barriers to Care: Identifying Support Needs and Strengths According to Autistic Adults and Parents

J. E. Lerner¹, H. K. Schiltz², N. Schisterman³, S. M. Ziegler⁴ and C. Lord⁵; (1)UCLA Semel Institute for Neuroscience and Human Behavior, UCLA Lord Research Lab, Los Angeles, CA, (2)University of Washington, Los Angeles, CA, (3)UCLA Semel Institute, Los Angeles, CA, (4)Child and Adolescent Psychiatry, Psykiatrien i Syddanmark, Odense, GA, (5)UCLA Semel Institute for Neuroscience and Human Behavior, Los Angeles, CA

Background: Autism spectrum disorder (ASD) is heterogenous in support needs and daily life experiences (Masi et al., 2017). To meet these needs, optimal systems of care must ensure ongoing access to effective services and supports that address a range of priorities and function in partnership with autistic individuals and families (Lord et al., 2022; Pellicano et al., 2022). As such, there is a need to directly ask a cognitively diverse sample of autistic adults and their parents about which factors have been most positively and negatively impactful across the adults' development.

Objectives: This study sought to 1) identify the most common positive and negative factors experienced by autistic adults and parents, 2) test for within-subject changes in endorsement of overall promotive factors from early childhood to adulthood, and 3) test for differences in factors between adults with differing cognitive ability (i.e., less cognitively able [LCA; verbal IQ<70] and more cognitively able [MCA; verbal IQ≥70]).

Methods: The current study included 91 autistic adults (LCA=45, MCA=46; $M_{AdultAge}=29.03$, $SD=1.20$). Respondents were 38 MCA autistic adults, 40 MCA parents, and 44 LCA parents and one legal guardian ($M_{ParentAge}=60.07$, $SD=6.30$) with 32 MCA participants including both a self and parent report. Autistic adults' VIQs ranged from 4 to 139. All LCA autistic adults fell within the profound autism range (VIQ<50). Participants completed a modified version of the Social/Emotional Functioning Interview (SEF-I; Rutter et al., 1988) which consists of open-ended items about helpful and problematic factors experienced across development.

Results: Compared to MCA parents, LCA parents tended to endorse more programming, formal, and structured supports as promotive, and unequipped professionals/caregivers as problematic. MCA parents tended to report employment, education, and informal supports as promotive, and family and interpersonal conflict as problematic. MCA parents reported similarly to MCA autistic adults (i.e., no significant differences) with self-reports emphasizing hobbies/extracurriculars as promotive and a lack of social support/isolation as problematic. There were more significant differences in promotive factors between LCA and MCA parents reported in adulthood than earlier in life ($ps<.05$). Formal and informal people supports were endorsed most often as promotive across developmental stage, reporters, and cognitive groups. Endorsement of generative activities and individual/external factors (e.g., hobbies/extracurriculars, employment, developing autonomy, structure/routine) significantly increased into adulthood for all groups. The proportion of LCA parents who endorsed at least one service as promotive was significantly higher in adulthood compared to adolescence ($ps<.05$).

Conclusions: Findings highlight prevailing service gaps such as the need for more skilled professionals and structural supports, interpersonal interventions, and increased opportunities for community engagement, as well as leverageable strengths like the importance of personal relationships across formal and informal support settings. Critically, results are aligned with the lived experiences of a cognitively diverse sample of autistic individuals. Perceived risk and resilience factors can therefore inform targeted mobilizations of care systems (i.e., acknowledging and addressing varied prioritizations among families of more and less cognitively able autistic individuals which may become more pronounced over time) and direction of autistic self- and stakeholder-defined research frameworks across the lifespan.

433.261 Integrated Primary Care Psychology (IPPC) Perspective: Abbreviated Autism Assessment

K. Lantier Galatas¹, C. Burns² and J. Philpott²; (1)Ochsner Health, New Orleans, LA, (2)Ochsner Hospital, New Orleans, LA

Background: With behavioral health needs of children and teenagers on the rise, the integration of pediatric psychologists into the pediatric primary care (IPPC) setting has become an increasingly popular effort to improve access to mental health services in the United States (Lines, 2022). In many IPPC clinics, psychologists see patients referred by their pediatrician for “warm handoffs.” These same day visits, consisting of clinical interview and brief recommendations, are often a patient’s very first touchpoint with a behavioral healthcare provider. Given that the pediatric primary care setting sees a patient population that is largely infants, toddlers, and young children, the IPPC psychologist is uniquely positioned to provide monitoring for developmental delays and neurodevelopmental disorders over time (Stancin et al., 2018).

Objectives: With waitlist times at specialty care clinic sometimes spanning 18 months, efforts have been made for IPPC psychologists who encounter patients with suspected autism in their initial consults to assess and diagnose these more “straightforward” clinical cases “in house,” by way of an “IPPC Abbreviated Autism Assessment” workflow. This project will discuss assessment batteries used, workflows and implementation efforts, barriers encountered, and ongoing collaboration across systems of care.

Methods: Data collection includes retrospective review of electronic medical records and clinic operations data. In this model, parent and teacher questionnaires are gathered at the initial consultation visit (ABAS-3, BASC -3, ASRS). Patients are then scheduled for a single follow up, during which cognitive screenings are administered (DAYC-2 Cognitive, or KBIT-2R), and a social/ play observation is conducted (CARS-2).

Results: Descriptive statistics will be presented to provide information regarding patient demographics, number of patients seen through IPPC, and percentage who received an autism diagnosis through formal evaluation. Data collection is still underway at the time of this submission and will be presented based on data from 2023 through the end of 2024. Briefly, since its implementation in 2023, this service line (conducted by two psychologists at one location) has had a steady flow of patient referrals (130+), providing a diagnosis to over 100 patients to date.

Conclusions: Utilization of IPPC touchpoints for autism assessment reduces barriers to diagnosis for many families, especially those of otherwise healthy children who present to the pediatrician only for annual visits. Monitoring, assessing, and diagnosing autistic patients within their medical home allows for decreased opportunities to be “lost to follow up,” increased rapport with families, and reduced reliance on specialty care for patients in need of expedient early intervention. Patients in this model leave their assessment visit with a diagnosis and the documentation needed to access services like applied behavioral analysis, without ever being placed on an 18+ month waitlist. While this workflow has been a successful pilot and has connected many patients with needed care, challenges with reliable triaging, clinical resources (e.g., limited availability of IPPC services in hospital settings across the state and limited clinical space in pre-existing pediatric clinics), and psychologist comfort with conducting autism assessment continue.

433.262 Integrating a Novel Web-Based Autism Detection Pathway into the Sri Lankan Health System: Perspectives from Public Health Workers in Colombo

S. Hewavithanagamage^a, J. Lakshika^a, V. S. Thebuwana^a, H. S. Sewwandi^a, M. Krishnan^a, B. Fernando^a, A. Seneviratne^a, A. Hewamalage^a and D. V. Vipulaguna^a, (1)Namaste Sri Lanka, Colombo, Western, Sri Lanka, (2)Namaste Sri Lanka, Colombo, Western Province, Sri Lanka, (3)Sri Lanka College of Paediatricians, Colombo, Western, Sri Lanka, (4)Ministry of Health, Sri Lanka, Colombo, Western, Sri Lanka

Background: Improving screening and early identification mechanisms for autism is necessary to ensure positive long-term developmental outcomes. Such sustainable and accessible autism detection pathways embedded within the existing healthcare system could help improve the quality of service delivery to Sri Lankans. The current norm in Sri Lanka is clinician-administered screening for autism, operating under the constraints of low sensitivity and limited capacity. This highlights the need for a more sensitive and universal detection pathway utilizing Sri Lanka’s well established public health sector, with Medical Officers of Health (MOH) and Public Health Midwives (PHM) at the forefront.

Objectives: To identify proposed solutions that can combat barriers to the integration of a novel web-based autism detection pathway into the existing Sri Lankan healthcare system, as perceived by Public Health workers in the Colombo district.

Methods: A qualitative descriptive study, based on a pragmatic epistemological approach, was conducted gathering data through focus group discussions and in-depth interviews with 16 MOHs (4 FGDs/ 6 IDIs) and 30 PHMs (5 FGDs / 6 IDIs) from the Colombo district. Recordings were transcribed, translated, combined with observer notes, and inductive thematic analysis was used to develop key themes emerging from the data.

Results: Time, space and human resource allocations were the key barriers identified. Participants proposed the following solutions: incentivizing PHMs, implementing the screening tool at home visits instead of busy clinics, and training all staff at MOH Offices to distribute the workload more evenly. To combat the barrier of low digital literacy and resources, adequate training was proposed as a solution, given the relatively high level of training and capacity building already allocated in the healthcare system for PHMs. Funding is required to solve the issues related to digital infrastructure. Low levels of autism awareness and community engagement among parents and healthcare workers could be addressed by displaying posters and videos at Maternal and Child Health clinics; and material disseminated via social media. Additionally, establishing processes for appropriate communication of detection results to parents, aimed at minimizing parental distress, and mechanisms for a simple and efficient post-detection process, including referrals for further care, are necessary for promoting community engagement.

Conclusions: The integration process of detection pathway should be designed with a clear understanding of barriers: the constraints of limited resources, low digital literacy and resources, and low levels of community awareness on autism. Incentives, adequate training and capacity building, and practical methods of administration were suggested solutions. A pragmatic approach is necessary when mobilizing the resources of a public healthcare system, to provide solutions for the identified barriers. Sri Lanka’s well-entrenched and strong public health care system, alongside enthusiastic public health workers, can be strong enablers in the effective implementation of the web-based autism detection pathway.

433.263 Interactive and Experiential Learning to Improve Delivery of Diagnostic Care for Families of Children with Autism

T. E. Foster^a, L. Bahrami^a, C. Theoret Miller^a, G. Zilinskaite^a, T. J. Minor^a and J. Hine^a, (1)Division of Developmental Medicine, Vanderbilt University Medical Center / VKC TRIAD, Nashville, TN, (2)Division of Pediatrics, Vanderbilt University Medical Center, Nashville, TN, (3)Division of Pediatric Neurology, Vanderbilt University Medical Center, Nashville, TN, (4)Vanderbilt University Medical Center / VKC TRIAD, Nashville, TN, (5)Vanderbilt University Medical Center, Nashville, TN

Background: Due to the growing prevalence of autism and a shortage of developmental-behavioral subspecialists, non-specialist providers like primary care providers (PCPs) are increasingly playing a key role in delivering care to children with autism. Families report increased satisfaction with care when an autism diagnosis is appropriately and informatively disclosed (e.g., when their concerns are validated by professionals and when they are given information about autism and the opportunity to voice questions/concerns). However, key professionals responsible for pediatric care (e.g., PCPs) report insufficient training in discussing the diagnosis and providing autism-focused recommendations and follow-up.

Objectives: In an attempt to address these limitations and improve service delivery for children with autism and their families, we developed a novel educational curriculum – comprised of an interactive online training module and a standardized patient encounter – geared toward training pediatric providers to navigate discussions and feedback/disclosure surrounding an autism diagnosis. The goal of this study was to evaluate the acceptability, utility, and impact of our curriculum on provider confidence in key areas of practice (e.g., making a formal autism diagnosis, communicating with and providing diagnostic feedback to families, and counseling families about recommendations and referrals).

Methods: We developed an online open-access interactive learning module to train pediatric providers to discuss an autism diagnosis while navigating cultural contexts, addressing common questions/concerns, and providing motivation and support for families' next steps. Participants completed embedded electronic (REDCap) pre- and post-surveys assessing demographics, past training/experience, confidence in key areas of practice, and participant feedback. After completing the module, a subset of participants completed a simulated encounter requiring them to practice delivering an autism diagnosis. Participant performance was evaluated using a rubric consisting of 10 numerical ratings tied to module content. Participants were provided with individualized feedback on their performance and completed surveys assessing simulation utility and impact (e.g., level of confidence in related practice areas).

Results: A Wilcoxon signed-rank test indicated statistically significant increases in participants' (N = 25) confidence in 4 of 6 practice areas (Table 1), including the three primary focus areas targeted by our curriculum. Preliminary participant feedback has indicated a high level of acceptability and satisfaction. Preliminary data regarding the simulated encounter has been positive, with all participants "agreeing" or "strongly agreeing" that they felt comfortable answering questions regarding autism diagnosis after completing the simulation. In addition, participants have described the simulation as "immersible and realistic," a "great way to practice common questions," and "a helpful framework to delivering any kind of unexpected news to families."

Conclusions: Preliminary feedback indicates participant satisfaction with the curriculum, improvement in provider confidence, and utility in future clinical practice. This suggests that open-access resources and interactive/experiential learning may help to equip providers with needed autism-focused training. We will continue to collect and analyze survey data and participant performance ratings to evaluate the acceptability, utility, and impact of our educational module and simulation on provider confidence and use of key target skills.

433.264 Keeping Students with Special Educational Needs (SEN) in School from Age 16 to 18 Reduces Their Risk of Later Disengagement

E. M. Weir¹, S. White², S. Griffiths³, M. Kovacs³, C. Allison⁴ and S. Baron-Cohen¹, (1)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, Cambridge, United Kingdom, (2)University of Cambridge, Cambridge, United Kingdom, (3)University of Oxford, Oxford, Oxfordshire, United Kingdom, (4)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, Cambridgeshire, United Kingdom

Background: 1 in 4 autistic adults has attempted suicide, and only 29% of autistic adults in the UK were employed in 2021. Disengagement from school, also known as becoming 'NEET' (Not in Employment, Education, or Training), is a key risk factor for unemployment, mental health conditions, and suicide across the lifespan. To reduce the number of students who become NEET, the United Kingdom introduced legislation in 2013 to raise the minimum participation age (RPA) from 16 to 18. However, the efficacy of the RPA for students with special educational needs (SEN) has not yet been investigated. Evaluation of the RPA is important for autistic people, as autism is the most common type of SEN in the UK.

Objectives: Establishing whether RPA Legislation reduced the proportion of students with SEN who became NEET in the two years after leaving mandatory education.

Methods: This study leveraged the lifetime educational records (ages 5-20) of 113,268 children with Education, Health and Care Plans (EHCPs) across England via the National Pupil Database from five consecutive cohorts who began school in 1998-2002. Students with SEN were compared by cohort year, to evaluate the efficacy of the RPA, with Cohort 1 serving as the reference group. Cohorts 1-3 completed education before RPA implementation and were followed up at ages 17 and 18. Cohort 4 completed education during the RPA transition year and was followed up at ages 18 and 19. Cohort 5 completed education in the first year of the RPA and was followed up at ages 19 and 20. Unadjusted and adjusted mixed effects regression models were employed, accounting for gender, ethnicity, socioeconomic status, major language, social services contact, exclusion/expulsion, absences, and local authority.

Results: Students with SEN in Cohort 5 were half as likely to become NEET in the two years following mandatory education compared to students with SEN in Cohort 1. Compared to Cohort 1, students with SEN in Cohorts 2-5 all had relatively lower risk of becoming NEET in the two years following mandatory education. Exclusions, socioeconomic status, absences, social services contact, and random effects from local authority all increased risk of becoming NEET. The RPA appears effective at reducing the number of students who become NEET in the two years following mandatory education, even when following up students to age 20.

Conclusions: Requiring all students to remain in education, employment, or training from ages 16-18 reduces disengagement among students with SEN in the two years following mandatory education, even after accounting for demographic factors. Preparation for implementation of the RPA (e.g., a new reporting structure on student outcomes from schools to local authorities) or other educational policies may explain the reduction in the risk of becoming NEET for Cohorts 2 and 3. These findings support the efficacy of the RPA for students with SEN for two years, though longer follow-up is needed. Policymakers around the globe should consider the utility of increasing the mandatory education age as a key risk reduction tool for reducing long term negative outcomes for autistic students and students with other SEN.

433.265 Leveraging Lived Experience to Support Autistic People and Their Families Post-Diagnosis

A. Brewer Curran¹, K. Boles², K. Sohl³, S. Shelton⁴, V. Nanclares-Nogues⁵ and M. Mahurin⁶, (1)Department of Pediatrics, University of Missouri, Columbia, MO, (2)Child Health, University of Missouri, Columbia, MO, (3)ECHO Autism Communities, University of Missouri School of Medicine, Columbia, MO, (4)University of Missouri, Columbia, MO, (5)Pediatrics, University of Missouri - Columbia School of Medicine, Columbia, MO, (6)Department of Child Health, University of Missouri, School of Medicine, Columbia, MO

Background:

The benefit of parent-to-parent support is documented in the literature to enhance family quality of life, family functioning, service utilization, thus impacting parents to thrive. (Moody et al. 2018; Bray et al. 2017). This evidence was a primary motivation for creating the ECHO Autism: Advocates (EAA) program. The EAA program delivers professional development to family and self-advocates with the aim to increase the knowledge and skills necessary to navigate complex support systems, actively connect people on the spectrum and their families to best-practice resources, influence policy, and provide emotional support. The EAA program is led by an interdisciplinary team of content experts who provide education and support to participants who have diverse educational backgrounds and life experiences. Virtual sessions are held twice monthly for 90-minutes, where didactic and de-identified case presentations deliver curriculum to participants regarding the areas of: Medical System, Education System, Eligibility-based Services, Mentorship, Employment, Evidence-based practices & Advocacy. EAA's robust training curriculum and ability to offer ongoing guided practice to support participants positions the program to provide the level of professional development necessary to train and support family and self-advocates to mentor other autistic people and their families in a professional or non-professional capacity.

Objectives:

- Examine if EAA is an effective program in preparing participants with the knowledge and confidence necessary to serve patients/families professionally
- Examine if EAA is effective in providing adequate ongoing guided practice to assist participants to feel confident in serving patients/families professionally

Methods:

A small cohort of EAA participants (n=4) was selected to examine if participating in EAA adequately prepared and subsequently supports them to guide patients/families recently diagnosed with autism as a paid "Connector" for the ECHO Autism Community Connections (EACC) program. Four sources of data have been analyzed to examine if participation in EAA provides adequate training and ongoing support to serve as an EACC Connector.

1. Participant demographics
2. Pre-/retro-pre/post-EAA program surveys completed by recruited Connectors
3. Qualitative data collected from a Connector focus group
4. Overall EACC program satisfaction data

Results:

All participants were parents (F=3, M=1) of autistic children and participated in the EAA program for an average of 4.5 years. Self-efficacy data was collected prior to starting the EAA program. On a 6-point scale that ranged from no confidence to highly confident/expert, scores were highest in the family mentorship domain (4.31) and lowest in Eligibility-Based services (1.7). Data collected during a focus group with 4/5 Connectors felt they were adequately educated about resources, learned appropriate vocabulary, understood the boundaries of providing emotional support, and practice meeting patients/families "where they are" because of participation in EAA.

To date, the EACC program has a high-level of satisfaction from both patients/families and diagnosticians.

Data analysis will continue through February 2025.

Conclusions:

EAA provides adequate training and ongoing guided practice for parents of autistic people who professionally mentor others with autism and their families. We hypothesize that full data analysis will show there is an increase in self-efficacy reported by Connectors who participate in EACC and EACC satisfaction data remains high.

433.266 Longitudinal Mental Health Care Use and Relapse of Mental Health Problems in Autistic Adults.

I. Selten^{1,2}, T. Ziermans³ and H. M. Geurts^{1,2}, (1)Department of Psychology, University of Amsterdam, Amsterdam, Netherlands, (2)Leo Kannerhuis, Parnassia Group, Amsterdam, Netherlands, (3)Department of Psychology, University of Amsterdam, Amsterdam, Noord-Holland, Netherlands

Background:

Many autistic adults experience co-occurring mental health problems, which negatively affect their wellbeing and lead to increased mental health service use. To optimize care for autistic adults, it is essential to better understand their real-world intervention use and to tailor existing interventions to autism-specific needs. A crucial aspect of mental health interventions is relapse prevention. Relapse refers to the re-occurrence of mental health problems after initial successful intervention. To date, relapse and relapse prevention received limited attention in autism guidelines and research. Therefore, we initiated a multi-method project, addressing real world intervention use, relapse and relapse prevention in autistic adults.

Objectives:

Examining longitudinal patterns of therapy, counseling, and medication use in a large sample of autistic adults, with one such pattern possibly indicating relapse (*e.g., using therapy – no intervention – using therapy*).

Studying the perspectives of autistic adults and their clinicians on relapse and a particular relapse prevention method (i.e. relapse prevention plan).

Methods:

First we conducted a quantitative study into real-world intervention use, using self-report data on intervention use of 445 autistic adults (18-87years) across five-to-seven years. We applied sequence analysis and hierarchical clustering to identify clusters of individuals with similar patterns of intervention use. Sensitivity analyses and cross-method validation were used to verify the obtained clusters.

Currently, we run a qualitative follow-up study, including participants from an outpatient clinic specialized in mental health care for autistic adults. We interview ~15 autistic adults about relapse and relapse prevention, followed by thematic analysis. Additionally, we conduct a Delphi-study including both autistic adults (n=8) and their clinicians (n=8), collecting suggestions to tailor the relapse prevention method to the needs of autistic adults.

Results:

We obtained four clusters with distinct patterns of intervention use (least intervention, mostly counseling, mostly medication, mixed use) that differed on several demographic variables. Most notably, the “*mixed cluster*” contained relatively more females and individuals with co-occurring psychiatric conditions. We did not identify a cluster with a pattern that indicated relapse.

The data collection of the qualitative study is ongoing, and results will be presented at the INSAR conference. Results include: 1) Autistic adults’ perspectives on relapse and factors contributing to relapse. 2) Suggestions of autistic adults and their clinicians to optimize relapse prevention, resulting in a relapse prevention plan tailored to autism-specific needs.

Conclusions:

Many autistic adults made frequent and prolonged use of interventions, although they varied in type and duration of intervention use. This reflects the clinical complexity of tailoring intervention approaches for autistic individuals, particularly for autistic females and those with co-occurring psychiatric conditions. Our findings imply that accessible and multi-disciplinary care is essential to adequately support autistic adults. We speculated that our quantitative approach was limited in detecting relapse, partly because relapse in autism may be difficult to define. Results of the interviews may shed light on this issue, paving the way for future studies into relapse. Finally, we highlight the potential clinical implications of our qualitative studies for improving relapse prevention in autistic adults, including the tailored relapse prevention method.

433.267 Main Therapies Performed on Brazilian Autistic Children and Adolescents, Monthly Investment and Family Income

L. de Oliveira¹, I. Farias², A. Lira¹, L. Lopes¹, C. Gregorutti³, C. Nascimento¹, V. R. D. Gomes¹ and A. C. Steinkopf¹, (1)Steinkopf Institute, Brasilia, Federal District, Brazil, (2)Nacional Council of Science and Technology Development, Brasilia, Federal District, Brazil, (3)University of Brasilia, Brasilia, Federal District, Brazil

Background: In 2023, the first phase of the non-governmental sociodemographic data survey *Mapa Autismo Brasil* - MAB (Autism Map Brazil) was carried out in the Federal District, with the aim of identifying and describing the characteristics of individuals diagnosed with Autism Spectrum Disorder (ASD).

Objectives: This study aims to characterize the results obtained in the MAB from the perspective of the health versus autism interface, specifically: to identify and describe the therapies, by type and frequency (number of hours/week), carried out by autistic children and adolescents aged up to 14 years and to categorize, by range, both the approximate financial investment and the income of the families responding to the MAB Phase 1 with regard to these services.

Methods: The MAB sampling method was non-probabilistic convenience, data collection took place through an online questionnaire, from July to September 2023, in the administrative regions of the Federal District, Brazil, and reached a total of 1,699 valid responses. Approved by the Ethics Committee (CAAE: 70226623.9.00005540). This study included responses provided by caregivers of autistic person aged between 0 and 14 years, to which a descriptive analysis was applied.

Results: Of the 1,699 valid responses, 1,184 (69%) fell into the age range between 0 and 14 years. Of this group, 50% are at level 1, 36% at level 2, 8% at level 3, and 5% did not know how to respond. For autistic person currently undergoing therapy (n=966), the most prevalent therapies were: Psychology, with 788 responses; Speech Therapy, with 712; Occupational Therapy, with 661; Pedagogy, with 430; Music Therapy, with 276; Nutritionist, Physiotherapy, Hippotherapy, Sports/Arts, Psychomotricity and other therapies accounted for 499 all together. About hours of therapy per week, caregivers indicated that 33% of autistic people have between 1 and 5 hours, 19% have more than 10 hours, 18% did not respond, 18% have between 5 and 10 hours, and 9% have less than 1 hour. Regarding the monthly financial investment in therapies and consultations, the data revealed that 28% of caregivers spend between R\$1001 and R\$3000; 22% between R\$501 and R\$1000; 13% between R\$100 and R\$500; 12% between R\$3001 and R\$5000; and 9% invest more than R\$5000 per month; 6% of respondents receive free therapies through the public healthcare and 5% rely on associations, foundations or other non-profit organizations to pay for therapies. Regarding the family income of caregivers, the results indicate: 38% have an income higher than four minimum wages; 17% declared having no income; 16% receive between one and two minimum wages; 13% between two and four minimum wages; 9% have an income lower than one minimum wage; and 5% preferred not to respond.

Conclusions: The main therapies received by children and adolescents with autism, between 0 and 14 years old, according to the data collected, are Psychology, Speech Therapy and Occupational Therapy, with a predominant workload in the range of 1 to 5 hours per week (33%), and monthly financial investment in therapies and consultations in the order of R\$500 to R\$3000 (50%).

433.268 Maltreatment and Foster Care Placement Outcomes Among Children with Autism and Intellectual Disability: A Population-Based Study

K. A. Anderson¹, M. Radey¹, E. Dolce² and L. Cheathom³, (1)College of Social Work, Florida State University, Tallahassee, FL, (2)College of Medicine, Florida State University, Tallahassee, FL, (3)School of Social Work, University of Alabama, Tuscaloosa, AL

Background: Children with autism spectrum disorder (ASD) and intellectual disability (ID) are disproportionately involved in child welfare systems, yet little is known about the intersection of disability status, maltreatment, and foster care placement outcomes. This study seeks to explore the characteristics, risk factors, and permanency outcomes of children with ASD and/or ID involved in the child welfare system, focusing on their experiences of maltreatment allegations and foster care placement compared to children without disabilities.

Objectives: The study aims to (1) examine differences in maltreatment allegations and substantiation rates, (2) assess child and family characteristics associated with foster care placements, and (3) evaluate permanency outcomes, including the likelihood of reunification, adoption, and remaining in foster care.

Methods: Using the Child and Caregiver Outcomes Using Linked Data (CCOULD), merged administrative data from Florida's child welfare and Medicaid systems (2015-2021), this study includes children with at least one Medicaid claim and one maltreatment report (N=651,044). Disability status was categorized into four groups: ASD-only, ID-only, ASD+ID, and no ASD/ID. Logistic regression models were used to assess the odds of substantiated maltreatment and of out-of-home placement. Among those with substantiated maltreatment, we compared permanency outcomes of children with disabilities relative to children without disabilities.

Results: Children with disabilities faced significantly higher odds of maltreatment reports, with children with ID-only and ASD+ID more likely to experience multiple maltreatment reports. However, children with ASD, especially those with co-occurring ID, had lower odds of substantiated maltreatment compared to children without disabilities. Despite fewer substantiated allegations, children with ASD-only and ASD+ID were more likely to be removed from their homes, especially in adolescence. Children with disabilities also spent longer periods in foster care, particularly in non-relative and congregate care settings. Children with both ASD and ID had the highest rates of prolonged foster care placements, with 53.8% spending five or more years in care compared to 25.5% of children without disabilities. Children with ID-only and ASD+ID were also more likely to remain in foster care or age out of the system rather than achieving permanency through reunification or adoption. Children with ASD-only had higher rates of adoption (28.7%), while those with ID were more likely to age out of care, with ID-only (13.2%) and ASD+ID (14.5%) groups having significantly higher odds of aging out compared to their non-disabled peers.

Conclusions: Children with ASD and ID experience distinct challenges within the child welfare system. Although they are less likely to have substantiated maltreatment allegations, they are more likely to experience prolonged foster care placements, with many aging out of the system. These findings highlight the need for tailored interventions that address the unique circumstances and needs of children with disabilities and improve their chances of achieving permanency.

433.269 Measuring the Support Networks of NON-Speaking Autistic Youth during Their Transition to Adult Medical Care

E. McGhee Hassrick¹, K. Bouvier-Weinberg² and H. Siddiqui³, (1)A.J. Drexel Autism Institute, Drexel University A.J. Drexel Autism Institute, Philadelphia, PA, (2)Drexel University, Philadelphia, PA, (3)AJ Drexel Autism Institute, Philadelphia, PA

Background: Autistic youth approaching adulthood are expected to transition from pediatric to adult healthcare providers and navigate adult-oriented systems. People with autism are particularly vulnerable during these transitions as resources for transition decrease. For transition-age youth on the spectrum who are non-speaking, these challenges may be compounded by functional language impairments and higher prevalence rates of co-occurring conditions. Coordination among healthcare providers and between healthcare providers and family/community supporters could be a key resource for non-speaking autistic youth during transitions, however, no studies have been conducted to measure the structure, composition or social capital exchanges that occur in the social networks around nonspeaking autistic youth.

Objectives: Use mixed-methods approach to characterize the healthcare transition networks of non-speaking autistic youth.

Methods: We used purposeful sampling and recruited caregivers from different cultural backgrounds and SES (n=6) and hospital supporters (n=22) of non-speaking autistic youth (n=4) from an urban hospital. A "name generator" question (Burt, 1984) was used to identify a roster of network supporters at home, in the extended family, in the community, at school, at the hospital and with hospital community partners. The social network survey was administered in face-to-face interviews with participants lasting 30-90 minutes. SNA analysis was done in RStudio (R version 4.2.2). Semi-structured qualitative interviews were conducted in person for 30-90 minutes and were recorded, transcribed and double coded in NVIVO with consensus coding for any unmatched codes. Thematic analysis was conducted to identify themes related to medical transitions for non-speaking autistic youth.

Results: Overall network size varied greatly among youth (Figure 1). Family (35%) and community (30%) made up approx. two thirds of the overall network. School (18%) and hospital providers (11%) and hospital community providers (7%) combined to make up the rest. Non-speaking youth had positive interactions with most of the people in their ecosystem network (mean 79%). Caregivers were able to access support and resources from their support network for their autistic youth. On average, 39% of people provided good ideas, 23% provided healthcare coordination. However, only 5% of network members provide support for the transition to adult healthcare providers, indicating a need for improved collaboration around healthcare services and support for transitions within the support networks. (See Table 1). Two themes were identified: (1) purposeful delayed transition to adult services (subthemes: parents reliant on providers to initiate and manage transition to adult care, preparation delays encouraged by providers, no transition manual or playbook, bureaucratic milestones navigation creates delays); (2) individualized pathways to adult services (subthemes: caregiver as expert about youth needs, hospital provides individualized comprehensive services, individualized multisystem connections required).

Conclusions: By systematically measuring the interactions of the ecosystem supporters of non-speaking autistic youth and how they coordinate to support the healthcare transition, we can provide an interactional baseline from which healthcare supporters and caregivers can work together to identify existing social network supports and gaps in services. This pilot study contributes innovative methods for including the transition support needs of non-speaking autistic youth.

433.270 Mental Health Challenges, Including PTSD, in Medicaid-Enrolled Autistic Adults: Insights from National Claims Data. K. J. McLean¹, J. Ventimiglia², J. Wright², C. B. Klein³, S. Voltaire⁴, G. L. Wallace⁴, T. W. Benevides⁵, L. G. Klinger⁶ and L. Shea², (1)A.J. Drexel Autism Institute, Philadelphia, PA, (2)A.J. Drexel Autism Institute, Drexel University, Philadelphia, PA, (3)TEACCH Autism Program; Psychology & Neuroscience, TEACCH Autism Program, UNC Chapel Hill, Chapel Hill, NC, (4)The George Washington University, Washington D.C, DC, (5)Institute of Public and Preventive Health, Augusta University, Augusta, GA, (6)TEACCH Autism Program; Psychiatry, UNC TEACCH Autism Program, Chapel Hill, NC

Background: Research frequently overlooks the full spectrum of mental health conditions experienced by autistic adults, often failing to adequately investigate and address the unique challenges and complexities associated with mental health issues within this population. This gap in understanding may contribute to underdiagnosis and inadequate treatment options. Understanding the prevalence of mental health conditions and service utilization patterns is essential for developing effective interventions. This study investigates the experiences of adults with autism (ASD), those with autism and intellectual disabilities (ID), individuals with only ID, and those without either condition, using 2019 National Medicaid claims data.

Objectives: The primary aim of this research is to analyze the prevalence of various mental health diagnoses—including anxiety, depression, PTSD, schizophrenia, suicidal ideation, suicidal attempts, bipolar disorder, and personality disorders—among distinct disability groups aged 30-64. Additionally, we seek to explore service utilization patterns for mental health services across these groups, with particular emphasis on PTSD claims to address the calls for increased focus in this area.

Methods: Using a national sample of 2019 Medicaid claims data, we stratified adults aged 30-64 into four groups: those with ASD, those with ASD and ID, individuals with only ID, and a control group with neither diagnosis. We calculated the proportions of individuals with claims for specific mental health conditions and stratified the data by sex and age groups (30-39, 40-49, and 50-64). Service utilization for psychiatric claims was examined to identify care settings, including inpatient, long-term care, emergency department, and outpatient services. Special attention was given to PTSD claims, analyzing both primary and secondary claims, and identifying the primary diagnosis associated with secondary PTSD claims.

Results: Among 18,190 autistic adults, 58.61% of men and 64.55% of women had Medicaid claims for anxiety in 2019. 32.47% of men and 39.9% of women had claims for depression. For the 6,193 adults with ASD+ID, anxiety was reported in 59.5% (men) and 57.54% (women), depression in 20.46% (men) and 28.05% (women). Women in the ASD and ASD+ID groups exhibited higher rates of depression compared to men, particularly within the 30-39 age group. Compared to autistic adults with ID, or adults with ID only, autistic adults without ID had the highest percentage of PTSD Medicaid claims (7.57%). Of those with PTSD claims, autistic adults accessed care primarily through outpatient services. For those with secondary PTSD claims, the primary diagnosis was often depression, schizophrenia, or bipolar disorder.

Conclusions: The findings highlight the need for targeted interventions addressing anxiety, depression, and PTSD among autistic adults, particularly women. Additionally, service utilization data underscores the importance of improving outpatient and community-based care to reduce reliance on emergency services. Future research should investigate the role of trauma in autistic individuals' mental health and develop tailored strategies to improve access and continuity of care in these population.

433.271 A Pilot Feasibility Randomized Controlled Trial of Remote-Delivered Parent Training Compared to Parent Education for Parenting Stress and Challenging Behaviors in Autistic Youth in Pakistan

N. Shafique¹, K. Bearss², N. Chaudhry³, N. Husain^{4,5} and A. Scarpa⁶, (1)Virginia Tech, Blacksburg, VA, (2)Psychiatry and Behavioral Sciences, Department of Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (3)Pakistan Institute of Living and Learning, Karachi, Pakistan, (4)Division of Psychology and Mental Health, University of Manchester, Manchester, United Kingdom, (5)Mersey Care NHS Foundation Trust, Manchester, United Kingdom, (6)Department of Psychology, Virginia Tech, Blacksburg, VA

Background:

Behavioral challenges in children with autism can significantly impede their adaptive functioning and educational progress, placing substantial emotional strain on parents. In Pakistan, parents encounter considerable obstacles in accessing resources due to insufficient awareness of autism and a limited availability of specialized services. Consequently, telehealth coaching for parents has emerged as an evidence-based intervention that is more accessible for vulnerable families, minimizing the need for intensive and potentially costly professional involvement (Bearss et al., 2018). Given the growing use of technology and the limited healthcare resources in Pakistan, there is an urgent need for affordable, accessible parent-training programs to support children with autism and their families.

Objectives:

This study aimed to assess the feasibility and acceptability of a remotely delivered Parent-Led Training for Disruptive Behavior (PTDB) intervention designed to reduce parental distress and manage disruptive behaviors in children with autism spectrum disorder (ASD). A nested qualitative study design was employed to explore the feasibility and acceptability of the intervention, providing insights to inform a future clinical and cost-effectiveness trial.

Methods:

Twenty mothers of children with autism spectrum disorder (ASD), aged 3 to 12 years ($M = 5.70$, $SD = 2.46$), were randomized into either the PTDB group ($n = 10$) or the Parent Education (PE) group ($n = 10$). The PTDB intervention included 11 core sessions, one telephone booster, and one virtual session over 24 weeks, facilitated by experienced therapists via Zoom, Skype, and MS Teams. Outcome measures, such as the Irritability subscale of the Aberrant Behavior Checklist (ABC), Vineland Adaptive Behavior Scales, Parenting Stress Index, and Clinical Global Impressions-Improvement Scale, were administered at baseline, week 12, and week 24. In-depth qualitative interviews ($n = 8$) were also conducted to explore participants' lived experiences of parenting a child with ASD and their experiences with the PTDB program.

Results:

Preliminary analysis demonstrated acceptability for the remotely delivered PTDB intervention, with reductions observed in the Irritability subscale scores for both the PTDB and Parent Education (PE) groups. Notably, the PTDB intervention showed preliminary efficacy over to the PE group in managing challenging behaviors and enhancing adaptive skills among children with autism spectrum disorder (ASD). However, no significant reduction in the scores of parental stress indexes were found. Qualitative interviews revealed that mothers experienced considerable stress, particularly due to their children's challenging behaviors, which often led to social isolation. Many mothers reported resorting to alternative treatments due to the lack of available resources and formal parent training programs. Despite technological challenges in remote areas of Pakistan, the findings highlight the potential use of the PTDB intervention and its acceptability among parents.

Conclusions:

These findings will guide the design of future adequately powered multi-site clinical trials and cost-effectiveness randomized controlled trials (RCTs) in Pakistan.

433.272 Mixed Method Assessment of Proximal Implementation Outcomes across Service Settings for Caregiver Implemented Reciprocal Imitation Training (CI-RIT)

S. Deese¹, Z. C. Rogers¹, Q. O. Wedderburn¹ and S. R. Edmunds², (1)University of South Carolina, Columbia, SC, (2)Psychology, University of South Carolina, Columbia, SC

Background:

IDEA Part C requires early interventionists (EIs) to use evidence-based interventions (EBIs) with families of birth-to-3-year-olds with developmental delays, including autistic children, in the “natural” environment (i.e., home or daycare). Whether an EBI is perceived as feasible, acceptable, and appropriate may affect its system-wide implementation and ultimately, child outcomes (Proctor et al., 2011).

South Carolina EIs received training in an EBI called Caregiver-Implemented Reciprocal Imitation Training (CI-RIT) that targets social communication. Because CI-RIT is parent-mediated, it is possible that delivery in community-based settings (e.g. daycares) could introduce unexpected barriers.

Despite seeing about one third of their caseload in daycares or out-of-home settings ($M=27.240\%$, $SD=19.591$), providers’ perceptions of CI-RIT’s feasibility, acceptability, and appropriateness (FAA) did not vary by the proportion of their caseloads they served in daycares vs. homes (Wedderburn et al., 2024). It is unclear whether these perceptions remained stable after further use of the intervention with their caseloads.

Objectives:

This study builds on prior quantitative findings and qualitatively examines providers’ perspectives on CI-RIT FAA depending on caseload characteristics and provider experiences after time spent using CI-RIT.

Methods:

We employed a convergent mixed methods analytic approach (QUAL – quant) by combining quantitative pre- and post-survey data ($n=44$) from CI-RIT training with qualitative interviews ($n=5$) collected 4 to 7 months later to explore the relationships between FAA and service settings. A rapid coding analysis process was used to create a data matrix of quotes about FAA and intervention setting. Thematic analysis of overall and subthemes were extracted deductively. Themes were compared with quantitative ratings of FAA to assess how overarching opinions on FAA may have changed, both over time and with increased use of CI-RIT.

Results:

Thematic analyses of interviews revealed that CI-RIT successfully helped both new and experienced EIs teach imitation skills to young children. EIs found CI-RIT easy to learn and adaptable to existing imitation-related goals. However, the EIs had feasibility concerns regarding fidelity, balancing priorities in settings with multiple children, and with children with multiple developmental concerns. CI-RIT uses a coaching model that relies on caregiver involvement, yet EIs found that many caregivers were hesitant or unwilling to participate actively in sessions or practice at home, particularly in daycare settings where caregivers were confused about their role and how to integrate CI-RIT into home routines. EIs continued to perceive CI-RIT as acceptable, feasible, and appropriate, but noticed potential implementation challenges tied to receiving coaching indirectly or in overstimulating real-world environments.

Conclusions:

This study examined EIs’ perspectives on the feasibility, acceptability, and appropriateness of CI-RIT. While initial perceptions of CI-RIT were positive across settings, our findings several months later revealed emerging challenges in non-home environments. Despite this, CI-RIT continued to be perceived as an effective intervention for teaching imitation skills. Future implementation of CI-RIT should provide enhanced support, clarified caregiver roles, options for adapting to diverse environments and involving other children, and an evaluation process for caregiver engagement. Addressing these barriers may further enhance the effectiveness of CI-RIT to benefit all children, regardless of environment or family circumstances.

433.273 Multidisciplinary Perspective: Autism Assessment Clinic for Children Aged 5 and Under

C. Burns¹ and **K. Lantier Galatas²**, (1)*Ochsner Hospital, New Orleans, LA*, (2)*Ochsner Health, New Orleans, LA*

Background: Multidisciplinary assessment of autism offers several benefits, including increasing access for families, who can receive an autism diagnosis as well as comprehensive medical, speech, and occupational therapy assessments in the same visit. Previous research has supported that there are similar diagnostic rates in interdisciplinary assessment approaches compared to psychology-led evaluations, with benefits including reduced appointment time and increased reimbursement rates (Gerdtz et al., 2018).

Objectives: The current study presents information regarding assessment procedures and outcomes for a multidisciplinary assessment for young children (under age 5) in a hospital setting, with a focus on families from underserved communities.

Methods: Data presented was collected from June 2022 to March 2023. Sample size was 237 patients who were seen through clinic. The multidisciplinary team consisted of a psychologist, medical provider (nurse practitioner or pediatrician), speech language pathologist, and occupational therapist. These providers provide a family-centered evaluation for children with suspected autism spectrum disorder. Psychology assessment procedures including completion of a developmental background from parent rating scales (ASRS, BASC-3, Vineland-3), autism assessment (ADOS-2 or CARS-2), and assessment of developmental functioning (Mullen Visual Reception domain).

Results: Of the 237 patients seen, 183 patients (77.22%) were male and 54 (22.78%) were female. Regarding race and ethnicity, 117 (49.4%) of patients identified as White, 87 (36.7%) identified as Black, 21 (8.9%) identified as Hispanic, 2 (0.9%) identified as Asian American and Pacific Islander, 7 (2.96%) identified as multiracial or not otherwise specified, and 3 (1.3%) chose not to say. Patients with Medicaid as their primary insurance comprised the majority of the sample (163 or 68.79%), followed by private insurance (66 or 27.85%), and 9 patients (3.8%) did not have insurance at the time of their appointment. An interpreter was used for 16 of the 237 families (6.75%). Regarding diagnostic outcomes, 198 patients (83.4%) received an autism diagnosis, while only 39 (16.5%) did not receive a diagnosis. Average age at diagnosis was 40.82 months ($SD=9.36$), with a range of 24 to 59 months of age. Wait times ranged from less than one month to 34 months, with an average of 9 months ($SD=6$).

Conclusions: Results indicate very high rates of diagnosis for patients referred to this clinic, which speaks to the accuracy of pediatrician referrals and the need for increase access to assessment. A significant barrier to access includes the long wait times identified, as well as the large amount of variability in wait time, which indicates operational challenges and barriers. The results also indicates potential barriers to access for children of different racial and ethnicity backgrounds, as the majority of children seen were identified by their parents as being either White or Black, and significantly fewer Hispanic and AAPI patients were seen through clinic. Although the demographics were generally consistent with the population of the greater New Orleans areas, qualitative information gathered through operational discussions indicate that Spanish-speaking families have more challenges navigating the scheduling and measure completion components of the evaluation. Potential solutions and future directions are discussed.

433.274 Multiple Pathways to Excellent Health Status in Autism: A Secondary Analysis of the 2022 National Survey of Children's Health

A. C. Quon¹ and **S. H. Ailey²**, (1)*Rush University, Chicago, IL*, (2)*College of Nursing, Rush University, Chicago, IL*

Background: Although health disparities in autistic people are well-documented, less is known about how multi-level health determinants combine with one another to contribute to inequitable outcomes. Owing to the limited resources available to address complex health determinants, researchers must identify what factors make a difference, for whom, and under what conditions, particularly for minoritized and marginalized groups like children with autism. Coincidence analysis (CNA) is a cross-case, mathematical approach that can pinpoint the minimally sufficient and necessary conditions for an outcome, and identify multiple pathways to the same outcome, making it a suitable method to examine intersecting determinants of health.

Objectives: Guided by the National Institute on Minority Health and Health Disparities Research Framework, the objective of this study was to identify key bundles of difference-makers that account for “excellent/very good” overall health status among a large sample of autistic children using CNA.

Methods: The 2022 National Survey of Children’s Health contains publicly available data on multi-level determinants of health for 1,726 children whose parents reported a current diagnosis of autism at the time of the survey, perceived overall health status of the child on a five-point Likert scale, and various other health and well-being factors. A literature review informed the selection of 62 potentially relevant factors for modeling the outcome of interest. CNA was applied to develop a model for explaining “excellent/very good” health among the sample.

Results: The initial exploratory analysis identified five of the highest scoring factors: intellectual disability severity, difficulty obtaining specialist care, family resilience level, chronic pain, and history of being overweight (as told by a healthcare provider). The final model explained “excellent/very good” health status via two combinations of factors: 1) no intellectual disability, no experience with chronic pain, and high family resilience, and 2) no need for specialist care and no history of being overweight. This two-pathway solution accounted for 86% of the cases reporting excellent/very good overall health with 80% consistency.

Conclusions: Given the complexity of autism health, research priorities include drawing upon innovative methods to better understand and address health disparities and their intersecting factors. CNA revealed combinations of multilevel health determinants that make a difference in the overall health status of autistic children. This new, nuanced understanding of specific phenotypes can guide future interventions and practices aimed at modifiable individual and family-level determinants of health.

433.275 Navigating Suicide Screening for Youth with IDD: Insights from Dbpnet

S. N. Wozniak-Kelly^{1,2}, K. E. Wallis¹, J. Cacia³, K. Wu^{2,4} and C. Nadler⁵. (1)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (2)PolicyLab, Children's Hospital of Philadelphia, Philadelphia, PA, (3)Developmental Behavioral Pediatrics, Children's Hospital of Philadelphia, Philadelphia, PA, (4)Qualitative Research Core, Children's Hospital of Philadelphia, Philadelphia, PA, (5)Children's Mercy Kansas City, Kansas City, MO

Background: Depression and suicide frequently co-occur in individuals with autism and intellectual and developmental disabilities (IDD), although there are limited evidence-based strategies to respond to positive suicide screens in clinical settings for patients with autism or IDD. As developmental-behavioral pediatrics (DBP), psychology, and psychiatry practices that serve these populations are frequently housed in pediatric hospitals, they are subject to the Joint Commission’s National Patient Safety Goal requiring universal screening for suicide risk in patients 12 years and older. Due to the lack of guidance for screening youth with IDD for suicide risk, there is a pressing need for the development of comprehensive strategies and guidelines tailored to support the needs of this population. Improved understanding of current practices as well as the barriers and facilitators to risk identification is critical.

Objectives: Identify variations in practices, facilitators, and barriers to universal suicide screening of children with IDs in pediatric developmental and behavioral health settings.

Methods: Clinicians from hospitals within the Developmental Behavioral Pediatrics Research Network (DBPNet) were invited to describe their suicide screening practices in their developmental-behavioral pediatrics, psychology, and/or psychiatry clinics. One representative per site was asked to complete surveys (summarized with descriptive statistics) and semi-structured interviews (summarized using thematic analysis) to further explore their site’s processes for suicide screening, actions taken in response to a positive screen, and procedures specific to patients with autism or IDD.

Results: Participants included 34 survey respondents and 21 interviewees (Table 1). Surveys revealed variation in suicide screening practices across sites; 44.1% of respondents reported that their practice conducts universal screening, but the processes in place to screen varied widely. All but 2 sites reported some monitoring efforts to ensure screening occurs, but only 4 sites (11.1%) specifically monitor for compliance for youth with IDD.

Interviews (Table 2) identified some facilitators for screening youth with IDD, such as standardizing procedures, training, and having additional staff and facilities available to respond to positive screens. Barriers to universal screening include factors at the patient, family, provider, and system levels. Insufficient mental health care systems in general, as well as a lack of IDD-specific supports, were identified as significant challenges for managing patients with positive suicide screening results.

Conclusions: Despite Joint Commission requirements and specific expertise in behavioral health, we observed wide variation in how suicide screening is implemented and the processes in place for responding to positive screens. Findings offer opportunities to standardize procedures to increase suicide risk identification and response.

433.276 Navigating the Adult Autism Diagnostic Process in Canada: Complex, Costly, and Inaccessible

A. Wickie¹, G. Iarocci², J. McLaughlin³, M. Schneider³ and N. E. Scheerer¹. (1)Psychology, Wilfrid Laurier University, Waterloo, ON, Canada, (2)Psychology, Simon Fraser University, Burnaby, BC, Canada, (3)Wilfrid Laurier University, Waterloo, ON, Canada

Background: Many autistic individuals face lifelong challenges, often feeling different, but do not receive an autism diagnosis until adulthood. **Objectives:** This study explored the experiences of autistic adults in Canada as they navigated the diagnostic process, aiming to highlight its strengths and weaknesses.

Methods: Seventy-four formally diagnosed ($n = 52$), and self-identifying ($n = 22$) autistic adults (ages 20-78, $M = 38.34$), in Canada, were surveyed using an online questionnaire. The survey examined the factors that led them to pursue a diagnosis, the time it took to get their diagnosis, and the positive and negative aspects of the experience.

Results: The sample contained 44 females, 13 males, and 17 other identified genders (i.e. non-binary, demi-female, autigender, agender, and gender queer). The sample was highly educated with 56 respondents (74.7%) having some form of post-secondary education or higher, 51 (68.0%) employed, with 34 respondents (48.6%) reporting above average income ($\geq \$75,000$ CDN annually). All formal diagnoses occurred in 2011 or more recently. Three prevalent co-occurring conditions were sensory challenges ($n = 68$, 80.9%), anxiety ($n = 58$, 81.7%), and depression ($n = 55$, 82.1%). Among these adults, ongoing social difficulties ($n = 64$; 86.5%), difficulties with friendships or intimate relationships ($n = 60$; 81.08%), and mental health concerns ($n = 56$; 75.7%) most often motivated them to seek a diagnosis. Shockingly, 27 respondents (39.7%) reported needing to see four or more professionals to obtain their autism diagnosis. The median cost for obtaining a diagnosis was \$1,500 CDN, although respondents reported spending anywhere from \$0 - \$25,000 CDN. The median amount of time to obtain a diagnosis was 11 months; however, the range was large, with respondents reporting anywhere from 0 - 460 months (nearly 40 years). Interestingly, 33 respondents (49.3%) received a Level 1 diagnosis (i.e., "requiring support"; 19 female, 5 male, 9 other), while 31 respondents (46.3%) did not receive an autism level with their diagnosis (19 female, 4 male, 8 other). This may suggest that many adults with lower support needs go undiagnosed in childhood. The most helpful resources during the diagnostic process were resources created by other autistic individuals and autistic professionals online (e.g., blogs, videos, websites, therapists; $n = 14$, 21.9%), and some individuals also reported not finding any resources helpful ($n = 14$, 21.9%). Conversely, the least helpful were "uneducated professionals" (e.g., family doctors, psychologists, etc.; $n = 26$, 40.6%), and the lack of age-appropriate resources or lack of resources designed for adults with lower support needs ($n = 16$, 25.0%). A deeply concerning finding was that 41.4% of respondents reported engaging in self-harm, highlighting the urgent need for improved support.

Conclusions: The findings demonstrate that the adult autism diagnostic process in Canada is often prohibitively expensive and complex, with long delays, multiple consultations, and significant barriers related to professional knowledge gaps. These challenges make it inaccessible to many adults, especially those with fewer financial resources or lower educational backgrounds. Urgent improvements are needed to better support autistic adults seeking diagnosis and care in Canada.

433.277 Neurodiversity-Affirming Terminology: Speech-Language Pathology Graduate Students' Patterns of Usage across School Years

G. A. Bravo and **E. A. Choi**, *Communicative Disorders and Sciences, San Jose State University, San Jose, CA*

Background: Speech Language Pathologists (SLPs) are obligated to provide services that align with neurodiversity-affirming values when working with autistic clients and their families (American Speech-Language-Hearing Association, 2024; Davies et al., 2024). Despite the critical impact neurodiversity affirming practices have on psychosocial emotional outcomes for autistic individuals, not all SLPs understand the faults in ableist practices and fail to embrace the change away from the medical model of disability. This is especially true regarding the alarming rise in SLPs who are willing, yet have not successfully adopted neurodiversity-affirming terminology and practices (Gaddy et Crow, 2023). In order to ensure that future SLPs have the intrinsic motivation to understand the autistic community and are educated on the importance of neurodiversity affirming practices, it is important to evaluate current trends of SLP graduate students' knowledge and utilization of neurodiversity-affirming terminology. **Objectives:** To gain a better understanding of SLP graduate students' knowledge of neurodiversity-affirming practices through differences in utilization of neurodiversity-affirming terms across school years.

Methods: Self-reported data were collected from 33 SLP graduate students enrolled at San Jose State University. Qualtrics surveys were completed anonymously and voluntarily by leveling year students ($n=14$), first year students ($n=9$), and second year students ($n=10$). Participants completed a set of questions with a 3-point Likert scale (rarely, sometimes, often) to disclose their utilization for each of the 8 pairs of pathologizing and neurodiverse-affirming terminology counterparts. Proportion analyses were employed to observe the different patterns of pathologizing versus neurodiversity-affirming terminology usage across school years.

Results: As expected, we observed a decreasing trend in the usage of pathologizing terms across the school years. Further, an increasing trend of "Rarely used" confirmed that students appear to appropriately not use pathologizing terms across the school years (i.e., 32.14% for leveling year students, 44.44% for first year students, and 54.50% for second year students). However, similar patterns were not observed in the neurodiversity-affirming terms. In fact, students across education year were indicating usage of affirming terms at chance level (e.g., approximately 30% across all 3 answer options). Upon closer evaluation of the 8 terminology pairs, only three specific pairs (i.e., individual with autism vs autistic individual, restricted interest vs area of interest, and non-verbal vs non-speaking) had increasing trends in usage of neurodiversity-affirming term and decreasing trends in usage of pathologizing term as the students gained educational experiences. Nevertheless, the other 5 terminology pairs did not follow the expected trends and were shown to have unpredictable patterns of usage.

Conclusions:

These findings suggest that while students may demonstrate decreased usage of pathologizing terminology, they may not be confident in their knowledge and utilization of neurodiversity-affirming terminology. The mixed patterns of usage observed between pairs may be an indicator of insufficient training on neurodiversity affirming terminology and practices. Further research is needed to better understand the clinical implications in using neurodiversity affirming terminology and practices of SLPs working with the neurodiverse population.

433.278 One-Year-Old Autism Diagnosis Among Medicaid-Enrolled Children from 2017 to 2019

O. J. Lindly¹, **C. Charlesworth**², **K. Watson**³, **V. I. Underwood Carrasco**², **V. Sutherland**³, **D. Folch**³ and **K. Zuckerman**¹, (1)Health Sciences, Northern Arizona University, Health Sciences Department, Flagstaff, AZ, (2)Oregon Health & Science University, Portland, OR, (3)Northern Arizona University, Flagstaff, AZ, (4)Division of General Pediatrics, Oregon Health & Science University, Portland, OR

Background: Autism diagnosis before children turn three is increasingly feasible and can facilitate access to needed services and supports during the critical early childhood period of development. Yet, limited research has investigated how the frequency of very early diagnoses (at ages 12-24 months, hereafter one-year-old diagnosis) versus early diagnosis (at age 2 or 24-47 months, hereafter age 2-3 diagnosis), are occurring in the U.S., particularly among Medicaid-enrolled children. Furthermore, little is known about geographic and racial and ethnic disparities in one-year-old diagnoses among this population.

Objectives: We examined (1) trends in very early autism diagnosis (at age 1) versus early diagnosis (ages 2-3) from 2017 to 2019; and (2) disparities in one-year-old diagnosis by race and ethnicity, adjusted for biological sex, and geography (state and rurality) among Medicaid enrolled children diagnosed between ages 12-47 months.

Methods: This was a retrospective cohort study in which data from 14 states in the Transformed Medicaid Statistical Information System Analytic Files (TAF) were analyzed. To be considered diagnosed with autism, each child needed to have had a diagnostic visit with a primary or specialty care provider, with a diagnosis code for autism between 2017 and 2019. Children in the cohort needed to have been enrolled in Medicaid for 11 of 12 months with no history of an autism diagnosis code before the diagnostic visit. Our main dependent variable was whether children were diagnosed with autism at age 1 (12-23 months) versus at age 2-3 years (24-47 months). Unadjusted and adjusted (by biological sex; further, by rurality and state) Ordinary Least Squares (OLS) regression models were fit to assess disparities in one-year-old diagnosis.

Results: The sample included 11,447 children including 9.3% diagnosed at age 1 and the rest diagnosed at 2 or 3 years old. The number of children diagnosed at age 1 increased from 2017 to 2019. There was statistically significant variability in one-year-old diagnosis by sex, race and ethnicity, and rurality (Table 1). Substantial variation in one-year-old diagnosis by state was also found (North Dakota = 1.1% to Georgia = 12.5%). OLS unadjusted and adjusted model results are shown in Figure 1. After adjusting for biological sex, rurality, and state, Black children were significantly less likely than white children to be diagnosed with autism at one year of age ($p = -1.24$; 95% confidence interval = $-2.18, -0.30$; $p = .009$). A similar association was found for American Indian and Alaska Native children ($p = -3.04$; 95% confidence interval = $-5.37, -0.72$; $p = .01$).

Conclusions: This study's results suggest that very early autism diagnosis (at age 1) is increasing among Medicaid-enrolled children. Nevertheless, disparities among children receiving a very early diagnosis exist – particularly in terms of children who are Black or American Indian and Alaska Native. Continued work is needed to reach children who have been historically underserved by autism services in the United States.

433.279 Optimizing Recruitment and Retention: The Role of Referral Networks in Parent-Child Interaction Therapy for Children with ASD

A. Peskin¹, M. Parladé², W. A. Rothenberg^{3,4}, J. F. Jent³ and D. Garcia³, (1)Mailman Center for Child Development, University of Miami, Miami, FL, (2)University of Miami, Coral Gables, FL, (3)University of Miami, Miami, FL, (4)Duke University, Durham, NC

Background:

Approximately one in four children with autism spectrum disorder (ASD) also have a disruptive behavior disorder (Kaat & Lecavalier, 2013; Ros-DeMarize, Klein & Carpenter, 2023), which often results in referrals to community mental health clinics (Mandell et al., 2005). However, for a variety of reasons sometimes these families get lost between referral and intake, or intake and graduation, thus not receiving the services they need.

Objectives:

This study examined the recruitment and referral network of a parenting program providing Parent-Child Interaction Therapy (PCIT) to children with ASD in a large urban academic medical center and affiliated community-embedded clinics, to determine whether specific recruitment/referral sources could impact the likelihood of families completing screening paperwork, attending intake and completing treatment.

Methods:

Data from 291 families of children with diagnoses of ASD referred between 2018 and 2022 were analyzed. Referral sources included but were not limited to community agencies, social media, and healthcare providers. Logistic regression analyses determined the likelihood of completing the screening paperwork, attending intake, and completing treatment based on recruitment/referral sources.

Results:

Likelihood of families completing their screening packets was greater for those referred by pediatricians ($OR = 3.387$, 95% $CI[1.591, 7.212]$, $p = .002$). Likelihood was also greater during COVID ($OR = 1.818$, 95% $CI[1.060, 3.119]$, $p = .030$). Likelihood of attendance at intake was greater for those referred by medical specialists (e.g., neurologists; $OR = 10.787$, 95% $CI[2.265, 51.370]$, $p = .003$), pediatricians ($OR = 2.870$, 95% $CI[1.144, 7.203]$, $p = .025$), community disability organizations ($OR = 4.731$, 95% $CI[1.669, 13.412]$, $p = .003$), and word-of-mouth ($OR = 15.559$, 95% $CI[1.893, 127.874]$, $p = .011$). None of the referral sources significantly predicted treatment completion.

Conclusions:

Effective recruitment and retention strategies are crucial for engaging families in mental health services. Findings emphasize the role of community and healthcare providers and word-of-mouth in improving treatment access and enrollment, highlighting the need for referral pipelines between pediatricians and mental health providers, and the importance of these for continuity of care, particularly in children with ASD. Additionally, the lack of significant findings for treatment graduation highlight previous findings that have emphasized treatment-specific factors (rather than referral factors) in determining which families complete treatment.

433.280 Overview of the Rural Access to Intervention and Support Evaluation (RAISE) Trial

E. R. Kielmeyer¹, A. K. Spittler², F. V. Alzhayri², A. R. Dixon³, A. Nicholson¹, A. Stainbrook¹, A. Swanson², M. Fleck³, K. Simcoe⁶, J. F. Hine², L. Wagner⁷ and Z. Warren⁸, (1)Vanderbilt University Medical Center / VKC TRIAD, Nashville, TN, (2)Vanderbilt University Medical Center, Nashville, TN, (3)Vanderbilt, Nashville, TN, (4)Vanderbilt Kennedy Center/TRIAD, Nashville, TN, (5)VUMC Dept of Pediatrics, VKC-TRIAD, Nashville, TN, (6)Vanderbilt University Medical Center- Treatment and Research Institute for Autism Spectrum Disorder, Nashville, TN, (7)Waisman Center, University of Wisconsin-Madison, Madison, WI, (8)Vanderbilt University Medical Center - Treatment and Research Institute for Autism Spectrum Disorder, Nashville, TN

Background: Telemedicine holds the potential to address barriers of access to assessment of children at risk for autism. Recent research on tele-assessment has examined its use in controlled research settings or in response to the COVID-19 shutdown. Given the broad range of family concerns and systems-level factors that may affect tele-assessments in clinical practice, there is a need to understand their impact when deployed in traditionally underserved communities. This project evaluates implementation and potential benefits of autism-focused tele-assessments for families with young children in rural districts of Tennessee to understand the mechanisms that support meaningful, sustained, and equitable real-world use of this model.

Objectives: In the current work, we present trial design and initial referral data capture from launch of this DOD-funded trial. Through a partnership with our state Part C system (TEIS: Tennessee Early Intervention System), this study investigates the clinical, familial, and service-system level impact of the introduction of tele-assessment across entire rural catchment areas. The work aims to identify and address barriers to successful implementation of this novel tele-assessment model in underserved areas with existing healthcare disparities.

Methods: Utilizing a stepped-wedge randomized cluster design, we are evaluating pre-post child, family, provider, and system-level impact of deployment across four rural Part C districts. Following baseline capture, implementation is rolled-out in 6-month intervals offering tele-assessment to families traditionally seen in-person (District A: April 2024, District B: October 2024; District C: April 2025, District D: October 2025). Data from referral and electronic records will assess how implementation: (1) affects the number and characteristics of children referred/identified, family engagement, and efficiency and cost-effectiveness of care; (2) examines potential moderating roles of family (e.g. race and socio-economic status) and systems-level (provider perceptions) factors on engagement and impact; and (3) evaluates the impact of family characteristics on diagnosis and family satisfaction with tele-assessment.

Results: 319 children from District A have been referred (195 baseline, 124 intervention). See Table 1 for demographic information of district referrals. A total of 154 appointments were scheduled during baseline (83 in-person, 24 tele-assessment) and intervention (36 in-person, 11 tele-assessment). Table 2 presents responses from TEIS providers about their perceptions of telemedicine pre-visit and feedback from Vanderbilt clinicians about their experiences with telemedicine post-visit. TEIS Providers ($n = 20$) believed that tele-assessment would improve access to services ($M = 4.42$) but were less confident that families would have the necessary resources ($M = 3.68$). Clinicians frequently noted that families completing tele-assessments had access to toys and equipment necessary for the evaluation ($n = 34$).

Conclusions: This ongoing project will provide a critical test of the model's impact on care of toddlers with ASD in rural settings. By embedding site-specific models of ASD tele-assessment within existing early intervention programs and evaluating performance with targeted groups of families, we will gather information necessary for deployment across systems responsible for identifying and facilitating treatment for young children from these areas. Preliminary data from launch suggest that TEIS providers in underserved areas see benefits to tele-assessment and clinicians are satisfied with caregiver involvement.

433.281 Parental Employment Changes in Families with Autistic Children

J. E. Rust¹, A. Jaffe², A. Roux³, K. A. Anderson³, V. Vasudevan⁴, A. Esposito⁵ and S. Spielman⁶, (1)A.J. Drexel Autism Institute, Drexel University, Philadelphia, PA, (2)Drexel University, Philadelphia, PA, (3)College of Social Work, Florida State University, Tallahassee, FL, (4)Autism Speaks, Gainesville, FL, (5)Autism Speaks, New York, NY, (6)Autism Speaks, Washington, DC

Background: Labor force participation is important among parents of autistic children in the U.S. to maintain employer-sponsored health insurance and to earn money for common out-of-pocket expenses. Autistic children often have many health and mental health medical needs that require time to attend and to coordinate, which can reduce the time a parent may be able to spend on employment. Research of non-autistic populations addresses this issue and shows that care coordination reduces parental employment changes by as much as half. Autistic children often have complex needs and more barriers to accessible care than other children with special health care needs (CSHCN), making it important to understand the role of care coordination in employment for families with autistic children.

Objectives: The objective was to examine changes in employment of parents with autistic children compared to parents with CSHCN. We examined the following questions: (1) What are the differences in changes of employment between parents of autistic children compared to parents of CSHCN? (2) How does receipt of care coordination impact changes to employment?

Methods: This study used the National Survey of Children's Health (2021-2022) to examine employment changes in two ways: 1) reduced hours or stopped working, and 2) avoided changing jobs to keep insurance. We estimated the prevalence of employment changes for parents with autistic children compared to parents of CSHCN and used multivariable logistic regression to examine associations with employment changes (including child characteristics, household characteristics, and care coordination status). Finally, we examined differences by age and insurance type stratified by care coordination status, to examine potential interaction of these variables in parents with autistic children and CSHCN.

Results: Parents of autistic children were more likely to experience changes in their employment relative to CSHCN (Figure 1). Care coordination was strongly associated with employment changes for parents of autistic children and CSHCN. More than half (59%) of parents of autistic children and one-third (36%) of parents of CSHCN ages 3-5 years who did not receive needed care coordination reduced hours or stopped working. For autistic children, this was nearly triple the rate of parents who received needed care coordination (21%). Further, within each type of insurance coverage, families who did not receive needed care coordination had the greatest rates of reducing or stopping work hours: 60% of parents of autistic children with both public and private insurance who did not receive needed care coordination reduced hours or stopped working.

Conclusions: Parents may need to reduce hours or stop working to support their child in receiving the services they need, but receipt of adequate care coordination may ameliorate some of this need. The findings from this study demonstrate the need for further research to examine the provision of care coordination and the reimbursement changes to support care coordination, ultimately improving parental employment outcomes and creating more support for families with autistic children.

433.282 Pathway to Change: A Comprehensive Evaluation of the Extensive Needs Service Pilot Program in Ontario

Z. O. Salami¹, A. D'Angiulli², I. Drmic³, J. Edwards⁴, G. Ferguson⁵, V. Rombos⁶, R. Baysarowich², K. Decker⁶, N. Denomey², L. Hayawi², T. Jeyabalan⁶, T. Johansen², K. Margallo⁷, N. Mitsakakis², R. Webster² and M. Penner⁸, (1)Holland Bloorview Kids Rehabilitation Hospital, East York, ON, Canada, (2)Children's Hospital of Eastern Ontario (CHEO), Ottawa, ON, Canada, (3)Autism Spectrum Disorder Service, McMaster Children's Hospital - Hamilton Health Sciences, Hamilton, ON, Canada, (4)Offord Centre for Child Studies, McMaster University, Hamilton, ON, Canada, (5)Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (6)Hamilton Health Sciences, Hamilton, ON, Canada, (7)McMaster Children's Hospital, Hamilton, ON, Canada, (8)Autism Research Centre, Bloorview Research Institute, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada

Background: Existing services often fail to meet the needs of children/youth with intersecting mental health, physical, and neurodevelopmental complexities. Without adequate care, many complex children/youth require acute care services, which are often not suited to their needs. Three Ontario children's hospitals are piloting a program (the Extensive Needs Service, ENS) to provide wrap-around care for individuals with intersecting complexities and unmet needs, including implementing measurement-based care within a rapid learning health system.

Objectives: To describe baseline characteristics of research participants in the Extensive Needs Service across three Ontario children's hospitals.

Methods: We identified key clinical outcome areas based on the funder goals for the program: family distress level measured via the Brief Family Distress Scale (BFDS); mental health/behaviour symptoms measured via the Behavior Assessment System for Children 3rd Edition (BASC-3); and resource-use measured via the Resource Use Questionnaire (RUQ). Participants are research consented children/youth and families receiving care through the ENS at three Ontario children's hospitals (Holland Bloorview Kids Rehabilitation Hospital (HB), McMaster Children's Hospital (MCH) and Children's Hospital of Eastern Ontario (CHEO)). Baseline patient-and-family reported outcome measures (PROMs) are distributed to families at the start of service and longitudinally to inform clinical care and program evaluation. Only participants who consented to research participation were included from HB and CHEO. MCH data were collected as a chart review with waiver of consent. We calculated descriptive statistics to describe the baseline characteristics of ENS clients.

Results: To date, 112 participants have been recruited (HB n=35; MCH n=56; and CHEO n=21). Participants (59% male; n=66) had a mean age of 11.4 years (SD 3.7; range 4-17); and came from varied racial/ethnic backgrounds and income levels. The three most common diagnoses (available for two out of the three sites (HB and CHEO)) included: autism spectrum disorder (n=36), anxiety (n=16), and attention-deficit/hyperactivity disorder (ADHD) (n=15). At baseline, median family distress level was reported at 5/10 ("things are very stressful, but we are getting by with a lot of effort")¹. Fifty-two percent of participants had visited the emergency department over the past two years for behaviour/mental health issues. Across participants, the mean BASC-3 T-scores were 75 (clinically significant), 65 (at-risk), and 77 (clinically significant) for the Externalizing subscale, Internalizing subscale, and Behavioral Symptoms Index, respectively.

Conclusions: Children/youth with a wide range of ages, backgrounds, diagnoses, and social situations are entering ENS with substantial family distress, unmet behavioral needs, and resulting acute care usage. Services for similarly complex children should be determined based on needs and not solely on diagnosis.

433.283 Perinatal and Postpartum Health Disparities Among Black Autistic Birthing People in the US Medicaid System

L. Shea¹, M. Sadowsky², S. Tao³, J. Ventimiglia⁴, D. L. Gassner⁵, N. Bhadra-Heintz⁶ and T. W. Benevides⁶, (1)A.J. Drexel Autism Institute, Drexel University, Philadelphia, PA, (2)A.J. Drexel Autism Institute, Philadelphia, PA, (3)Drexel University, Philadelphia, PA, (4)Social Work, AJ Drexel Autism Institute, West Hempstead, PA, (5)University of Pennsylvania, Philadelphia, PA, (6)Institute of Public and Preventive Health, Augusta University, Augusta, GA

Background: Amid a national Black maternal health crisis, the use of data from the largest public health insurer (Medicaid, which funds almost half of births in the US), presents an opportunity to generate findings that are relevant for policy and programmatic reform. Medicaid is also the largest funder of behavioral health care and insures high rates of autistic people. Little is known about perinatal health outcomes among Black autistic birthing people. Previous research centered on the experiences of Black birthing people indicates that minoritized identities, including race, ethnicity, and disability status, may contribute to additive risk for adverse perinatal outcomes.

Objectives: Identify perinatal outcomes among a national longitudinal sample of Black autistic birthing people enrolled in public health insurance and compare them to outcomes among Black birthing people with intellectual disability (ID) and without either autism or ID diagnoses

Methods: National Medicaid claims from January 1, 2008, to December 31, 2019 included Black autistic birthing people, Black birthing people with ID, and a random sample of Black birthing people without autism or ID. Comparison cohorts for each group for white individuals and individuals with other or multiple race/ethnicity were also constructed. Black birthing people and comparison cohorts included individuals with a documented birth during the study period. Perinatal outcomes utilized in previous research among individuals with I/DD were compared using univariate and multivariate logistic regression models. The probability of postpartum anxiety and depression was estimated using Kaplan-Meier and Cox proportional hazards regression models.

Results: More than 3,350 Black autistic birthing people were identified and were younger (mean age 23, SD = 5.9) than their peers with ID (25.5, SD = 6.8) and no autism or ID (26.4, SD = 6.3). Across all groups, most Black birthing people lived in urban areas (79%). Compared to their Black peers with ID or no autism or ID, a higher proportion of Black autistic birthing people had a known miscarriage, stillbirth, or termination (18.8%, vs. 18.5% and 17.7%) and postpartum anxiety (7.1%, vs. 6.5% and 1.9%). In adjusted analyses, Black autistic birthing people had elevated odds for known miscarriage, stillbirth, or termination (1.3; 95%CI 1.13–1.43) and preeclampsia (1.4; 95%CI 1.1–1.7) when compared to their white autistic peers.

Conclusions: In the US Medicaid system, identified Black autistic birthing people are younger than and experience adverse perinatal outcomes at higher rates compared to their peers. Findings underscore the urgent need for awareness about reproductive healthcare broadly and in adolescence and young adulthood. Individualized strategies for effective prenatal, childbirth, and postpartum care to ensure equitable access to maternal healthcare for Black autistic people are needed and should be generated from community-driven processes. Focusing policy and programmatic change in the Medicaid system could support improvements for thousands of Black autistic birthing people.

433.284 Predictors of Depressive Symptoms in Direct Support Workers and Professionals Working in Residential Settings

A. A. Lachapelle¹, M. M. Dufour¹, V. Martin², K. Kutlesa³ and J. Dube⁴, (1)Psychoeducation, University of Montreal, Montreal, QC, Canada, (2)School of management-Departement of organisation and human resources, Université du Québec à Montréal, Montreal, QC, Canada, (3)Psychology, Laval University, Quebec, QC, Canada, (4)IRSST, Montreal, QC, Canada

Background: In Quebec, autistic adults or adults with an intellectual disability (ID) can live in different types of residential settings depending on their support needs (MSSS, 2014). Direct support workers (DSW) and direct support professionals (DSP) may be exposed to occupational risks that can affect their physical and psychological health, such as the presence of depression symptoms (Bottini et al., 2020). Several factors can lead to depressive symptoms including multiple job demands, work stress and inadequate organizational resources (Gray-Stanley et al., 2010). However, social support is a protective factor for workers' mental health (Ryan et al., 2021). The working conditions of DSWs and DSPs working with autistic adults or adults with ID in Quebec is an issue that has been little explored, although advocates have highlighted several problems in the residential system, including staff turnover.

Objectives: To explore the predictive factors of depressive symptoms in DSW and DSP in the Quebec housing system for autistic adults or adults with ID.

Methods: Quantitative analyses were performed on data collected from 56 participants during the first week of the longitudinal project "Taking Care of Those Who Take Care." A multiple linear regression model was run using a depression severity score obtained from the Patient Health Questionnaire (9 items; Kroenke et al., 2001) as the dependent variable. Independent variables were organizational factors measured by the COPSOQ-III questionnaire (Berthelsen et al., 2020), and the total score of the Social Support Scale (10 items; SPS; Caron, 2013). Variables were introduced simultaneously to build the regression model.

Results: Participants were 43 women and 13 men, with an average age of 37 years old. Most worked between 33 and 40 hours per week, 15.8% had a PHQ-9 score in the moderate range and 5.3% in the moderately severe and severe ranges. The variables included in our regression model were the perception of social support score (SPS), the average number of hours worked per week, and the perception of the negative impact on their personal life caused by the amount of energy their job demands (COPSOQ). This resulted in a statistically significant model, $F(3.52) = 14.311, p < .001, R^2 = .452$. Individual predictors were further examined and indicated that social support ($t = 3.381, p = .001$), number of hours worked ($t = -3.378, p = .001$) and perceived negative impact of work on personal life ($t = 4.309, p < .001$) were significant predictors of depressive symptoms.

Conclusions: Our analysis shows the more negative their perceptions of the impact of work on their personal lives and the less social support they perceive they have, the more severe their symptoms of depression appear to be. These conclusions are like other studies on DSWs and DSPs working in other contexts (Ryan et al., 2021). Surprisingly, in our model, those who worked fewer hours per week had lower depression scores.

Further analyses will explore this relationship. Finding long-term solutions to support DSW and DSP is essential for them to support autistic adults and adults with intellectual disabilities.

433.285 Predictors of Intent to Use Caregiver-Implemented Reciprocal Imitation Teaching within the Part C Early Intervention System

S. R. Edmunds¹, A. R. Borowy¹, Q. O. Wedderburn² and K. Rowland², (1)Psychology, University of South Carolina, Columbia, SC, (2)University of South Carolina, Columbia, SC

Background: Caregiver-Implemented Reciprocal Imitation Teaching (CI-RIT) is an evidence-based naturalistic developmental behavioral intervention (NDBI) for social communication (Ingersoll, 2012). CI-RIT and other NDBIs have been implemented within IDEA Part C publicly funded early intervention (EI) systems (e.g., CI-RIT: Wainer et al., under review; ESDM: Rogers et al., 2022; Rooks-Ellis et al., 2024; Project ImPACT: Pellecchia et al., 2023; Pickard et al., 2024). However, while Pellecchia and colleagues (2024) conducted a mixed methods study of predictors of EI providers' use of individual caregiver coaching strategies, there are few studies on factors that might predict EI providers' use of the NDBI as a whole in their ongoing practice.

Not only do attitudes about an evidence-based practice (EBP) contribute to intent to use it (e.g., Theory of Planned Behavior, Armitage et al., 2001), they may also interact with organizational characteristics, client characteristics, and other implementation determinants (Becker-Haimes et al., 2021).

Objectives: We employed a causal model of EBP use (Becker-Haimes et al., 2021) to understand how providers' training background, attitudes (i.e., social validity) and self-efficacy in CI-RIT predicted EI providers' initial intent to use CI-RIT after an initial, in-person training.

Methods: EI providers ($n=123$) in South Carolina were trained in CI-RIT across four trainings offered throughout the state in partnership with Part C. 108 providers (88%) elected to participate in research and completed surveys on their demographic and caseload characteristics, caregiver coaching practices (pre-training), and attitudes about (i.e., social validity of), self-efficacy, and intent to use CI-RIT on a 7-point Likert scale from "Strongly Disagree" to "Strongly Agree" (post-training). Given Becker-Haimes' model (Figure 1), we would expect providers' CI-RIT social validity and self-efficacy, but not provider characteristics, to predict intent to use CI-RIT.

Results: Providers had varied amounts of experience ($M=8.472$ years, $SD=7.718$), and with autism ($M=10.476$, $SD=8.216$). They somewhat agreed that CI-RIT was socially valid ($M=5.099$; $SD=0.322$) and agreed that they felt confident/efficacious in using CI-RIT ($M=5.944$, $SD=0.869$). When entered together into a multiple regression predicting EI providers' ratings of intent to use CI-RIT, neither years of experience with autism nor the percentage of their caseload with social communication concerns predicted their intent to use CI-RIT (Table 1). However, the degree to which they rated CI-RIT as socially valid and their self-efficacy to do CI-RIT both uniquely and significantly predicted their intent to use CI-RIT. CI-RIT social validity and self-efficacy were not significantly correlated, $r=.122, p=.209$.

Conclusions: Our results supported our hypothesis; in line with the causal model of EBP use, providers' CI-RIT social validity and self-efficacy ratings both uniquely predicted increased intent to use CI-RIT in their practice, but provider characteristics that were not in the original theory did not significantly predict intent to use. Of note, EI providers' ratings of CI-RIT social validity were unrelated to how confident they felt about using CI-RIT. These findings, combined with future work understanding how organizational and client characteristics predict CI-RIT use, may help us target implementation strategies to support CI-RIT in early intervention to improve social communication in young autistic children.

**433.286 A Community-Based, Qualitative Approach to Queer and Transgender Autistic Healthcare Experiences**

H. R. Steinberg¹, K. Ardeleanu², T. Garfield³, S. Voltaire², K. Chvasta³ and L. Shea³, (1)AJ Drexel Autism Institute, Philadelphia, PA, (2)A.J. Drexel Autism Institute, Philadelphia, PA, (3)A.J. Drexel Autism Institute, Drexel University, Philadelphia, PA

Background: Recent research suggests that autistic people are more likely to identify as transgender or queer compared to non-autistic people. These populations face significant challenges accessing healthcare, especially for individuals with multiple marginalized identities. Queer and transgender patients and autistic patients are at higher risk for worse health outcomes and lower access to healthcare. Emerging research suggests that queer and transgender patients face greater difficulty accessing affirming providers and adequate care, which contributes to prolonged and increased health issues over time.

Objectives: This study used qualitative interviews to 1. understand barriers to healthcare access for queer and transgender autistic adults, 2. contextualize these barriers as they relate to accessibility and quality of therapeutic services and gender-affirming care, and 3. explore how these barriers contribute to how these individuals feel about their health.

Methods: This study is part of a larger community-based study with 65 queer and transgender autistic adults. We used a community-based approach when recruiting and interviewing participants. We reached out to 19 community organizations in the Philadelphia area. Sixty-eight percent of the sample identified as nonbinary, 23% identified as cisgender, 6% identified as binary transgender, and 3% of participants were unsure or did not disclose their gender identity. Semi-structured, open-ended interviews were used conducted. The interview guide spanned a range of questions and topics, including queer and gender identity, autistic identity, childhood, family life, education, health, and social relationships. The first author read through a few of the interviews and conducted thematic and line-by-line coding on material that was relevant to answering the research question. A preliminary coding scheme was developed with primary and sub-categories. The research team embodied a diversity of demographic characteristics and queer and autistic identities.

Results: We found that queer and transgender autistic adults felt positively about the integration of these identities, and they felt affirmed when healthcare practitioners approached these identities with respect and sensitivity. Healthcare was described as inaccessible and very stressful for many. Negative experiences with practitioners, such as misgendering, inadequate and insensitive communication around gender-affirming care, and dismissive responses to disclosure of self-identified autistic identity, constituted additional challenges specific to this population. Limited insurance coverage was cited as a barrier to seeking out culturally competent providers. Interviewees reported a variety of chronic and complex issues that negatively impacted their health and well-being, particularly when they struggled to access appropriate services to address them.

Conclusions: Queer and transgender autistic patients benefit from accessing healthcare in contexts where their identities are validated and understood. We argue that health care systems must address the significant barriers to care described and work to be more sensitive and responsive to the needs of this population. Research and advocacy on this topic are needed to promote healthcare reform that will better support the health of neurodivergent and queer and transgender individuals.

433.287 Provider Perspectives on EarliPoint Adoption and Implementation

A. Gonzalez Laca¹, J. Kim², L. Ransom¹, N. Menon³ and J. L. Kuhn¹, (1)Pediatrics, Emory University School of Medicine, Atlanta, GA, (2)Emory University, Atlanta, GA, (3)Department of Psychology, Emory University, Atlanta, GA

Background:

Challenges of long waitlists in accessing an autism evaluation continue to persist in the system. EarliPoint has the potential to greatly improve the efficiency of autism evaluations, thereby alleviating waitlists and creating earlier access to care.^{1,2} Clinicians across medical and psychology fields are currently using, considering, or are unfamiliar with the device. The technology represents a significant shift in clinical practices. As a result, we anticipate that some clinicians will welcome the change; while others may be more resistant to modify their practices. This study uses a mixed methods design to understand clinician perspectives across factors that are theorized to influence the spread of new technology according to the *Diffusion of Innovations Framework*.^{3,4}

Objectives:

- To understand clinician perspectives on factors theorized to influence the spread of EarliPoint into standard autism diagnostic evaluation care
- To identify implementation barriers, facilitators, and strategies to support the implementation of EarliPoint that is most beneficial to families, clinicians, and systems

Methods:

We used snowball sampling to recruit clinicians from across the U.S. (Table 1) and from disciplines who either already provide autism diagnostic services or who are well-positioned to do so with additional training. Participants engaged in a 90-minute virtual session that consisted of: i) a demographic and professional background survey, ii) an overview of the EarliPoint device and evidence behind it, iii) the Perceived Characteristics of Intervention Scale (PCIS),⁵ and iv) a semi-structured qualitative interview. The interview guide was structured in alignment with subdomains of the PCIS and additional domains from prior applications of the *Diffusion of Innovations Framework* to health service organizations. Audio recordings were transcribed and de-identified by the study team. An initial a priori coding structure was developed in alignment with the interview guide, and modified during group coding to reflect nuances that arose from the data and inter-coder agreement. We used NVIVO 14 software for coding, and its framework matrix feature for analysis.

Results:

Preliminary data from 16 providers suggest that pediatricians generally expressed openness and excitement about EarliPoint, with a primary implementation barrier of requiring additional training and resources to expand their scope of practice. Psychologists described a primary barrier of misalignment of processes and output of EarliPoint with their current practices. Many psychologists expressed concerns that clinicians could become over-reliant on EarliPoint and a preference to use it as an add-on to current assessment batteries as opposed to a replacement that would promote efficiency. The PCIS survey findings (Table 2) display a trend of more positive perceptions of EarliPoint among pediatricians ($M=4$, $SD=0.99$) than psychologists ($M=3.09$, $SD=0.91$), with nuances across the PCIS subdomains and qualitative findings.

Conclusions:

Clinician perspectives are vital when studying the implementation of innovations that can bring significant implications to changes in workflow and clinical care. While pediatricians reported on average a higher level of compatibility for adopting the technology into their practice, psychologists were less motivated. These findings highlight the need for tailored training and resources to address the specific concerns of different provider groups to optimize impact at the population level.

433.288 Re-Imagining the Autism Diagnostic System for Young Children through the Echo Autism: STAT Early Diagnostic Program

K. Sohl¹, V. Nanclares-Nogues², A. Brewer Curran³, K. Boles⁴, M. Odum⁵ and M. Mahurin⁶, (1)ECHO Autism Communities, University of Missouri School of Medicine, Columbia, MO, (2)Pediatrics, University of Missouri - Columbia School of Medicine, Columbia, MO, (3)Department of Pediatrics, University of Missouri, Columbia, MO, (4)Child Health, University of Missouri, Columbia, MO, (5)ECHO Autism Communities, University of Missouri, School of Medicine, Columbia, MO, (6)Department of Child Health, University of Missouri, School of Medicine, Columbia, MO

Background:

In recent decades we have seen a global rise in the prevalence of autism spectrum disorders (ASD), with an insufficient number of professionals trained to meet this demand and increased wait times for families. The ECHO Autism: STAT Early Diagnostic Model (EDx) was developed in 2017 as part of the ECHO Autism: Primary Care model (Mazurek et al., 2017) to increase access to early identification and diagnosis of young children between the ages of 14-and 48-months with unambiguous characteristics of autism. This program professionally develops community primary care physicians and practitioners (PCPs) to screen, identify, evaluate, differentiate and diagnosis and provide longitudinal primary care for children on the autism spectrum. The current study analyzed the data from the case presentation forms completed by participating clinicians.

Objectives:

Increase local capacity of clinicians in underserved areas who can provide high-quality, best-practice autism evaluations for a subset of young children presenting with clear autism characteristics to decrease wait times and increase access to diagnostic assessments by equipped community clinicians.

Methods:

ECHO Autism: EDx includes explicit training and guided practices on the core elements of autism diagnostic best practices: structured behavioral observation, comprehensive history, and synthesis through clinical expertise. First, community PCPs receive training on the Screening Tool for Autism in Young Toddlers (STAT) and achieve reliability on this measure. Then PCPs participate in twice-monthly, 90-minute ECHO Autism: EDx virtual guided learning sessions, where a de-identified case is presented by one of the community PCPs, followed by an interactive, interdisciplinary discussion to help guide the learning and develop next steps for the case example. The presenting PCP fills out a deidentified case presentation form through a secure data capture, REDCap, with information regarding age, gender, developmental history, family history, evaluation measures/results, behavioral observations, and final diagnostic determination using DSM-5 diagnostic criteria. Data were analyzed from case presentation forms between 2017 and September 2024.

Results:

595 cases were presented (72% male) with a median age of 2.67 years (median age range 1.17 (male) and 1.25 (female) to 6.83 (male) and 6.41 (female). 85% of the cases travelled 30 or less miles to the PCPs office. 70% of cases waited three months or less to see their STAT PCP, with a median value of 1.5 months.

Conclusions:

The ECHO Autism: STAT EDx program has improved primary care providers' (PCPs) self-efficacy in diagnosing and managing autism, leading to reliable and accurate diagnoses in young children with unambiguous autism characteristics (Mazurek et al., 2020; Sohl et al., 2023). This study demonstrates that children are now receiving timely, high-quality diagnostic evaluations, with average wait times reduced to 1-3 months, compared to the state median of 7.6 months (Missouri DMH data, 2023). By training and supporting PCPs, we are creating a system that adapts to the complexities of each child's presentation, enabling PCPs to diagnose and monitor young children at high risk for autism, while also freeing up specialty centers to focus on cases with more subtle or complex presentations.

433.289 Reflexive Thematic Analysis of Pediatric Residents' Perspectives of Best Practices in Autism Care

N. Piroddi¹, L. Zwaigenbaum², L. A. Sacrey³, S. Thompson-Hodgetts⁴ and H. M. Brown⁵, (1)Department of Pediatrics, University of Alberta, Edmonton, AB, (2)University of Alberta, Edmonton, AB, Canada, (3)Autism Research Centre, University of Alberta, Edmonton, AB, Canada, (4)Occupational Therapy, University of Alberta, Edmonton, AB, Canada, (5)Educational Psychology, University of Alberta, Edmonton, AB, Canada

Background: Autism is a complex, heterogeneous condition that requires personalized interdisciplinary care. Previous studies have shown that pediatricians feel they are expected to be proficient with the skills necessary to diagnose and care for autistic children, but often feel that their education surrounding autism care has been lacking. Currently, there is no literature on the perspectives of pediatric residents to providing best practice care for autistic children, and there has been no evaluation of autism in the medical education system in both medical school and in pediatric residency.

Objectives: The overarching objective of this study was to explore the experiences of pediatric residents in providing care for autistic children in Canada and identify any gaps in training to inform strategies to enhance autism education and better prepare the next generation of pediatricians for real-world practice.

Design/Methods: Twelve pediatric residents from medical schools across Alberta and British Columbia, Canada were interviewed. An interpretive description methodology was used to conduct semi-structured interviews, and a reflexive thematic analysis approach was used to analyze interview data. Interviews were transcribed, coded, and analyzed iteratively to generate insights about the current state of autism care education.

Results: Seven key themes emerged from the analysis, divided into two categories. Category 1 themes focused on the factors of best practice care for autistic patients, which include the flexibility and optimization of care of the child, family understanding and kindness towards the family throughout the diagnostic process and long-term care, and multidisciplinary care. Category 2 themes focused on barriers to providing best practice care in education, which include residents' perception that training regarding autism care is inadequate, a sense of role confusion when working with autistic children, applicability of what is learned in residency compared to what is seen in real-world practice, and wanting to play a role in long-term care for autistic children, despite it not being taught well in training.

Conclusions: This study highlights critical gaps in providing best practice care for autistic children, and underscores the need for better training in areas such as diagnosis, long-term care, education, and collaboration. The findings support recommendations for expanding autism education within pediatric residency programs, emphasizing practical, hands-on learning opportunities with a clearer definition of residents' roles in autism care. Addressing the gaps in providing best practice care can ultimately improve the capacity of pediatricians to provide comprehensive, patient-centered care, ultimately enhancing the health and quality of life of autistic individuals.

433.290 School Administration Decision-Making and Perspectives on Autism-Specific Classrooms

E. Rotheram-Fuller, J. Hart-Barnett, J. Fleming, M. Geiselhofer and H. Rathiel, Arizona State University, Tempe, AZ

Background: Although IDEA mandates the inclusion of students with disabilities in the least restrictive environment, the placement of students with autism in self-contained classrooms remains controversial. This study addresses a critical gap by examining how administrators navigate this complex decision-making process, and perceive the efficacy of their program.

Objectives: This study investigates the placement decision-making process and perceptions of program efficacy amongst administrators in one district as a case study, with potential implications for other districts exploring centralized autism-specific classrooms. A teacher-trainer, principal, and district special education director were interviewed within this school district where all elementary-level self-contained classrooms for students with ASD were established in one school.

Methods: The Southwest (pseudonym) Elementary School District was targeted for this study, as their district educated the majority of their students with ASD who were significantly impacted by autism within one school in multiple self-contained autism-specific classrooms. The school adopted the TEACCH (Treatment and Education of Autistic and related Communication- handicapped Children) model to support their students, and the teacher-trainer, principal of the school, and school district special education director were all interviewed using a semi-structured interview protocol to examine their decision-making process, and perceptions of the efficacy of their program model. Interviews were analyzed using thematic coding, allowing for key themes related to decision-making and program efficacy. To ensure reliability, data were triangulated across interviews.

Results: The decision to maintain all autism-specific classrooms within one school in the district was made prior to the employment of the three administrators interviewed. However, they maintained this model because they felt the benefits outweighed the challenges for the students in this program. There was strong agreement amongst the administrators that the self-contained model was beneficial for their students for several reasons: 1) students were amongst peers that accepted their diversity of behaviors and learning styles, 2) they were able to provide efficient, cost-effective, centralized training and support to teachers who were all working with students with autism within the one school, 3) they believed teachers felt more supported because they had peers to turn to who could help support each other's' students, 4) students had consistency in the teaching model and procedures over time, reducing anxiety and increasing emotion regulation, and 5) parents appeared to support and gravitate to the program (only 88/303 students were from the local district area). Key challenges included limited peer interaction, space constraints, transportation, and recruitment difficulties.

Conclusions: Administrators were overwhelmingly positive about the self-contained autism classrooms within the one school in their district. Even though there were limitations identified, they were concerned that if students were moved to different campuses, they would lose the sense of community identity around autism that had been developed within their school, as well as the consistency in curriculum programming. The findings suggest that centralized autism-specific classrooms may offer logistical benefits but come with trade-offs, particularly around student inclusion, and grade-level academic expectations. These insights could inform policy discussions on balancing specialized support with inclusive opportunities.

433.291 School-Based Writing Support for Autistic Youth: IEP Goals, Professional Involvement, and Caregiver Perceptions

M. C. Zajic¹ and **N. S. McIntyre²**, (1)Health Studies & Applied Educational Psychology, Teachers College, Columbia University, New York, NY, (2)University of Central Florida, Orlando, FL

Background: While research indicates that writing is often a particularly challenging skill for many autistic students, less is known about how professionals support the development of specific writing skills both in general and as part of special education goals. Gaining deeper insights into the writing needs of autistic youth and how professionals support learning in these areas could inform the design of more effective instructional approaches to foster both writing and related literacy skills.

Objectives: This study examines school-based writing practices that support autistic students. Specifically, it investigates the inclusion of writing-related goals in Individualized Education Programs (IEPs), the professionals involved in supporting students' writing skills, and caregivers' perceptions of school-based writing support services.

Methods: Participating caregivers were recruited through SPARK and had an autistic child with a professional autism diagnosis. They completed an online survey about their child's access to educational resources during 2019-2020, prior to the COVID-19 pandemic. The caregivers (n=785) were predominantly mothers, most with a college (63%) or advanced (28%) degree, living in the U.S. Children were mostly White (68%), male (78%), and in elementary school during 2019-2020 (64%). About half of the children qualified for free or reduced-price lunch (45%), and 18% had a co-occurring intellectual disability. Most children attended public or charter schools (87%), with others in private schools (8%) or home-schooled (5%). Children's Vineland-3 Written subdomain scores varied (M=11.47, SD=4.30).

Results: Most children (80%) had an IEP, with 62% having a writing-related goal. The goals focused on handwriting (64%), keyboarding (25%), spelling (41%), grammar (41%), punctuation (41%), sentence composition (53%), and paragraph composition (47%). Various professionals—general educators (GE), special educators (SE), reading specialists (RS), speech-language pathologists (SLP), occupational therapists (OT), and paraeducators (PE)—supported autistic students' writing development. Daily support was most frequently provided by SE (36%), followed by PE (22%) and GE (13%). The lowest levels of daily support came from RS (4%), SLP (4%), and OT (3%). Frequent support was most often provided by SE (25%), followed by PE (14%), GE (13%), SLP (10%), and RS (7%). Infrequent support was primarily delivered by OT (33%) and SLP (29%), with lower levels from SE (13%), GE (12%), RS (10%), and PE (9%). Most caregivers of children with writing-related IEP goals agreed (80%) that their child was making formal progress, while 20% disagreed. Among all caregivers, 76% agreed that their child was making general progress in writing, with 24% disagreeing. A similar proportion (78%) felt their child's writing needs were being met, while 22% disagreed.

Conclusions: Our findings provide new insights into the frequency of school-based writing supports for autistic students. While many students had writing-related IEP goals, these goals varied widely across different skills. Importantly, a range of educational professionals were involved in supporting these goals, underscoring the need for multidisciplinary collaboration to enhance the literacy skills of autistic youth. Although most caregivers agreed that their children were making progress in writing, further research is needed to explore why some felt that their child was not receiving adequate school-based writing support.

433.292 Service Navigation Use Among Urban, Suburban & Rural Black Families with Autistic Children

J. E. Vossenber¹, **A. S. Rhames¹**, **N. Harris²**, **H. McCarter¹** and **C. corsello Orahovats¹**, (1)The TEACCH Autism Program, The University of North Carolina, Chapel Hill, NC, (2)Autism Society of North Carolina, Raleigh, NC

Background: Black families with autistic toddlers experience significant disparities in accessing early diagnosis and intervention services, including delays in the age of diagnosis and limited access to intervention services (Bilaver, et.al., 2021, Constantino, et. al., 2020, Wiggins, et. al., 2020). Rural families experience significant barriers to accessing services, including a lack of available providers with the training and experience necessary to deliver high quality services (Mello et al., 2016). To address barriers to care, service navigators have been incorporated into the care system to help families with autistic children identify services needed to support their child (Feinberg et al., 2021). While there is clearly a need, there is limited information regarding service navigation use and preferences across rural and urban Black families.

Objectives: The purpose of this study is to understand service navigation usage and preferences of rural and urban Black families with autistic children. Specifically, this study aims to 1) identify the primary reasons Black families of autistic children reach out to a service navigator 2) determine if those reasons differ based on urbanicity and 3) determine whether race and/or lived experience as a parent are preferred in a service navigator by Black families.

Methods: Families requested service navigation through a web-based resource designed specifically for Black families in North Carolina through a Qualtrics survey. Information obtained through the survey was de-identified, demographics data and service requests were extracted, and a qualitative analysis was performed to identify themes of requests for Black families across NC.

Results: A total of 43 service navigation requests were received between February-October 2024. One request was excluded from the sample as it was from a community service provider. Of the remaining 42 requests, ages ranged from 2 to 49 years, with an average of 8.76 years (SD= 9.09). When the two outliers (over 40 years) were removed, the average was 7.09 (SD=4.50). The majority of requests were from urban areas (47.61%), followed by suburban areas (30.95%) and the fewest from rural areas (16.66%). Two requests were from outside of NC. In terms of preferred qualities of a service navigator, 54.77% preferred to connect with a parent of a child with autism while 71.43% preferred to connect with a Black service navigator.

Several themes emerged from the requests, including service navigation requests for 1) diagnostic evaluations, 2) general services and information, 3) financial support, 4) specific therapeutic and recreational support, and 5) educational support. Themes were more comparable amongst suburban and urban groups, as rural participants did not request financial or school-related service navigation.

Conclusions: Black families of autistic children requested support navigating and connecting with a variety of services. Findings provide initial support for the need for service navigation to aid Black families as they navigate complex systems to support their children. Additionally, variations determined during the thematic analysis indicate that the requests of Black families with autistic children in rural counties in North Carolina may vary in comparison to suburban and urban counties. Implications will be discussed.

433.294 Sustainment of an Autism and Developmental Screening and Referral Intervention in US Primary Care Practices Serving Latinos: A Real-START Follow-up Study

M. Solgi¹, C. Dick², A. Feryn³ and K. Zuckerman⁴, (1)School of Medicine, Oregon Health and Science University, Portland, OR, (2)Seattle Children's Autism Center, Seattle Children's, Seattle, WA, (3)Biostatistics and Design Program, Oregon Health and Science University, Portland, OR, (4)Division of General Pediatrics, Oregon Health & Science University, Portland, OR

Background: Provider training interventions positively impact Autism Spectrum Disorder (ASD) and developmental screening rates. While these interventions increase screening and billing rates, it is important to determine whether these interventions are sustainable in the long term.

Objectives: To determine the long-term sustainability of an autism and developmental screening intervention.

Methods: This project was a follow-up of the REAL-START study conducted from 2016-2018, in which 6 Oregon primary care clinics serving >50% Medicaid and >25% Latino patients were trained on developmental and autism screening. The training consisted of one initial and three follow-up sessions on site at each clinic. In the original study, we used Electronic Health Record data to measure autism screening rates (using the Modified Checklist for Autism in Toddlers-R (M-CHAT-R) and general developmental screening rates (using the Ages and Stages Questionnaire - 3 [ASQ]), billing for screenings performed, and Early Intervention (EI) referral after a positive screen. Outcomes were measured at baseline (Period 0) and in 4 post-intervention periods (Periods 1-4) spaced 3, 6, 9, and 12 months after the initial intervention. To measure sustainment, we conducted a follow-up chart review 4 years after the initial intervention (Period 5; using 2020-2021 data). We conducted a mixed logistic regression with a random intercept for the provider for each outcome, exponentiated coefficients to compute odds ratios (likelihood, or odds, relative to baseline), and calculated predicted probabilities with bootstrap 95% confidence intervals for all time periods so we can compare Period 5 to each of the 4 prior study periods. Each model was adjusted for site, visit type, family preferred language, and ethnicity.

Results: The predicted probability of completing the M-CHAT-R increased in the follow-period, showing values of 0.69, 0.80, 0.89, 0.94, and 0.93 for baseline and the initial 4 periods, versus 0.96 in Period 5 (95% CI: 0.94, 0.98). A similar trend was observed for completing the ASQ with predicted probabilities rising during the follow-up chart reviews: 0.63, 0.79, 0.90, 0.95, and 0.94, versus 0.95 in Period 5 (95% CI: 0.91, 0.98). When analyzing both screenings together, the predicted probabilities show an upward trend across the chart periods: 0.46, 0.65, 0.82, 0.90, 0.88, and 0.93 (Figure 1). In contrast, the predicted probability of billing at least once during the first four chart periods (0.85, 0.90, 0.93, 0.95, and 0.96) decreased to 0.93 in the follow-up Period 5 (95% CI: 0.90, 0.96). EI referrals after positive screens did not show significant changes throughout the original study periods or the follow-up periods.

Conclusions: To our knowledge this is the first study of long-term sustainment of ASD screening training in primary care. Primary care providers in community clinics continued to screen at higher rates 3 years after the intervention had ended, but did not sustain billing practices. EI referral rates were not altered in either the initial intervention or in the follow-up.

433.295 Teacher Perceptions and Support for Autistic Students in General Education

M. Dean¹ and Y. C. Chang², (1)Education, California State University Channel Islands, Camarillo, CA, (2)Special Education and Counseling, California State University, Los Angeles, Los Angeles, CA

Background: An increasing number of autistic students are educated in inclusive settings, yet many general educators have limited knowledge about autism and feel unprepared to effectively support these students (de Boer et al., 2011). Teachers in low-income and under-resourced settings face additional barriers, including limited time for collaboration and a lack of school-wide support towards inclusion (Iadarola et al., 2015).

Objectives: This research examines general education teachers' perceptions of a) the social challenges of autistic students, b) the social supports general education teachers provide to support autistic students in general education settings, and b) teacher perceptions of the experiences of female autistic students.

Methods:

The study included 173 general education teachers across different grade levels (preschool=3, TK/K= 20, 1st-5th grade= 67, 6th-8th grade= 38, 9th-12th grade= 45). Approximately 80% (n=139) of the teachers were female and the teachers' average age was 47.65 years (SD=24.23 years). Teachers were from 28 different school districts in the Southwestern region of the United States, and 76% worked in Title I schools. Teachers completed The Autism Awareness Survey (Heidgerken et al., 2005; Tipton & Blacher, 2013), and three open-ended question prompts: 1) Identify challenges for their students with autism specifically related to social functioning in the classroom and during free time, 2) List the strategies you use to support students with autism in the general education setting, and 3) Are you currently, or have you in the past taught a female student with autism? Please describe the girl's behavior and social relationships.

Results:

The total correct score for the 14 items ranges from 28 to 56, with a mean of 41.28 (SD=6.81). The highest correct responses were: 1) There is one intervention that works for all children with autism (94.71%), 2) Children with autism can grow up to live independently (97.67%), and 3) There is a cure for autism (88.24%). The highest incorrect responses were: 1) Changing a child's diet will lessen the severity of autism symptoms (32.35%), 2) Autism is a developmental disorder (30.18%), and 3) Autism is an emotional disorder (30.23%).

Teachers identified 15 different social challenges experienced by autistic students. The top three reported social challenges were: 1) Joining/initiating social interactions, 2) Reading social cues, and 3) Reciprocity. Teachers reported 37 different strategies to support autistic students in their classes. The top three strategies were: 1) extra time, 2) visuals, and 3) sensory accommodations.

Only 43% of teachers had taught a female autistic student. When teachers described the experiences of autistic girls compared to autistic boys, girls were described as being more isolated/socially disconnected (40%), socially motivated (33%), and having more difficulty reading social cues (31%).

Conclusions:

The findings corroborate previous research that identified similar patterns of correct and incorrect knowledge of autism among university faculty (Tipton & Blacher, 2013). Qualitative findings highlight general educators' professional development needs to increase their knowledge of autism, including autism in females, and their implementation of evidence-based interventions in inclusive settings.

433.296 Telemedicine in Pediatric Dermatology for Children with Autism: Addressing Nutritional Deficiency, Allergy, and Skin Infections in Resource-Limited Settings of Nepal

S. Joshi, Dermatology, Mahabaudha Medical Center, Kailali, Sudur Paschim, Nepal

Background:

In Nepal, the incidence of autism is increasing, and many children on the autism spectrum experience significant nutritional deficiencies, resulting in higher susceptibility to skin infections, allergies, and impaired growth. The situation is further complicated by the limited number of pediatric dermatologists, particularly in remote and difficult-to-reach areas like the Himalayan region. This study aims to compare the prevalence of skin infections, allergic conditions, and growth outcomes between children with autism and their neurotypical peers, highlighting the impact of telemedicine in these areas.

Objectives:

To evaluate the relationship between autism, nutrition, allergy prevalence, and skin infections among children in Nepal, and assess the effectiveness of telemedicine in early diagnosis and management of these conditions.

Methods:

A cross-sectional study was conducted between June 2022 and March 2023, involving 60 children aged 3 to 12 years, 30 of whom were diagnosed with autism spectrum disorder (ASD) and 30 neurotypical children. Nutritional assessments included weight-for-age, height-for-age, and BMI measurements. The prevalence of skin infections and allergies was documented through clinical evaluations and telemedicine consultations. Statistical analysis was performed using chi-square tests and logistic regression to identify significant associations between autism, nutrition, allergy, and skin infection rates.

Results:

Among children with autism, 57% had moderate-to-severe malnutrition, compared to 34% of neurotypical children ($p<0.01$). Children with autism showed a significant delay in growth, with a mean height-for-age z-score of -2.7, compared to -1.8 in neurotypical children ($p<0.05$). The prevalence of skin infections in children with autism was 42%, significantly higher than the 24% observed in neurotypical children ($p<0.05$). Allergic conditions such as eczema and allergic rhinitis were more prevalent in the autism group (37%), compared to neurotypical children (22%), with $p<0.05$. Telemedicine consultations allowed early diagnosis and timely intervention, leading to a 28% reduction in the recurrence of skin infections in children with autism over the study period. Parents of children with autism reported high satisfaction (82%) with telemedicine services, particularly regarding timely access to nutritional counseling and allergy management.

Conclusions:

This study highlights the higher burden of malnutrition, allergies, and skin infections in children with autism compared to neurotypical children in Nepal. The integration of dermatology-focused telemedicine has facilitated early diagnosis and improved health outcomes for children with autism, reducing the incidence of skin infections and improving growth trajectories. Statistical analysis showed significant associations between autism, malnutrition, and the prevalence of skin infections and allergies ($p<0.05$), reinforcing the need for targeted interventions in these areas.

Telemedicine is a vital tool for managing pediatric dermatology and allergy cases among children with autism in resource-limited regions like Nepal. Children with autism are at a significantly higher risk of malnutrition, skin infections, and allergies, making early intervention critical. Expanding telemedicine services in remote areas is essential for improving health outcomes, particularly for vulnerable populations such as children with autism. Telemedicine offers a scalable solution to the challenges of delivering dermatological care in underserved regions, particularly for children with autism who face additional health risks. Policymakers and healthcare providers should prioritize telemedicine infrastructure to bridge the gap in care and improve long-term health outcomes.

433.297 The Autism Occupational Therapy Coaching Program: Building Capacity through the Use of a Neurodiversity-Affirming Lens

M. Pena¹, C. Provvidenza², A. Townley², S. Holman², J. Chong³ and S. Kingsnorth⁴, (1)Holland Bloorview Bloorview Kids Rehabilitation Hospital, Bloorview Research Institute, Canada, Toronto, ON, Canada, (2)Evidence to Care, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (3)Autism Services, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (4)Teaching and Learning Institute, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada

Background:

Occupational therapists (OTs) play a vital role in supporting the pediatric autism community. Providing service and care delivery that aligns with evolving best practices is essential. Until recently, promoting neurotypical behaviours and norms have been the dominant healthcare approach utilized by OTs. However, emerging evidence from the neurodevelopmental field has prompted a shift towards providing care that reflects a neurodiversity-affirming (NDA) approach. Occupational therapy regulatory bodies are updating standards and expected competencies, necessitating changes to care practices. To change approaches to care however, OTs need knowledge and skills on how to implement an NDA approach. Yet, current professional development opportunities related to autism are inadequate, leaving many OTs lacking confidence in supporting autistic clients.

Objectives:

To address this knowledge and practice gap, the Autism Occupational Therapy Coaching (AOTC) Program was developed. This poster presentation will describe the development of the AOTC Program, and implementation and evaluation efforts.

Methods:

Kern's Six-Step Approach for Curriculum Development for Medical Education and Bloom's Taxonomy were used to create the AOTC professional development program. Autism research and best practices, and a needs assessment informed program development. A synchronous, virtual-based format combined with a multi-modal approach to education was used. An evaluation strategy consisting of pre and post-program surveys was conducted to assess program satisfaction and opportunities for optimization, and self-reported shifts in knowledge, attitudes, and intended behaviour change. The Most Significant Change technique was also used as an evaluative method post-program delivery to monitor perceived changes the AOTC program brought to participants.

Results:

The AOTC Program was delivered to 117 OTs over eight months to seasoned practitioners (5 years or more of clinical experience), recent graduates (less than 5 years of clinical experience) and students. Positive shifts were reported in problem-solving, application of an NDA approach, and use of reflective techniques in clinical decision making. Participants identified that the program format and structure fostered a psychologically safe environment, allowing OTs to learn, exchange knowledge, and build connections with their peers. They valued the case-based, small group format and the collaborative atmosphere. Participants reported increased confidence in applying an NDA approach and developed skills that changed their mindset, such as approaching client behaviors with a sense of curiosity and reflecting on assumptions made about the needs of clients and families. In terms of program optimization, suggestions for improvement included providing a platform for continuous engagement and resource sharing.

Conclusions:

This professional development program provided OTs with the knowledge, skills, and training needed to implement an NDA approach when supporting the pediatric autism community. The real-time, virtual format of the AOTC program proved to be a successful approach for delivering autism-specific capacity building opportunities. Future opportunities for program enhancement include fostering ongoing learning and engagement among the AOTC OT participants through networking and information sharing.

433.298 The Availability and Accessibility of Medicaid-Funded Peer Support Services for Autistic Adults in the United States

L. Tomczuk¹, K. J. McLean², J. Gifford³, L. Shea³ and W. Song³, (1)A.J. Autism Institute, Drexel University, Philadelphia, PA, Philadelphia, PA, (2)A.J. Drexel Autism Institute, Philadelphia, PA, (3)A.J. Drexel Autism Institute, Drexel University, Philadelphia, PA

Background: Autistic adults in the U.S. face a higher risk of mental health conditions, yet there are few mental health services specifically tailored to their needs. Peer support, which provides shared knowledge, emotional support, and guidance from those with lived experience, has been shown to be effective in promoting recovery, reducing depression, improving emotional well-being, and increasing needed engagement with physical and mental health services. Many peer support programs are funded through Medicaid, providing a crucial and affordable source of support for eligible individuals. To ensure these services meet the unique needs of autistic adults, it is important to evaluate their availability, scope, and how effectively they address access barriers and service gaps.

Objectives: The purpose of this project is to assess the current availability and accessibility of Medicaid-funded peer support services for autistic adults in the United States.

Methods: States that were contacted based on the order in which Medicaid-funded peer support services were established in that state according to KFF. A brief, ten-question survey was administered to state behavioral health leaders involved with peer support services that queried about specific funding mechanisms associated with Medicaid-funded peer support services, scope of services, billing codes, changes to funding structure over time, target populations, and plans for peer support services in the future. Surveys were completed either over Zoom or electronically via Qualtrics. Data collection remains in process.

Results: Leaders from twelve states completed the survey. Ten states reported that peer support services fall under the provision of services offered through their Medicaid state plans. In the two states where peer support services were not part of the Medicaid state plan, services were covered by Medicaid waivers. Peer support services funding was not reported to have changed over time in the majority of states. For states that provided billing code information, codes differed by state but remained consistent over time. Most states did not consider autistic adults or adults with developmental/intellectual disabilities as a target population for Medicaid-funded peer support services receipt. Two states explicitly mentioned discussions of expanding service eligibility to autistic adults and adults with intellectual and developmental disabilities. Data analyses are ongoing.

Conclusions: Understanding the current landscape of peer support services in the United States is crucial to developing effective strategies to ensure that autistic people, a population with high occurrence of mental health conditions, gain access to and fully benefit from such services. Thousands of autistic adults in the U.S. qualify for Medicaid-funded peer support services due to comorbid mental health diagnoses, but many cannot access these services. However, peer support services have the potential to benefit more individuals on the spectrum if scope of services and billing procedures model those of states that have successfully implemented Medicaid-funded peer support services for autistic people.

433.299 The Effects of a “Sensory Toolkit” Education on Comfort Level and Self-Efficacy Among Medical Teams Working with Pediatric Autistic Patients in Outpatient Settings

V. M. Colantuono, E. Bernabe, M. Harrison, M. Grau, A. Lewis, J. Sciolla and B. Freedman, Nemours Children's Health, Wilmington, DE

Background: Autistic persons experience disparities in healthcare access and delivery (Nicolaidis et al., 2013) and encounter unmet healthcare needs four times greater than their neurotypical peers (Karpur et al., 2019). Autistic youth are more likely to have frequent medical visits and experience challenges during healthcare interactions (Bultas et al., 2016; Vohra et al., 2014). These difficulties are often related to sensory aspects of care (Hand et al., 2021), such as touch, sounds, and difficulties processing sensations from the body and environment (Syu et al., 2020). Medical providers report low levels of comfort working with autistic patients (Fingert et al., 2014) and only a minority of medical providers report high confidence in communicating, completing physical exams, and identifying accommodations for autistic youth (Nicolaidis et al., 2020).

Objectives: The study team examined the effects of a “sensory toolkit” intervention on outpatient medical staff’s comfort and self-efficacy in working with autistic youth. Data were also collected on the acceptability, appropriateness, and feasibility of integrating the sensory toolkit into the medical practice.

Methods: A multidisciplinary healthcare team of Psychologists, Physicians, Board Certified Behavior Analysts, and Certified Child Life Specialists developed a sensory toolkit: a portable kit filled with various sensory items (e.g., noise canceling headphones, chewy tubes, fidgets, etc.), and corresponding education on accommodations and environmental and behavioral adaptations in healthcare settings to support the sensory needs of autistic youth. Seven outpatient clinics completed anonymous surveys immediately pre- (n=63) and post- (n=31) education. Surveys included questions on demographics, Likert scale ratings of comfort level working with autistic patients (Broder-Fingert et al., 2014) and self-efficacy in treating autistic patients (Nicolaidis et al, 2021), levels of challenge/reward in providing care to autistic youth, and (post only) the acceptability, appropriateness, and feasibility of the sensory toolkit (Weiner et al., 2017).

Results: Comparative analyses examined changes in comfort and self-efficacy pre- v. post-education. Significant increases were found in the following: comfort using non-vocal communication (e.g., pictures to communicate, assisted and augmentative communication, etc.), comfort inquiring about communication needs, overall comfort in conducting visits, self-efficacy in identifying accommodations to facilitate care, self-efficacy in completing necessary exams/procedures, self-efficacy in helping patients stay calm/comfortable, self-efficacy in making necessary accommodations, and overall self-efficacy in working with autistic patients (Table 1). The sensory toolkit was found to be acceptable, appropriate, and feasible, with most respondents expressing agreement or strong agreement to these questions (Table 2). Exploratory analyses found that having previous autism-specific training led to significantly higher comfort levels pre-education (p=0.033). Demographic variables including age, sex, and tenure did not correlate with any significant differences in comfort or self-efficacy.

Conclusions: The sensory toolkit was found to be a valid and accepted intervention in outpatient clinics. Results indicated significant changes in medical staff’s comfort and self-efficacy in working with autistic youth. The lower return rate for post-surveys suggests that continued evaluation will be needed. Nevertheless, these findings support the preliminary efficacy of training for outpatient medical staff on the implementation of autism-specific, sensory-based interventions to promote inclusive healthcare experiences for autistic patients.

433.300 The Influence of Session Modality on Parent Participation Engagement and Family-Centered Care in Part C Early Intervention

H. Tokish, A. Pomales-Ramos and B. R. Ingersoll, Psychology, Michigan State University, East Lansing, MI

Background: Telehealth use has rapidly increased in community service settings, including the Part C Early Intervention (EI) system, particularly in response to the COVID-19 pandemic. Telehealth intervention may mitigate barriers to service access and previous studies suggest it promotes parent knowledge, fidelity, and satisfaction. However, little is known about how telehealth impacts other important parent experiences, including engagement and family-centered care (FCC), in community service settings. While research suggests parent engagement in child psychotherapy promotes child outcomes, few studies examine parent participation engagement (PPE)—active and independent contribution to child treatment—in community-based autism intervention. Furthermore, though the Part C EI system emphasizes the provision of FCC (i.e., practices that value and incorporate family perspectives and priorities), little research explores whether service modality impacts parent experiences of FCC. As telehealth EI continues to be offered post-pandemic, it is vital to understand how service modality impacts these core tenets of Part C and valuable parent experiences more broadly.

Objectives: Examine whether intervention session modality—telehealth versus in-person—impacts PPE and parent-reported FCC in Part C.

Methods: Parents ($n=147$) and EI providers ($n=83$) were recruited from an ongoing RCT examining the effectiveness of a parent-mediated social communication intervention. Parents participated in weekly EI sessions with their provider for four months. Session modality was chosen by each parent-provider dyad. Up to three session recordings were collected for each dyad ($n_{\text{total}}=333$, $n_{\text{telehealth}}=51$, $n_{\text{in-person}}=282$) and were behaviorally coded for PPE using a standardized observational coding scheme. A subset of parents ($n_{\text{total}}=49$, $n_{\text{telehealth}}=4$, $n_{\text{in-person}}=45$) completed the Family Centered Practices Scale regarding the extent to which their provider utilized practices consistent with FCC. For FCC analyses, session modality was determined by the modality used in at least 75% of sessions.

Results: Given the repeated/nested nature of the PPE data, a 3-level multilevel model examined the influence of session modality on PPE, controlling for intervention condition. Since previous research suggests single parents exhibit reduced PPE, the model also controlled for marital status. Preliminary results indicate higher PPE in telehealth versus in-person sessions ($t(185)=-2.65$, $b=-.36$, $p=.009$). Since FCC was measured only once, a multiple linear regression examined the impact of session modality on parents' FCC perceptions. The regression controlled for intervention condition and minoritized status, as prior studies suggest minoritized families experience reduced FCC. Service modality did not significantly predict parent-reported FCC ($t(48)=-1.39$, $b=-2.92$, $p=.17$).

Conclusions: Preliminary findings suggest parents exhibit higher active engagement during telehealth EI sessions compared to in-person. This is likely because telehealth restricts direct work with the child, potentially promoting parent engagement by necessity. FCC results suggest similar parent experiences of FCC across service modalities but are currently underpowered. Data collection is ongoing to increase sample size, particularly for FCC analyses. Though current findings may be confounded by pandemic enrollment time, they support growing literature that telehealth may preserve and even promote valuable parent outcomes, including engagement and FCC. Thus, telehealth may remain a reasonable alternative to in-person sessions in Part C. Further analyses will examine potential parent-level moderators to inform individualization of service delivery.

433.301 The Lived Experience of Students with Autism in Higher Education: Challenges, Supports, and Strategies for Success
C. Little, University of Sydney, Camperdown, AUSTRALIA

Background:

The number of students with an autism spectrum disorder (ASD) entering higher education has increased significantly in recent years (Tan et al. 2024). However, these students often face unique challenges in navigating academic, social, and institutional aspects of college life. Understanding their lived experiences is crucial for developing effective support systems and promoting inclusive educational environments.

Objectives:

This study aimed to:

- Explore the lived experiences of students with ASD in higher education settings.
- Identify key challenges and barriers faced by these students.
- Investigate effective support strategies and coping mechanisms employed by students with ASD.
- Develop recommendations for institutions to enhance the educational experience and outcomes for students with ASD.

Methods:

A qualitative phenomenological approach was adopted, involving in-depth, semi-structured interviews with 30 Autistic students (aged 18-40) from a major University in Australia. This methodology aligns with recent studies emphasising the importance of first-hand accounts in understanding the autistic experience in higher education (Green & Shaughnessy, 2023). Participants were recruited through disability support services offices. Interviews focused on their academic experiences, social interactions, institutional support, and personal strategies for success. Thematic analysis, following the guidelines outlined by Braun and Clarke (2023), was used to identify recurring patterns and themes in the data.

Results:

Four major themes emerged from the analysis

Academic Challenges: Participants reported difficulties with executive functioning, sensory sensitivities in classroom environments, and anxiety related to group work and presentations

Social Navigation: Many students experienced challenges in forming friendships, interpreting social cues, and participating in extracurricular activities

Institutional Support: While most participants acknowledged the availability of support services, many found them insufficient or not tailored to their specific needs as students with ASD

Personal Strategies: Students developed various coping mechanisms, including time management techniques, self-advocacy skills, and seeking out quiet spaces on campus.

Conclusions:

This study provides valuable insights into the lived experiences of students with ASD in higher education, building upon recent research in this field. Findings highlight the need for more comprehensive and individualised support services, increased awareness among faculty and peers, and the importance of fostering inclusive campus environments. Future research should focus on long-term outcomes and the effectiveness of targeted interventions for supporting students with ASD in higher education settings.

433.303 A Community Based Housing Model to Support Independent Living for Young Adults with Autism

C. Z. Webb¹, G. Stobbe², F. Zollars³ and A. Deliganis¹, (1)Thrive Seattle, Seattle, WA, (2)Seattle Children's Autism Center, Seattle, WA, (3)The University of Washington, Seattle, WA

Background:

Adults with autism face many challenges in living independently, including high housing costs and finding support services.. (Scheeren et al., 2021). People in many cities struggle with high housing costs. Seattle area apartment rents are among the highest in the nation and continue to increase (Balk, 2024, Apartments.com). New approaches to affordable housing and support service delivery are needed for the ever-increasing number of young autistic adults as they seek stable independent living opportunities.

Objectives:

This research describes an innovative community program which combines affordable in-city apartment living with supportive services for autistic young adults and the outcomes of the initial cohort of participants.

Methods:

A total of 32 self-identifying autistic young adults without intellectual disability enrolled and moved into their apartments between August 2021 and August 2024. Age ranged from 19 to 49 with an average age of 24.6 and the majority of participants were male (81.3%). Data was collected from enrollment assessments and ongoing progress reports.

Results:

The program was based in a newly constructed apartment building open to the general public. The building's rents are considered affordable for those with only 50% of the Adjusted Median Income (AMI) so that no more than 30% of income would be spent on housing including rent, basic utilities and fees. Service costs were in addition to housing and included 1:1 coaching, small group instruction around basic living skills such as cooking, and social groups and community building. On average, young adults spent 15.6 months (range from 2-35 months) in the program. Ten were still enrolled in the program at the time of this research, nine had returned to home or live with family, and 13 moved on to independent living with minimal or no support. Participants who had higher community engagement (work, school or volunteering) and lower support needs during their time in the program were more likely to live independently after leaving the program.

Conclusions:

The results of this initial analysis demonstrate that programs geared toward helping autistic young adults with independent living could be adopted in many high housing cost cities. Challenges that remain include addressing stable and fulfilling employment and social opportunities. Funding for the increasing costs of housing and services, particularly sourcing public funds, may enable expansion of the program to many more individuals. Next steps for additional research may include a deeper exploration of the variables impacting outcome after leaving the program, particularly around employment.

433.304 Transformation of Preschool Autism Services in Nova Scotia – the First 2 Years

M. Thomas¹, J. L. MacDonald², N. Ash³ and E. Christian³, (1)Dalhousie University / IWK Health, Halifax, NS, Canada, (2)IWK Health/ NS Health, Sydney, NS, Canada, (3)IWK Health, Halifax, NS, Canada

Background: Over the past 10-15 years, Nova Scotia has witnessed a continually growing demand for diagnostic assessments and interventions, and a consistent upward trend in the number of children receiving an autism diagnosis. Families have reported challenges in navigating the system and available interventions have not met the needs of all families. In April 2022, the province announced new and enhanced preschool autism services to be developed in NS to include a greater number and range of interventions and supports, that are well coordinated and tailored to the needs of children and their families. Ongoing evaluations of these changes are important, to understand and refine processes and ensure effective and equitable service delivery across the whole province.

Objectives:

1. Compare data collected for the calendar years 2018 to 2022 to the calendar years of 2023 and 2024 concerning number of referrals for diagnostic assessments, number of professionals qualified to perform assessments, number of diagnostic assessments undertaken, and their distribution across the province.
2. Document the new educational resources and interventions available, or soon to be available, developed through work with families that respect the diversity of strengths and needs of autistic individuals, their families and communities.

Methods: Data have been collected for more than 20 years on autism diagnosis rates in different areas of the province and the uptake of a naturalistic developmental behavioural intervention (NDBI), the main autism specific intervention offered to preschool children prior to the transformation of services. The data from 2018 to 2022 will be compared to data collected during 2023 and 2024. The creation of a centralized diagnostic waitlist, a centralized clinical intake and care coordination team, with service delivery throughout the province along with a new outcomes-based measurement digital platform will facilitate robust data collection and tracking of clinical outcomes at a child/family level, clinician level, and system/ program level going forward.

Results: Preliminary results indicate that on average 35 children/month were referred for a diagnostic assessment in 2018 and 65/month in 2023, with 25 assessments/month completed in 2018 and 38 assessments/ month in 2023. In 2018, 13 children/month commenced NDBI intervention with 21/month in 2022. In 2024, additional interventions became available. In addition, 8 information handouts and 19 videos have been uploaded to a dedicated webpage since the Fall of 2023 as part of an accessible Autism Education Series for families and practitioners. Full results will be available to be presented.

Conclusions: Nova Scotia is undertaking a rapid and ambitious transformation of services for preschool children suspected of having, or with an autism diagnosis, and their families. Interrogating data on referral rates, numbers of diagnostic assessments, numbers and variety of interventions, and new information resources, indicate that in the context of increasing demand, a greater variety and volume of assessments and provision are being offered.

433.305 “My Best Teachers Understood That Our Mental Health Was a Lot More Important:” Characterizing the Student-Teacher Relationships of Autistic Students and Their Impact on School Experiences

A. Eisenhower¹, S. Levinson², N. Nadwodny³, S. Cohen⁴, K. Joseph¹, L. P. Thammathorn¹, B. VanHook⁵, N. Hamsho¹ and J. Blacher⁶, (1)Department of Psychology, University of Massachusetts Boston, Boston, MA, (2)Eating Disorders Center for Treatment and Research, University of California San Diego, San Diego, CA, (3)Psychology, University of Massachusetts Boston, Boston, MA, (4)University of California, San Diego, San Diego, CA, (5)Organization for Autism Research, Arlington, VA, (6)School of Education, University of California, Riverside, CA

Background: Autistic students often describe their school experiences as marginalizing, isolating, and marked by ableism and neuronormative expectations (Goodall, 2018; Parekh, 2023). The quality of autistic students’ relationships with teachers—be they positive and warm or conflictual and strained—may shape autistic students’ overall school experiences (McGrath & Van Bergen, 2015; Losh et al., 2022); however, existing research on the nature and impact of student-teacher relationship quality has focused almost solely on teacher reports of these relationships.

Objectives: To examine the nature of student-teacher relationships experienced by autistic students and the role of these relationships in shaping autistic students’ K-12 school experience and in furthering affirming or ableist experiences in school.

Methods: We conducted interviews with 19 autistic individuals (ages 15-43; 40% current high-schoolers; 47% people of color; 32%/32% women/non-binary) and gathered open-ended written responses from 52 teachers of autistic elementary-age students (90% with Master’s; 52% white; 94% women) in the U.S. Current findings reflect 19 autistic interviewees and 31 teachers; analyses is ongoing for the remaining 21 teachers. Using a critical constructivist qualitative approach informed by grounded theory, we coded interviews inductively. Written responses were coded deductively to determine whether teachers evidenced themes similar to students.

Results: Our results highlighted two dimensions of student-teacher relationships as central in shaping school experiences: *trust* and *humanization*. Further, positive student-teacher relationships were observed to be a foundation for resistance and affirmation, while strained student-teacher interactions served to perpetuate ableism and autism stigma. Within these two dimensions, key themes are italicized below.

First, beneficial student-teacher relationships were those in which teachers trust that students know themselves and their needs. This trust was marked by *attunement to students’ mental health and sensory needs* and *flexibility in responding to mental health and sensory needs*. When teachers demonstrated this trust in students’ self-knowledge and withstand dominant views of neurodivergent students, the resulting positive student-teacher relationship empowered both teachers and students to *resist ableist systems and structures*. On the other hand, when trust was absent, *teachers disbelieved autistic students* and *misperceived autism characteristics as misbehavior*.

Regarding humanization, strong student-teacher relationships were marked by teachers who viewed their students as whole people, for whom autism was a central but contextualized piece of who the student was. These teachers showed a *holistic interest* in students beyond their academic performance, and also brought their own *authentic selves*, such as by sharing aspects of their personal lives with students. These relationships in turn drove teachers to *reject dominant, negative views* of neurodivergent students. Alternatively, in strained student-teacher relationships, teachers often *endorsed dominant, dehumanizing views* around autism and neuronormativity. In turn, enforcing these neuronormative expectations and demands often triggered an *escalating cycle of harsh and exclusionary discipline*.

Conclusions: Findings suggest that student-teacher relationships may serve to foster affirmation and self-determination or, alternatively, perpetuate ableism, carcerality, and stigma, for autistic students. We will highlight recommendations for schools and teachers to develop student-teacher relationships that empower autistic students, encourage teachers to dismantle ableist school structures, and facilitate autistic students’ sense of belonging in school.

433.306 Trends and Variations in Prescriptions of Psychotropic Medications Among Autistic People Under Medicaid Coverage

G. Liu¹, E. H. Dennis¹, L. Kong¹ and M. J. Murray², (1)Public Health Sciences, Penn State University College of Medicine, Hershey, PA, (2)AUTISM AND DEVELOPMENTAL DISABILITIES, Sheppard Pratt, Baltimore, MD

Background: Psychotropic medications are frequently prescribed for autistic people. Our recent work showed increased psychotropic medication use among privately insured autistic people. However, little is known about psychotropic use among autistic people covered by Medicaid.

Objectives: This study examined CMS's Medicaid claims databases on the trends and variation in prescriptions of psychotropic medications.

Methods: Using the 2008-2021 CMS MAXX/TAF® databases, Autistic people (aged 5 or older) based on diagnosis codes, ICD-9: 299.xx and ICD-10: F84.xx were identified. Annual trends and variations among sub-populations and polypharmacy, defined as prescriptions across multiple medication classes within 90 days, were examined. Psychotropic medications were categorized as: 1) antidepressants; 2) mood stabilizers/anticonvulsants; 3) antipsychotics; 4) anxiolytics; 5) stimulants; 6) non-stimulant ADHD medications. Descriptive analyses and multivariable regressions were performed to examine trends and variations among subpopulations, adjusting risk factors and confounders.

Results: Our study cohort consisted of 1,479,326 unique individuals, of which with 75.0% were males and 25.0% females, together contribute to 5,981,277 annual observations. The majority of the cohort (52.6%) are white, following by Hispanic, all races (18.6%) and Black, non-Hispanic (14.8%). Over half (52.8%) were of 5-12 years old, following those aged 13-15 (32.4%). Older adults (aged 50+) accounts for only 3.5% of the cohort. Most lived in the South US census region (34.1%), following by Northeast (22.9%), Midwest (21.7%), and the West (21.4%). Prescriptions of Antipsychotics had been in steady decline from 52.0% in 2008 down to 44.0% in 2019, then had a sudden drop in 2020 to 25.4%, perhaps due to the Covid-19 lockout, but rebounded in 2021 back to the prepandemic level at 44.4%. In contrast, prescriptions of antidepressants had been steadily increasing, from 31.6% in 2008 all the way to 51.0% in 2021. Patterns in prescriptions the other four classes of psychotropics have changed much less through the same years of observed in this study. (Figure 1A). Concurrent prescriptions of psychotropic medication from 3+ different classes had slightly increased from 29.5% in 2008 to 36.5% in 2021. The multivariable regression shows (Table 1) that autistic whites were at the highest risk of concurrent prescriptions of 3+ different classes of psychotropics, while in comparison, the Blacks were at relatively less risk: adjusted Odds Ratio (aOR) 0.59; 95% Confidence Interval (CI) [0.59-0.60]. So were the Hispanic, all races (0.59; [0.59-0.60]). Adolescent and young adults (age 13-25) had the highest risk (1.74; [1.73-1.76], reference age bracket: 5-12). Those who lived in the Midwest census region had the highest risk (1.03; [1.02-1.04]; reference: South) while those in the West had the lowest risk (0.61; [0.60-0.62]).

Conclusions: Our results show that while prescriptions of antipsychotics had been declining, prescriptions of antidepressants were on its way up instead. The white had the highest risk of concurrent prescriptions of 3+ different psychotropic classes. So were the adolescents and young adults. Future studies are warranted to examine the multi-level factors attributed for the prevalence of psychotropic polypharmacy and identify potential points of intervention.

433.307 Trends in Primary Care Provider Autism Diagnosis Among U.S. Children from 2013 to 2023: Effects of Child Age, Race and Ethnicity, and Poverty Level

V. Sutherland¹, T. D. Hocking², V. I. Underwood Carrasco³, M. Gillis⁴, A. Woods⁵, D. Folch⁶, K. Zuckerman⁶ and O. J. Lindly⁷, (1)Northern Arizona University, Flagstaff, AZ, (2)Université de Sherbrooke, Sherbrooke, QC, Canada, (3)Oregon Health & Science University, Portland, OR, (4)SRI, New York, NY, (5)SRI, Boston, MA, (6)Division of General Pediatrics, Oregon Health & Science University, Portland, OR, (7)Health Sciences, Northern Arizona University, Health Sciences Department, Flagstaff, AZ

Background: Timely autism diagnosis by a trained specialist is typically a difficult and lengthy process, disproportionately affecting under-resourced families in the U.S. Primary care providers (PCPs) are often the first healthcare professionals to interact with children regularly, giving them the unique position to impact autism diagnostic delays. PCPs historically have not received training on how to diagnose autism and frequently refer children to specialty care providers for diagnosis. Given workforce shortages and high demand for autism diagnostic services, wait times are often long and can perpetuate inequities. To address these issues, PCP autism diagnostic training initiatives such as ECHO Autism-STAT are becoming more widespread. Little research has examined the effects of these initiatives across the U.S. and over time.

Objectives: Identify interactions of age, race and ethnicity, and income over time with the likelihood of PCP autism diagnosis among U.S. children ages 3-17 years from 2013-2023. We hypothesized significant trend changes in these interactions due to recent PCP autism diagnosis training initiatives and the potential effects of the COVID-19 pandemic.

Methods: This was a secondary analysis of census.gov yearly National Survey of Children's Health data from 2016 to 2023. Diagnosis year was constructed from the child age difference between time of survey completion and autism diagnosis. We only considered diagnosis after 2012 (2013 - 2023) to account for small cell sizes and changes in policy and practice (e.g., DSM-V criteria), and to reduce recall bias. Diagnosing provider types were collapsed into a binary response variable of PCP versus other providers. Diagnosis year, age at diagnosis, biological sex, race and ethnicity, language, income, confounding/differential diagnosis conditions, and functional impairment status were included as covariates. General Estimating Equations (GEE) were used to account for any covariance between observations due to survey structure. The model considers interaction terms between the diagnosis year and the other explanatory variables. A linear spline (knot = 2018, Figure 1) was used to better fit the interaction terms. Non-significant explanatory variables were removed until the most parsimonious model remained.

Results: The final GEE model results (Table 1) show several sign reversals for interaction term estimates around the 2018 knot. Lower household income was associated with a higher probability of autism diagnosis by a PCP vs non-PCP. The interaction term for lowest household income shows the likelihood of PCP diagnosis decreased pre-2018 but then increased post-2018. Similarly, the interaction term for Hispanic children vs. white non-Hispanic showed a decreasing likelihood of PCP diagnosis pre-2018 but then an increased likelihood post-2018. The probability of PCP diagnosis decreased for older children, and the interaction term showed a small but significant increase in this over time.

Conclusions: Results suggest PCP autism diagnosis has increased among U.S. children in the past decade. Children with lower household incomes, who are younger, or who are Hispanic were most likely to receive a PCP autism diagnosis, with the greatest increases in PCP diagnosis occurring after 2018. PCP autism diagnosis training initiatives may help to reduce persistent inequities in autism diagnosis.

433.308 Understanding Barriers to Inclusion in Elementary Education for Autistic Students

A. Buck¹, J. Worley², H. J. Nuske³, D. Cooney⁴, M. Dunphy⁴ and D. S. Mandell¹, (1)Psychology, University of Pennsylvania, Philadelphia, PA, (2)Penn Center for Mental Health, Philadelphia, PA, (3)Penn Center for Mental Health, University of Pennsylvania School of Medicine, Philadelphia, PA, (4)University of Pennsylvania, Philadelphia, PA

Background: Autistic children in the School District of Philadelphia are primarily educated in segregated classrooms: Since 2008, the district experienced >500% increase in self-contained kindergarten-through-5th-grade autism support (AS) classrooms. Previous research indicates that most AS teachers favor increased inclusion but have concerns about general education teachers' preparation to educate these children (Rosen et al., 2018). The Philly Autism Instructional Methods Support (AIMS) program has attempted to increase inclusion in the district with limited success. Although district leaders recognize that segregation is neither best for students nor financially sustainable, they continue to rely heavily on self-contained AS classrooms.

Objectives: To elucidate barriers to inclusive education for autistic elementary school students in a large, urban school district.

Methods: We surveyed 33 AS teachers in 27 schools where Philly AIMS provides classroom consultation and 17 general education teachers at 1 school where Philly AIMS provides school-wide inclusion consultation. Teachers completed surveys on inclusive practices, inclusion barriers, and perceptions of inclusion success. Inclusive practices were defined by the number of AS students attending general education during the day and the percentage of the day they were included. Barriers were presented and ordered by frequency of endorsement. Perceptions of inclusion success were rated on a 5-point scale, where 5 represented the highest self-confidence in successfully preparing (AS) or including (general education) autistic students in general education. Survey data from AS teachers were collected at the beginning of the year and from general education teachers mid-year. Thus, AS teacher data represent a priori barriers and anticipated inclusion success, while general education data reflect barriers and success in practice. Descriptive analyses examined variation in inclusion across classrooms and alignment between a priori and in practice barriers. Ordinal regression and t-tests assessed whether teacher type predicted perceived inclusion success and whether average success ratings differed by teacher type.

Results: Data collection and analyses are ongoing. To date, both AS and general education teachers endorsed staffing, time for activities like joint planning and IEP meetings, and training as prominent barriers to inclusion. AS teachers were more likely to rate inclusion success higher than general education teachers ($p=.014$). AS teachers' mean success rating was 3.5, compared with general education teachers' average of 2.6 ($p=.007$).

Conclusions: Despite knowledge that children with autism should be placed in the least restrictive environment, the number of segregated elementary AS classrooms in this district is growing at an alarming rate. AS and general education teachers identify the same barriers to inclusion, emphasizing the need for more staff, time to plan for student movement from AS to general education classrooms (e.g., joint planning), and training. AS teachers' greater confidence in inclusion success highlights a misalignment in expectations between AS and general education teachers regarding inclusion. Given general education teachers' responsibility for inclusion, their confidence and buy-in are crucial for increasing inclusive practices. By the time of presentation, we will have increased sample size and will explore trends in inclusion practices over time and effects of district-level factors (e.g., school climate, leadership) on inclusive education.

433.309 Understanding Client Complexity: A Model for Clinical Case Management

L. Sneed¹, B. Pfingston² and D. A. Samelson³, (1)Research Institute, Catalight, Walnut Creek, CA, (2)Research Institute, Catalight, Walnut Creek, CA, (3)Clinical Excellence, Catalight Foundation, Walnut Creek, CA

Background:

Over the last 20 years, ASD prevalence has substantially increased from 1 in 150 to 1 in 36 (Maenner et al., 2023). Behavioral health organizations and insurance companies are tasked with the responsibility of ensuring these individuals receive behavioral health care appropriate for their specific needs (Bottema-Beutel et al., 2020). Catalight is a large behavioral health organization serving over 20,000 people with I/DD, predominantly ASD (~95%). Catalight developed a comprehensive case management program to holistically serve their patient population, including a diverse multidisciplinary team. Clinical case notes are taken for every patient any time a clinical discussion occurs with their treatment team, family, the patient themselves, between the multidisciplinary team, and other clinical collaborators.

Objectives:

In this analysis we wanted to understand if the average number of clinical case notes over the course of their length of stay in their respective intervention predicted the client's complexity based on known factors of more difficulty to treat (e.g., parental stress, number of dangerous behaviors, older age, adaptive skills, etc.).

Methods:

To analyze this, we randomly sampled 2,000 patients' medical record and analyzed ~50 variables on each client utilizing a multiple linear regression. Upon identifying variables that significantly predicted the average number of clinical case notes, this model was then adapted into a simple algorithm which would predict based on client intake factors how much clinical case management each respective client would likely need over the course of their treatment.

Results:

The random sample included 2,000 patients, 1,000 who have discharged from treatment and 1,000 who were still receiving treatment. In the sample, 99% had a confirmed diagnosis of autism spectrum disorder based on the DSM-5 or DSM-IV criteria. The mean age of individual's included in the analysis was 5.5 ($SD = 4$) with a range of 1 year to 32 years. The average length of stay was 33 months ($SD = 19$) with a range of clinical case notes from 1 – 277 with an average of 21 clinical case notes ($SD = 18$).

Of the numerous variables included in the model, three variables significantly predicted the average number of clinical case notes: the number of dangerous behaviors the client exhibited ($\beta = .056$), age ($\beta = .08$), and a score of their daily living skills ($\beta = .02$) adaptive score from the Vineland-3.

Conclusions:

Upon identifying key variables that predicted case complexity, the authors developed an algorithm depicting relative complexity of the patient population which would then support both clinical case management and treatment planning. The original model of 2,000 patients found ~12% of the patient population would have relatively low complexity, ~80% of patients would have average clinical complexity, and ~10 would have relatively high case complexity. When applied to the total population of 20,000 patients 15% of the population was low complexity, 70% were average complexity, and 15% were high complexity. Upon reviewing with the multidisciplinary teams, this was reflective of their respective caseloads. This model will continue to be monitored and adapted over the next six months.

433.310 Understanding Patterns of Service Use for Autistic Adults: A Pilot of Life History Calendars

J. Koenig¹, **M. D. Prigge²**, **J. Morgan³**, **J. E. Lainhart¹** and **L. Bishop³**, (1)University of Wisconsin-Madison, Madison, WI, (2)University of Utah, Salt Lake City, UT, (3)University of Wisconsin - Madison, Madison, WI

Background: Life history calendars (LHC) are a tool for collecting retrospective data on a range of life events, including details on start date, duration, and overlap of life events. Included life events can cover a range of topics, including living arrangements, health status, and education. The visual of the calendar matrix assists participants with recalling timing of events. LHC can be used to understand patterns of service use, but this method has not been used with an autistic population, to the best of our knowledge.

Objectives: We sought to pilot the use of LHC for the autistic adult population as well as to describe patterns of service use.

Methods: The parents of 28 autistic adults participating in a study on aging completed LHC including events related to service receipt (e.g., applied behavioral analysis and occupational therapy), service dosage, and certain major life activities (e.g., employment and college attendance) from birth to time of data collection. Ages of autistic participants ranged from 18 to 49 (mean: 29.8; s.d.: 7.5). We used simple logistic regression to assess the association between service receipt and adult vocational outcomes (employment, college attendance).

Results: Overall, 64.3% received early intervention, 78.6% were ever in special education, 28.6% received Applied Behavior Analysis therapy, and 64.3% attended any preschool. 46.4% had ever seen a mental health therapist, while 64.3% were ever on psych meds. While 53.6% received Supplemental Security Income at some point, 60.7% were ever enrolled in Medicaid and only 18.5% received disability services. Additionally, 78.6% had ever been employed, 50% attended any college, and 57.1% received services from vocational rehab. Most participants received services in childhood. While 78.6% ever received speech therapy, only 21.4% received it as adults. Similarly, 60.7% received occupational therapy, but only 2 (7.1%) received it in adulthood. 17.9% received physical therapy in childhood, but none did as adults. Social skills trainings were received by 75% overall, but only 35.7% in adulthood. Preliminary findings suggest that ABA receipt in childhood was associated with 70.6% lower odds of ever being employed ($p=0.2$). Participation in vocational rehabilitation was associated with 44% greater odds of employment ($p=0.7$). Receipt of early intervention services was associated with being 72.8% less likely to ever attend college ($p=0.12$). Ever participating in social skills trainings was associated 89.8% lower odds of attending college ($p=0.05$).

Conclusions: LHC present a feasible and low-cost method for collecting retrospective data on service use and other life events for autistic adults. This can improve understanding of patterns of service use and major life events like educational attainment and important interpersonal relationships. Future work should aim to better understand how timing, dosage, and lifespan patterning of service utilization and significant life events affect outcomes that are meaningful to autistic.

433.311 A Qualitative Lens on the Role of Implementation Leadership in Supporting the Use of Ebps with Autistic Children in Inclusive Settings

P. Ghosh Choudhuri¹, **A. Sridhar²** and **J. Locke³**, (1)University of Washington, Seattle, WA, (2)Department of Psychology, Michigan State University, East Lansing, MI, (3)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA

Background: In the United States, the Individuals with Disabilities Education Act (IDEA) requires autistic students to be educated in their least restrictive environment, which has increased their inclusion in general education settings. This has escalated the need for educators to effectively use evidence-based practices (EBPs) in schools. Numerous organizational factors, including implementation leadership, defined as behaviors that principals or other administrators do to support educators' use of EBPs with autistic students, play a crucial role in promoting and sustaining the use of EBPs among educators (Locke et al., 2019). Understanding how school leadership supports educators and paraeducators can lead to creating strategies that promote the successful implementation of EBPs and ultimately improve child outcomes (Cook & Odom, 2013).

Objectives: This project examines what implementation leadership looks like in public elementary schools within the context of EBP implementation with autistic students in general education settings.

Methods: In this mixed methods study, participants included 154 general education teachers, 137 special education teachers, and 62 paraeducators ($N=353$). Participants completed the School Implementation Leadership Scale (SILS), which is a 21-item rating scale with 7 subscales that assess the degree to which their school leader is knowledgeable (understands EBP and implementation), supportive (supports EBP adoption/use), proactive (anticipates and addresses implementation challenges), perseverant in implementing EBPs (responsive to challenges), communicative (bidirectional communication surrounding EBP implementation), centered on the school's vision/mission (integration of EBP implementation with core objectives), and available (accessible to staff needs/problems). Eighty-two participants were randomly selected for a semi-structured interview to discuss their high or low EBP implementation. These interviews lasted around 30-45 minutes, and participants were offered \$40.

Results: Aggregated mean scores on the SILS (Total $M=2.34$) subscales show how educators rate their school's leadership qualities (Table 1). These results illustrate that leadership provides moderate levels of support and availability, but demonstrates lower levels of being knowledgeable, perseverant, and proactive, with particularly weak communication around autism-focused EBP use.

Three independent coders developed a codebook for coding transcripts and reached interrater reliability (97%). Preliminary analyses show that educators desire leadership support through recognition, appreciation, and validation for their EBP implementation efforts. They also expressed the need for professional development for both educators and leadership, emphasizing the importance of knowledgeable leaders. Educators want leadership to provide time for collaboration and communication to discuss implementation strategies and EBPs during staff meetings, highlighting the need for communicative, proactive, and perseverant leadership. They also want the school's vision and culture to focus on collaboration and inclusivity, as it impacts their ability to properly implement EBPs.

Conclusions: The results suggest that implementation leadership within schools play an important role in fostering an inclusive environment for educators to implement EBPs for autistic youth. Leadership should continue to show support, availability, and knowledge. However, educators express a strong desire for more opportunities for collaboration and open, bi-directional communication with leadership. The results highlight the importance of having a strong leadership and an inclusive school culture to improve the implementation of EBPs and enhance outcomes for autistic students in general education settings.

433.312 Understanding the Barriers to Hiring Autistic People As Perceived By Employers in the UK

M. Freeth¹, **M. Day²** and **C. Wood³**, (1)Psychology Department, The University of Sheffield, Sheffield, United Kingdom, (2)University of Sheffield, Sheffield, South Yorkshire, United Kingdom, (3)Psychology, The University of Sheffield, Sheffield, United Kingdom

Background: According to recent figures from the UK Labour Force Survey, only around 3 in 10 of autistic adults are in employment. The equivalent figure for disabled people overall is 5 in 10, versus 8 in 10 for non-disabled people. Further, employed autistic people are less likely to hold senior roles and they face the largest pay gap of all disability groups, suggesting that many in work are underemployed (ONS, 2023). Supporting more autistic people into employment is a major priority of the UK's National Autism Strategy (2021-2026). However, little is known about the barriers employers perceive to hiring autistic people.

Objectives: 1) To establish how much employers know about Autism; 2) To identify the barriers employers perceive to employing more autistic people; 3) To establish whether demographic factors influence intentions to employ autistic people.

Methods: A pre-registered mixed-methods survey was conducted on a nationally representative sample of 1212 individuals with recent hiring experience. The largest industry groups were in the educational, health/social work, manufacturing, information/ communication, financial/insurance, and science/technology sectors. Knowledge of Autism was assessed using the Autism Symptomatology Knowledge Assessment (ASKA) and the Autism Stigma and Knowledge Questionnaire (ASK-Q). Perceived knowledge of autism was assessed using the total score from McMahon's (2020) 6-item questionnaire. The Capability, Opportunity, Motivation – Behaviour framework (COM-B) and the Theoretical Domains Framework (TDF), were used to identify perceived barriers to hiring autistic people.

Results: Levels of Autism knowledge in this population were similar to those reported in other general population samples (ASKA mean = 18.6; ASK-Q mean = 41.4). It was noteworthy that perceived knowledge was not associated with actual knowledge on either scale. Encouragingly, intentions to hire autistic people and to make adjustments to the hiring process were high. However, there were key barriers around knowledge (e.g., of autism and adjustments), organisational processes (e.g., for making and monitoring adjustments) and strategies (e.g., personal hiring and working practices). Intentions to hire autistic people were higher for younger participants, men, people with higher levels of autism knowledge and those with more experience of previously hiring autistic people. Qualitative insights demonstrated that stereotyped beliefs about autistic people (e.g., lower productivity) and the consequences of hiring autistic people (e.g., higher costs) were present in the sample, as was the belief that some roles were unsuitable for autistic people (e.g., customer-facing roles).

Conclusions: This study demonstrated that important targets for intervention are improving employer knowledge of autism and building more inclusive hiring practices. These findings are significant for development of policies aimed at improving employment outcomes for autistic people.

433.313 Understanding the Substance Use and Mental Health Service Needs of Autistic Adults: Experiences, Insights, and Recommendations

M. Ressel¹ and G. Iarocci², (1)Simon Fraser University, Burnaby, BC, Canada, (2)Psychology, Simon Fraser University, Burnaby, BC, Canada

Background: Previously presumed to be rare, recently, there has been increasing recognition of the overlap between autism and substance use (Sinclair et al., 2023). Although research into the substance use of autistic people remains limited by sample size, scope, and inconsistent findings (Ressel et al., 2020), an emerging body of literature suggests that autistic individuals may be more likely to misuse substances and experience worse substance-related consequences than non-autistic individuals (Butwicka et al., 2017; Solberg et al., 2019; Weir et al., 2021), particularly when there is co-occurring attention deficit hyperactivity disorder (ADHD). Furthermore, traditional interventions for substance misuse may be poorly aligned with the unique needs of autistic individuals (Helverschou et al., 2019; Walhout et al., 2022) and autistic people may face numerous barriers to accessing substance use services (Brosnan & Adams, 2022). More information on the experiences of autistic people who have struggled with substance use is needed so that clinicians, service providers, and policymakers can create safe, effective, and accessible substance prevention and mental health support services for this population.

Objectives: This study aims to explore the experiences of autistic substance users.

Methods: Semi-structured interviews were conducted with diagnosed autistic adults who reported prior or current problematic substance use. Data collection began in May 2020 and is ongoing. Reflexive content analysis (Nicomis, 2024) will be used to identify themes and subthemes across autistic narratives of substance use in the following broad categories: patterns of substance use, perceptions of the relationship between substance use and autism, benefits and risks of substance use, and experiences with substance use and other mental health services including treatment effectiveness, barriers to engagement, and suggestions for improvement.

Results: 21 participants (10 male, 8 female, and 3 nonbinary) aged 20-55 ($M = 33.29$, $SD = 9.60$) have completed the interview to date. Thus far, our sample is predominately composed of White Canadian residents without intellectual disability. All participants have co-occurring psychiatric diagnoses, of which anxiety and ADHD are the most frequently reported. Cannabis was the most frequently reported substance used. Although participants' experiences of substance use and substance use services vary, common themes were identified, including substance use to manage autism-related difficulties and co-occurring mental and physical health problems, inaccessibility and limited provider knowledge of autism in mainstream mental health services, and the importance of harm reduction practices. Participants also provided recommendations to improve existing substance use and mental health services for autistic individuals, including autistic-led training, a neurodivergent affirming approach, and a focus on personalized support.

Conclusions: Many autistic adults reported engaging in substance use to self-medicate, particularly during stressful life events. Others perceived substance use as repetitive behaviour/restricted interest or as a compensatory strategy. The findings highlight the need for service providers to be aware of vulnerability to substance use among autistic individuals and to work collaboratively with autistic clients to effectively manage autistic and co-occurring mental health symptoms and substance use. Further research is required to understand the mechanisms underlying the coping and compensatory functions of substance use identified in this study.

433.314 Unintended Consequences: Declines in Vocational Rehabilitation Services and Outcomes Among Autistic Individuals Following Implementation of the Workforce Innovation and Opportunity Act

A. Roux¹, J. E. Rast¹, J. P. Taylor², H. N. Whittenburg³, J. Bromberg³ and L. Shea¹, (1)A.J. Drexel Autism Institute, Drexel University, Philadelphia, PA, (2)Washington State University, Pullman, WA, (3)Drexel University, Philadelphia, PA

Background: The federal Vocational Rehabilitation (VR) program is a critical public funder of employment services for autistic people. Yet, in response to stubbornly poor employment outcomes, despite decades of research showing pathways to career success, the Workforce Innovation and Opportunity Act (WIOA) became law in 2014 and implementation began in 2016. WIOA required states to shift 15% of their VR funding to Pre-Employment Transition Services (Pre-ETS) for students with disabilities without increasing overall VR state funding. WIOA also directed half of state supported employment funds to assist students with “most significant disabilities.” No studies have analyzed the effects of WIOA implementation on access to employment services and subsequent outcomes.

Objectives: To characterize changes in VR services and employment outcomes following WIOA implementation.

Methods: We analyzed VR service utilization and employment outcomes for 44,522 autistic individuals in FFY 2014-2016 (pre-WIOA) and 74,480 individuals in PY 2017-2019 (post-WIOA) using data from the Rehabilitation Services Administration 911 (RSA-911) database. We examined changes in demographics, VR services use, and outcomes using bivariate analyses and sequential multilevel regression models.

Results: Across years, autistic people who received VR services were on average younger at application (18 and under = 44% to 41%), more likely to be in high school (29% to 41%), and more often deemed “most significant disability” (70% to 81%) post-WIOA implementation. Receipt of all categories of VR services declined from pre- to post-WIOA including administrative (85% to 71%), job-related (68% to 52%), education/training (30% to 11%), and other (37% to 22%). Of 15 individual services evaluated, only one did not change: benefits counseling (5.7% vs 6.1%). Notably, post-secondary education and training fell from 8% to 3%, and supported employment fell from 24% to 18%. Finally, the percentage of autistic VR service users who were employed at VR exit fell from 60% to 49%. Services rates consistently declined across age groups (<18, 18-29, >29) and for all major service categories, and post-WIOA employment rates fell significantly across age groups. Education/Training services declined the most across age groups. Despite declines in delivery of traditional VR services, those who received job-related services were five times as likely to attain employment than those who did not receive job-related services. Odds of employment among those who were ages 30+ at VR application fell from 50% more likely to only 10% more likely after WIOA implementation, compared to those who were 18 and under.

Conclusions: The concept of “earlier is better” was the foundation of WIOA-driven shifts to deliver Pre-ETS to students with disabilities. However, the shifting of state VR funds toward Pre-ETS without an accompanying increase in VR dollars resulted in an overwhelming decline in receipt of almost every individual VR service type, and a significant decrease in rate of successful employment at VR exit. Deficient performance post-WIOA extended to middle and older age groups, indicating that declining VR performance was pervasive following WIOA implementation, generating significant concerns about implementation of WIOA’s mandated budget shifts. Examining post-COVID outcomes to evaluate trends is imperative as data become available.

433.315 Building Self-Compassion to Strengthen Well-Being: The Effectiveness of a Virtual Acceptance and Commitment Training for Family Caregivers of Autistic People

L. Man¹, H. Dahary², C. Magnacca³, S. Mishra², K. Fung⁴, A. Porthukaran², L. Steel⁵, J. Siu⁶, N. Bobbette⁶, B. Redquest⁷, K. M. Thomson⁷, M. Penner⁸, J. A. Weiss⁹, Y. Lunskey¹⁰ and J. Lake¹¹, (1)Centre for Addiction & Mental Health (CAMH), Toronto, ON, Canada, (2)Centre for Addiction and Mental Health, Toronto, ON, Canada, (3)York University, Toronto, ON, Canada, (4)UHN - Toronto Western Hospital, Toronto, ON, Canada, (5)1025 Queen Street West, CAMH, Toronto, ON, Canada, (6)Queen's University, Kingston, ON, Canada, (7)Applied Disability Studies, Brock University, St. Catharines, ON, Canada, (8)Autism Research Centre, Bloorview Research Institute, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (9)Psychology, York University, Toronto, ON, Canada, (10)Azrieli Adult Neurodevelopmental Centre, Centre for Addiction and Mental Health, Toronto, ON, Canada, (11)Psychiatry, University of Toronto, Toronto, ON, Canada

Background:

Family caregivers of autistic people report higher stress, anxiety, and depression than other caregivers, yet few mental health services are available to them. Even fewer involve caregivers in their design and delivery. Our prior research demonstrated that our co-led and partnered, in-person, Acceptance and Commitment Training (ACT) program improved the wellbeing and psychological flexibility of family caregivers of people with neurodevelopmental conditions. With the onset of the pandemic, we adapted our intervention to be delivered virtually and studied its real world implementation in teams across Canada.

Objectives:

To evaluate the acceptability and effectiveness of a group-based, virtual ACT intervention, co-led by family caregivers and clinicians for caregivers of autistic people.

Methods:

A total of 85 family caregivers of autistic people participating in virtual ACT workshops across Canada consented to the research evaluation. We examined wellbeing measures (i.e., parental stress, low mood, mental well-being and resilience) and ACT process measures (fusion, flexibility, self-compassion and values) at pre-, post- and at 8-week follow-up using online surveys. We used repeated measures ANOVAs to examine changes across time. We used a multiple linear regression to examine the contribution of fusion, psychological flexibility, self-compassion and values after the program to the well-being outcomes found post-program.

Results:

Family caregivers' mean age was 47 ($SD = 10$, range: 19-69), cisgender women (81%), biological and adoptive parents (86%) of an autistic person, married (86%), attended college, university or postgraduate education (82.3%) and white (64%). Pre-to-post and pre-to-follow-up improvements in parental stress, mood, mental well-being and resilience were found ($ps < 0.01$) (see Table 1). Caregivers also reported being less fused (i.e., less glued to societal narratives) and, more psychologically flexible, self-compassionate and engaged in values-oriented living ($ps < 0.01$) (see Table 2). Finally, post-program self-compassion levels predicted changes to post-program measures of well-being, post-program values predicted lower post-program parental stress and higher post-program resilience, and post-program psychological flexibility predicted improved post-program mood.

Conclusions:

Our virtual ACT workshops hold potential to meaningfully improve skills like self-compassion and aspects of mental well-being among caregivers of autistic people. Findings represent an important step toward understanding the benefits of virtual ACT for this population when implemented in the community.

433.316 Unpacking the Implementation Climate in General Education Settings in Public Schools: A Sequential-Explanatory Mixed-Methods Study

A. Sridhar¹, P. Ghosh Choudhuri² and J. Locke³, (1)Department of Psychology, Michigan State University, East Lansing, MI, (2)University of Washington, Seattle, WA, (3)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA

Background: The increasing prevalence of Autism Spectrum Disorder - impacting 1 in 36 children in the U.S. – significantly impacts public schools, where many autistic youth are either partially or fully included in general education settings. Several evidence-based practices (EBPs) are effective for autistic youth; however, EBP implementation across settings is impacted by various organizational-level factors. Implementation climate – the perception about whether use of the EBP is expected, supported, and rewarded by those intended to use the practice- is one of the strongest predictors of EBP use (Locke et al., 2021; 2022; Williams et al., 2022). Yet, little is understood about the implementation climate within general education in public schools; understanding this context is imperative to increase EBP implementation within these settings.

Objectives: We used a sequential explanatory design to explore the constructs comprising implementation climate in general education settings in public schools.

Methods: 154 general education teachers, 137 special education teachers, and 62 paraeducators (N= 353) completed the School Implementation Climate Scale (SICS), a 21-item rating scale made of up seven sub-scales: Focus on EBP, Educational Support for EBP, Recognition for EBP, Rewards for EBP, Use of Data to Support EBP, Existing Supports for EBP, and EBP Integration. A subset of 82 participants were randomly selected to complete semi-structured interviews, which further explored EBP use to support the inclusion of autistic children. Interviews lasted between 30-40 minutes. Participants were provided \$60 for completing surveys and \$40 for interviews.

Results: Aggregate mean scores on the SICS (Total $M = 1.77$) subscales illustrate educators' perceptions regarding implementation climate at their schools (Table 1). Results indicated a moderate focus and integration of EBPs in schools, some existing and educational supports, and recognition but limited use of rewards for EBP use.

Qualitative analysis began with developing a coding scheme. Three independent coders reached interrater reliability (97% average) on a subset of interviews. Qualitative analysis is expected to be completed by January, 2024. A consensus process is used to resolve discrepancies. Preliminary qualitative analyses revealed that EBPs such as reinforcement are well integrated into some schools. However, findings indicated that general education teachers in particular may benefit from additional education supports (e.g. access to education, training, professional development) in order to increase buy-in and "ownership" of using EBPs with autistic youth. Educators also reported that with a greater push for inclusion of autistic youth in general education settings, there is a need for increased recognition of efforts to use EBPs in these contexts.

Conclusions: Results illustrate educators' current perception of implementation climate within general education settings. Educators report an increased emphasis on inclusion of autistic youth in general education classrooms. However, both quantitative and qualitative results indicate limited access to supports, data, rewards, and recognition for using EBPs with autistic youth in these settings, particularly for general education teachers. Findings highlight that implementation of EBPs does not occur in isolation, and that it is imperative to consider organizational constructs such as implementation climate when implementing EBPs to support autistic youth in general education settings.

433.317 Using Practitioner-Implemented Video Models to Teach Vocational Social Skills in a Rural Public School

A. S. McLucas¹ and B. Gonçalves², (1)Virginia Tech, Blacksburg, VA, (2)Curriculum Instruction and Special Education, University of Virginia, Charlottesville, VA

Background:

Young autistic adults and adults with intellectual disability (ID) regularly experience lower employment rates compared to peers with and without disabilities. These individuals often require additional support to learn social skills commonly used to solve problems and interact with coworkers on the job. In rural U.S. communities, students may lack access to job experiences or related service providers to support them in acquiring these skills resulting in the need for high-quality, classroom-based interventions. Video modeling (VM) is an effective intervention for teaching a variety of skills to autistic individuals and individuals with ID, including social skills. However, fewer studies examine the effects of VM to teach vocational social skills (VSS) and most studies occurred in non-classroom settings.

Objectives:

This study was designed to test the effects of VM plus feedback to teach VSS to young adults on the autism spectrum or with ID in a rural public school classroom, and to assess for generalization to a community-based work setting. We interviewed each participant, their teacher, and their caregiver to assess vocational needs and used this information to inform our procedures to increase the relevance of the intervention to students in a rural community.

Methods:

This study used a multiple probe across behaviors design and occurred in rural public school post-high transition program. Two male autistic students (ages 17 and 20) and one female with ID (age 21) participated, and an instructional assistant served as the intervention agent. We used interviews to align our procedures with participant goals then conducted a VSS assessment (Lerman et al., 2017) to identify three behavioral targets per participant. Targeted skills included common VSS and problem-solving skills requiring social interaction such as responding to missing materials or notifying the supervisor when you complete a task. We implemented the intervention in the classroom using a simulated workplace setting. Following intervention we conducted probes to assess generalization of skills to a new supervisor then conducted probes in a community-based work setting to assess generalization. Each participant rewatched the video models then had an opportunity to engage in each learned skill. Finally, we used a brief interview to assess for social validity and assessed for maintenance during a two-month follow up.

Results:

The intervention was effective at increasing the use of VSS in a simulated work setting within the classroom when implemented by a practitioner (see Figures). Additionally, participants successfully utilized learned skills in a community-based work experience and maintained most of the skills two months following intervention. Generalization to a new implementer was mixed. Participants indicated the intervention was enjoyable, effective, and useful.

Conclusions:

Students with autism or ID often require additional instruction to learn common VSS, and resources can be lacking in rural schools. Conducting these interventions in the classroom can be an accessible way for teachers in rural public schools to teach critical transition-related skills without requiring access to community work experiences. These results suggest that VM plus feedback can successfully teach VSS in the public school and generalize these skills to a work setting.

433.318 What It Takes to Recruit Underrepresented Populations: Recruitment and Retention of Low-Resourced Families with an Autistic Child

D. J. Abate¹, M. L. Covello², A. Bennett³, A. S. Carter⁴, D. Collins⁵, E. Feinberg⁶, R. Kommareddi³, J. L. Kuhn⁷, S. Lluna⁸, N. Menon⁹, J. Molina¹⁰, M. Much-Hichos¹¹, R. Nunez Pepen¹⁰, D. Truong¹², Z. Wong¹³, S. Broder-Fingert¹⁴ and J. S. Miller³, (1)E. K. Shriver Center, E. K. Shriver Center, University of Massachusetts Medical School, Worcester, MA, (2)The Center for Autism Research/CHOP, Philadelphia, PA, (3)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (4)Department of Psychology, University of Massachusetts Boston, Boston, MA, (5)Children's Hospital of Philadelphia, Philadelphia, PA, (6)Brown University School of Public Health, Providence, RI, (7)Pediatrics, Boston Medical Center, Boston, MA, (8)Psychology, Florida International University, Boston, MA, (9)Pediatrics, Emory University, Marcus Autism Center, Boston, MA, (10)Boston Medical Center, Boston, MA, (11)Psychiatry, Boston Medical Center, Boston, MA, (12)IDD Authority Service, Texana Center, Rosenberg, TX, (13)McGaw Medical Center of Northwestern University, Chicago, IL, (14)UMASS Medical School, Boston, MA

Background: Lack of representation from minority and low-income families in autism research has impacted the field for years and lends itself to systemically erasing narratives from populations that need support. This can be especially detrimental for racial minority and low-resourced families with an autistic child, who are often not sufficiently represented in research to identify health disparities¹. Previous literature has described inaccessibility of research materials among the barriers to participate in research for Black families with an autistic child². Similarly, socially disadvantaged individuals demonstrate poor retention in medical research due to factors such as an inability to remain in contact with researchers, practical barriers, and forgetting to participate in follow-up visits³. To eradicate these barriers, the current study describes the efforts needed to recruit and retain low-resourced families with autistic children in two urban healthcare networks.

Objectives: Compare the recruitment and retention of a predominately low-resourced sample of families with an autistic child for follow-up versus cross-sectional recruitment and reflect on methods utilized to increase research accessibility.

Methods: Families of autistic children aged 6-11 years who had previously participated in a randomized controlled trial of Family Navigation^{4,6} as a facilitator for early autism diagnosis at either Boston Medical Center or Children's Hospital of Philadelphia (EARLY; $N = 60$) and a comparison group of age-matched autistic children receiving care in either setting (Community; $N = 48$), were contacted to participate in a study examining the impact of early autism diagnosis upon child behavior and treatment service receipt. Research staff documented the number of texts, emails, phone calls, and mailings they sent participants for both recruitment and retention purposes (i.e., completion of parent questionnaires and child diagnostic evaluation) to examine whether these strategies differed between study cohorts.

Results: There were no statistically significant differences in age, gender, Hispanic ethnicity, and receipt of government assistance between the two cohorts. There was a trend toward a difference in participant race ($p=0.08$), with more Black families in the EARLY cohort. (Table 2). In order to recruit and retain a high number of EARLY Cohort families ($n=60$ of 137 eligible families; 44EARLY Cohort families required an average of 9.4 contacts, while the Community Cohort families required an average of 4.7; $p < 0.01$, calculated by a Welch two-sample t-test).

Conclusions: There is an essential need to include families of low-resourced backgrounds in research to create representative samples and identify barriers or disparities in healthcare. This is supported by the increased recruitment and retention efforts required for the EARLY Cohort.

Recruitment of low-resourced longitudinal samples requires different effort than low-resourced cross-sectional samples. Breaking down resource barriers like transportation, food, and cost for the research study allowed more families to participate that can play a critical role in autism research to better understand the systemic barriers and disparities that exist in this population.

433.319 Trauma and Autism: The Use of the Echo Autism: Advanced Diagnosis Program to Support a Population in Need

V. Nanclares-Nogues¹, A. Brewer Curran², M. Odum³, J. N. Constantino⁴, K. Sohl⁵, M. Mahurin⁶, K. Boles⁷ and L. Nebeker⁸, (1)Pediatrics, University of Missouri - Columbia School of Medicine, Columbia, MO, (2)Department of Pediatrics, University of Missouri, Columbia, MO, (3)ECHO Autism Communities, University of Missouri, School of Medicine, Columbia, MO, (4)Children's Hospital of Atlanta, Atlanta, GA, (5)ECHO Autism Communities, University of Missouri School of Medicine, Columbia, MO, (6)Department of Child Health, University of Missouri, School of Medicine, Columbia, MO, (7)Child Health, University of Missouri, Columbia, MO, (8)Autism Society of America, Alexandria, VA

Background: In recent years, research has shown a greater risk of adverse events and trauma in people on the autism spectrum, particularly those assigned female at birth (AFAB). The presence of trauma can complicate the overall clinical presentation, requiring clinicians to be appropriately trained to understand and address this need. ECHO Autism: Advanced Diagnosis (ADx) equips community diagnosticians with the skillset needed to provide comprehensive autism evaluations for people of all genders across the lifespan who have complex or nuanced presentations. Through case-based learning, the ECHO Autism: ADx program guides and supports community-based diagnostic clinicians in providing best-practice autism diagnostic evaluations throughout the lifespan. The current study analyzed data from case presentation forms completed by the presenting clinicians.

Objectives: To increase the capacity of local clinicians in underserved areas who can provide high-quality, best-practice autism evaluations for patients of all ages and genders. The analysis seeks to identify how many people out of the ECHO Autism ADx dataset are at a greater risk for adverse events and trauma and to explore the impact of underrepresented groups (AFAB) being diagnosed by community-based diagnosticians. **Methods:** Community diagnosing clinicians (i.e., psychologists and select physicians) participated in a year-long program of virtual case-based learning sessions. In these sessions, clinicians presented de-identified cases from their practice to a multidisciplinary team of experts, as well as colleagues in the community, for clarification and guidance. Prior to presenting, a community clinician filled out a deidentified case presentation form through a secure data capture system (REDCap) about an existing patient. The case form included demographic information, developmental, medical, and behavioral findings, including trauma related experiences, and DSM-5 diagnostic criteria. Data from the case presentation forms, collected between 2019 and September 2024, were analyzed to understand age, gender, and trauma-related experiences documented in the case forms.

Results: Out of 121 cases presented, 57% were assigned male at birth (AMAB) with an average age of 9.6 years (range: 2.5-33 years), while the average age for AFAB individuals was 14.72 years (range: 3-44 years). 119 had information about trauma-related experiences. AFAB cases were found to be older at diagnosis and more likely to have experienced trauma. AFAB cases were reported to be 1.27 times more likely to have experienced abuse, 7.44 times more likely to have experienced sexual trauma, and 1.93 times more likely to have experienced physical trauma compared to AMAB cases. Additionally, adults (19 and over) were significantly more likely to have experienced abuse, sexual trauma, or physical trauma than non-adult (18 and younger) cases (69%, 50%, and 40% respectively).

Conclusions: ECHO Autism: Advanced Diagnosis has demonstrated the ability to increase the self-efficacy of clinicians to diagnose and care for patients with autism (Nanclares et al., 2023). The current data analysis supports recent findings that people with autism are at greater risk for adverse events and trauma, in particular AFAB individuals. In addition, the data shows that the program is supporting clinicians who are caring for an often underrepresented and underdiagnosed population.

433.320 Unlocking the Spectrum: The Use of the Echo Autism: Advanced Diagnosis Program to Enhance Access to Diagnosis across the Lifespan for All Genders.

V. Nanclares-Nogues¹, M. Odum², A. Brewer Curran³, J. N. Constantino⁴, L. Nebeker⁵, M. Mahurin⁶, K. Boles⁷ and K. Sohl⁸, (1)Pediatrics, University of Missouri - Columbia School of Medicine, Columbia, MO, (2)ECHO Autism Communities, University of Missouri, School of Medicine, Columbia, MO, (3)Department of Pediatrics, University of Missouri, Columbia, MO, (4)Children's Hospital of Atlanta, Atlanta, GA, (5)Autism Society of America, Alexandria, VA, (6)Department of Child Health, University of Missouri, School of Medicine, Columbia, MO, (7)Child Health, University of Missouri, Columbia, MO, (8)ECHO Autism Communities, University of Missouri School of Medicine, Columbia, MO

Background:

The rise in autism prevalence has outpaced the number of professionals needed to meet the demand (Smith et al., 2020). More recently, there has been an increase in referrals for women and individuals throughout the lifespan. The ECHO Autism: Advanced Diagnosis (ADx) program was developed to address the diagnostic gap for individuals of all ages whose presentation may be more complex or nuanced. Through case-based learning, the ECHO Autism: ADx program guides and supports community-based diagnostic clinicians to provide best-practice autism diagnostic evaluations across the lifespan. The current study analyzed the data from the case presentation forms completed by presenting clinicians within the ECHO Autism: ADx program.

Objectives:

Increase local capacity of clinicians in underserved areas who can provide high-quality, best-practice autism evaluations for individuals of all ages and genders to decrease wait times and improve access to diagnostic assessments by well-equipped community clinicians.

Methods:

Community diagnosing clinicians (i.e., psychologists and select physicians) participated in a year-long program starting with an ADOS-2 introductory training, followed by participation in twice-monthly, 90-minute ECHO Autism virtual case-based learning sessions, where clinicians present de-identified cases from their practice for clarification and guidance to a multidisciplinary team of experts, as well as to community colleagues. Participating clinicians complete pre- and post-surveys regarding self-efficacy, knowledge, and satisfaction with the program. Additionally, data are collected on the types of individuals being evaluated by the ECHO Autism clinicians through case presentation forms. Each community clinician completes a deidentified case presentation form through a secure data capture, REDCap, with information regarding age, gender, developmental history, family history, evaluation measures/results, behavioral observations, and final diagnostic determination according to DSM-5 criteria. Data were analyzed from the case presentation forms between 2019 and September 2024.

Results:

121 cases were presented (57% male) with an average age 9.6 years for male (range 2.5-33 years) and 14.72 for female individuals (range 3-44 years). Notably, a near equal proportion of male and female cases were presented for discussion, an interesting finding given the nuances often associated with the evaluation of female cases. 106 cases had documented wait time to see an ECHO Autism clinician: 77 (73%) were seen in less than three months, 95 (90%) were seen within 6 months. The median wait time was 1-3 months, in contrast to the state median wait time of 7.6 months (2023 DMH report).

Conclusions:

ECHO Autism: ADx has demonstrated the ability to increase clinician self-efficacy to diagnose and care for individuals with autism (Nanclares et al., 2023). The current study shows that wait times have been reduced by more than half, and females are being evaluated at nearly the same rate as males. The program is also supporting clinicians who are caring for individuals of all ages and genders with complex and nuanced presentations, an often underrepresented and underdiagnosed population. Notably, there is extremely limited access for adult autism evaluations at Missouri's Autism Centers of Excellence. This program has expanded access to adults, highlighting the impact of this program on autistic individuals across the lifespan.

433.321 Understanding Service Barriers to Improve Autism Supports for Indigenous Families in Canada

V. C. Fong¹, M. Schneider² and J. McLaughlin², (1)The University of British Columbia, Burnaby, BC, Canada, (2)Wilfrid Laurier University, Waterloo, ON, Canada

Background: Canada's Constitution recognizes three distinct Indigenous groups—First Nations, Métis, and Inuit—which together comprise approximately 1.8 million individuals, or about 5% of the nation's total population (Statistics Canada, 2022). Previous research has demonstrated that Indigenous parents in Canada face compounded challenges when trying to access autism services for their children. To address these inequities, it is crucial to consider the role of service providers, who are instrumental in supporting families and helping them navigate complex systems of care. Their perspectives can provide valuable insights into systemic and institutional barriers that Indigenous families encounter when accessing services. By examining the experiences of both Indigenous caregivers and service providers we may improve our understanding of the challenges families face and better guide the development of more equitable support systems.

Objectives: The objectives of the current study were to understand the main barriers that Indigenous families face when accessing autism services for their children and to explore potential solutions for improving both access to and quality of those services.

Methods: Twelve service providers with a minimum of one year of experience working with Indigenous families of autistic children in Ontario were recruited for participation in interviews. Interviews were transcribed and coded. Data analysis involves using a thematic approach. In addition, Indigenous parents are also being recruited and their perspectives will be incorporated into the findings.

Results: Indigenous families face significant barriers when accessing services for their children, including geographic isolation, historical trauma, and administrative delays. Geographic isolation often limits the availability of nearby services and can create transportation challenges, making it difficult for families in remote areas to attend appointments. Historical trauma can fuel mistrust in service providers, resulting in families being reluctant to seek assistance. Additionally, burdensome paperwork and slow processing times create bureaucratic barriers that delay access to essential services. Solutions for addressing these barriers included capacity building through training local professionals and leveraging existing expertise within Indigenous communities to enhance cultural competence and foster trust. Additionally, increasing awareness and implementing outreach initiatives can help families navigate available services more effectively.

Conclusions: Overall, these findings provide insight into the various challenges that Indigenous families experience and highlight possible strategies for improving equity in service provision.

433.322 Promoting Equity in Autism Services for Newcomer Families: Insights from Parents and Service Providers

V. C. Fong¹, J. McLaughlin² and M. Schneider², (1)The University of British Columbia, Burnaby, BC, Canada, (2)Wilfrid Laurier University, Waterloo, ON, Canada

Background: Newcomers represent a growing population in Canada, with recent data indicating that 437,180 immigrants arrived in 2022, over 40% of whom settled in Ontario. Although many newcomers move to Canada seeking better support for their families, previous research has shown that they continue to face significant barriers to accessing services. Recognizing the role of service providers in bridging these gaps and helping families navigate these challenges, it is crucial to explore their perspectives. Their insights can help shed light on systemic and organizational barriers that newcomer families encounter when seeking supports. By examining the views of both newcomer parents and service providers we can enhance our understanding of these challenges and inform the development of more equitable support systems.

Objectives: The objectives of the current study were to understand the main barriers that newcomer families face when accessing autism services for their children and to explore potential solutions for improving both access to and quality of those services.

Methods: Fifteen service providers with a minimum of one year of experience working with newcomer families of autistic children in Ontario were recruited for participation in interviews. Interviews were transcribed and coded. Data analysis involves using a thematic approach. In addition, newcomer parents are also being recruited and their perspectives will be incorporated into the findings.

Results: Newcomer families experience barriers related to having unmet basic needs, fragmented care, and a lack of culturally responsive services. Newcomer families often experience challenges related to housing and employment, impacting their ability to focus on their child's service needs. Additionally, fragmented care and service silos can lead to inconsistent support, making it difficult for families to navigate the system. The lack of culturally responsive services can further alienate families, as they may feel that their needs and values are not understood or respected. Solutions included creating more access points in the community, such as local service hubs that offer families opportunities to access tailored information and support. Training and education for professionals on current policies and services can improve their ability to assist families effectively. Lastly, enhancing cultural responsiveness among service providers can help create a more welcoming environment for families from diverse backgrounds.

Conclusions: Together these findings provide insights into systemic challenges, gaps in service provision, and suggest potential strategies for improving access to and the quality of autism services for this underserved population.

Virtual Poster Session

104 - Dissertation Awards, Early Career Investigator Awards, and Keynote - Karen Adolph

May 3rd, 2025, 8:30 AM - 10:00 AM - 6ABC

Award Presentations</p> Dissertation Awards Early Career Investigator Awards <p>Day 3 Welcome Remarks</p>
<p>Keynote Address - Karen Adolph - "How Behavior Develops"

219 - Executive Function Development in Autism: Multimodal Insights into Early Indicators, Neural Mechanisms, and Outcomes

May 3rd, 2025, 10:30 AM - 12:30 PM - 6B

Panel Chair: Erin Kang, *Department of Psychology, Montclair State University, Montclair, NJ*

Discussant: So Hyun Kim, *School of Psychology, Korea University, Seoul, Seoul, Korea, Republic of (South)*

This panel provides critical insights into key aspects of executive function (EF) development in both autistic and non-autistic children. Presenting findings from robust, well-characterized samples, the session highlights the distinct behavioral and neural mechanisms underlying EF, as well as its impact on academic, social, and developmental outcomes. The panel will explore attention mechanisms, such as focused attention and vigilance, in early development in infants with elevated likelihood for autism, ADHD, or NF1. One presentation will examine differences in early EF development between autistic toddlers and preschoolers compared to non-autistic peers, exploring neural correlates of EF. Additionally, the role of EF in predicting academic and social outcomes in autistic kindergarteners will be discussed using a multimodal measurement approach. Moreover, distinct neural markers of cognitive flexibility, assessed through event-related potentials (ERPs), and their relationship to both performance-based and real-world behaviors, will be compared between autistic and non-autistic youth. Overall, by examining EF across multiple levels of analysis and from various disciplines, these presentations contribute to a deeper understanding of early EF indicators, neural markers, and their potential to inform targeted interventions that promote cognitive development and improve school and social outcomes.

Introduction

E. Kang, Department of Psychology, Montclair State University, Stony Brook, NY

219.001 Focused Attention and Vigilance in 10- and 14-Month-Olds at Elevated Likelihood for Autism/ADHD or with NF1

F. Penza¹, T. Bazelmans^{1,2}, J. Begum Ali³, T. Charman¹, M. H. Johnson^{1,5} and E. Jones^{6,7}, (1)Centre for Brain and Cognitive Development, Birkbeck, University of London, London, United Kingdom, (2)Department of Psychology, Institute of Psychiatry, Psychology & Neuroscience, King's College London, London, United Kingdom, (3)Centre for Brain and Cognitive Development, Birbeck, University of London, London, United Kingdom, (4)Department of Psychology, Institute of Psychiatry, Psychology & Neuroscience, King's College London, London, United Kingdom, (5)Department of Psychology, University of Cambridge, Cambridge, United Kingdom, (6)Centre for Brain and Cognitive Development, Birkbeck University of London, London, United Kingdom, (7)Department of Child and Adolescent Psychiatry and MRC Centre for Neurodevelopmental Disorders, Institute of Psychiatry, Psychology & Neuroscience, King's College London, London, United Kingdom

Background:

Attention is one of the early mechanisms that has been found to be associated to different neurodevelopmental conditions including autism and ADHD and is thought to be a critical component to the emergence of executive functions. In infancy, attention control is often measured by measuring the time an infant is engaged with a stimulus (ie. focussed attention [FA]), however the ability to maintain attention after stimulus presentation, which is a form of sustained attention, or vigilance, has been less studied.

Objectives:

Here we compare FA, vigilance and movement during a puppet paradigm in a group of infants enriched for diverse developmental outcomes, including autism and ADHD traits.

Methods:

171 infants were seen at 10 and/or 14 months as part of a prospective, longitudinal infant sibling study: 29 Typical likelihood (TL), 80 Elevated likelihood (EL)-autism, 32 EL-ADHD, 20 EL-autism+ADHD & 35 diagnosed with NF1. Infants took part in a live puppet performance where the puppet would appear in the same spot from behind a curtain five times for 4-8 seconds. After each appearance there was a break period during which nothing was presented. The breaks were 25, 15, 15, 5 and 25 seconds long. We coded the videos offline for looking behaviour to measure proportion of looking at the puppet (FA) and proportion of time looking where the puppet was during breaks (vigilance). Movement was measured using an accelerometer (Biopac) attached to the child's foot and average amount of movement during FA, vigilance and looking elsewhere were calculated. We used mixed models to look at the effect of group, condition and their interaction. We included time (10 vs 14 months) and its interaction effect with group and condition, but this was not significant. Parents reported on ADHD and autism traits at 36 months using the Child Behaviour Checklist and Social Responsiveness Scale.

Results:

For looking, there was a significant condition ($p < .001$), group ($p < .001$) and interaction ($p = .004$) effect. As expected, infants showed more FA (.79-.90) compared to vigilance (.16-.25). To parse out the results of the interaction effect, we ran two separate mixed models. The NF1 group showed less FA compared to the TL, EL-autism and EL-ADHD groups. The NF1 group also showed less vigilance compared to the EL-autism, but not the other groups. As expected, movement was lowest during FA, higher during vigilance and highest when looking elsewhere ($p < .001$). No group or group x condition interaction effects for movement were found. Less FA at 10 months was associated with more ADHD traits at 3 years (Kendall tau: -.19, $p = .008$), but not at 14 months (-.13, $p = .065$) or with autism traits ($p > .408$).

Conclusions:

Children diagnosed with NF1, but not EL-autism and EL-ADHD, show difficulties with FA from 10 months and FA at 10 months associates with later ADHD traits. The ability to maintain attention to a stimulus might be more critical at this age and the skills to control attention over sustained periods of time may still be emerging, although vigilance should be studied at later timepoints to confirm this.

219.002 Measuring Early Executive Function Differences in Autistic Toddlers and Preschoolers

S. Faja^a, G. Sideridis^a, G. Schmur^a, D. Y. Her^a, A. Jones^a and M. Surmacz^a, (1)Boston Children's Hospital, Harvard, Boston, MA, (2)Developmental Medicine, Boston Children's Hospital/Harvard Medical School, Boston, MA, (3)Laboratories of Cognitive Neuroscience, Boston Children's Hospital, Brookline, MA, (4)Boston Children's Hospital, Brookline, MA, (5)Laboratories of Cognitive Neuroscience, Boston University, Brookline, MA, (6)Boston Children's Hospital, Boston, MA

Background: Executive function underlies a variety of important developmental outcomes, suggesting that better understanding of its developmental course could provide key information about developmental trajectories and intervention outcomes in autism. Yet, there is little work examining the early development of executive function in autistic toddlers and preschoolers.

Objectives: To determine whether executive function is unitary or multidimensional among toddlers and younger preschoolers. To determine whether autistic toddlers and preschoolers exhibit differences in executive function relative to non-autistic peers. To explore neural correlates of executive function.

Methods: The sample included 132 two-year-olds (65.6% autistic) and 101 four-year-olds (61.4% autistic). Children completed an executive function battery that included working memory, set-shifting, inhibition, and delay tasks. Each domain was measured using at least two tasks – one was developmentally appropriate for the chronological age of the sample and the other was sensitive to executive functioning as early as 12 months of age. One-, two-, and four-factor confirmatory models were tested to evaluate the factor structure of executive function in both age cohorts. Then ANCOVAs were computed using factor scores between diagnostic groups controlling for nonverbal developmental level. Electroencephalography was collected during a non-social resting task, the Child Attention Network Task, and the Dimensional Change Card Sort Task.

Results: The one-factor solution best fit for both the two-year-old ($rs = .337-.794$) and four-year-old ($rs = .494-.813$) cohorts. Within the two-year cohort, controlling for nonverbal developmental level, executive function differed between the diagnostic groups, $F(1,128) = 25.46, p < .001$. We further examined group differences among two-year-olds with nonverbal developmental quotients of 80 or above ($n = 31$ autistic, $n = 34$ non-autistic) and found executive function also differed by diagnosis, $F(1,62) = 21.35, p < .001$. Within the four-year cohort, controlling for nonverbal developmental level, executive function differed between the diagnostic groups, $F(1,97) = 7.50, p = .007$. We further examined group differences among four-year-olds with nonverbal developmental quotients of 80 or above ($n = 27$ autistic, $n = 35$ non-autistic) and found executive function also differed by diagnosis, $F(1,59) = 12.01, p < .001$. Autistic children had lower executive function scores than non-autistic children across all four comparisons. Analyses are ongoing for resting EEG and event-related tasks related to executive function.

Conclusions: Results provide support for unitary executive function during toddlerhood in a transdiagnostic sample that included autistic, developmentally delayed, and neurotypical children. Using a robust measure of executive function that addresses potential limitations related to task impurity and sensitivity to executive function performance at a range of developmental levels, we detected group differences between autistic and non-autistic toddlers and preschoolers above and beyond nonverbal developmental level. This suggests that autistic children experience delays in this key cognitive domain as early as age two that continue throughout preschool. We will also examine neural correlates of early cognitive differences.

219.003 Executive Function Predicts Academic and Social Skills in Autistic Kindergartners Based on a Multimodal Approach
A. B. Choi¹, **H. Lee¹**, **L. Kuhn²**, **J. Kim³**, **S. J. Hong⁴**, **A. Di Martino⁵**, **F. J. Morrison⁶**, **C. Lord⁷** and **S. H. Kim⁸**, (1)Korea University, Seoul, Korea, Republic of (South), (2)Frank Porter Graham Child Development Institute, University of North Carolina, Chapel Hill, NC, (3)Korea Institute of Science and Technology, Seoul, Seoul, Korea, Republic of (South), (4)Center for Neuroscience Imaging Research, Institute for Basic Science, Suwon, Gyeonggi-do, Korea, Republic of (South), (5)Child Mind Institute, New York, NY, (6)Department of Psychology, University of Michigan, Ann Arbor, MI, (7)UCLA Semel Institute for Neuroscience and Human Behavior, Los Angeles, CA, (8)School of Psychology, Korea University, Seoul, Seoul, Korea, Republic of (South)

Background: Many autistic individuals experience challenges with executive function (EF), which is a set of higher-order cognitive processes that underlie goal-directed behaviors (Lezak et al., 2012). These difficulties persist across the lifespan (Demetriou et al., 2018; Dijkhuis et al., 2020), emphasizing the need to explore EF in early childhood, particularly during the transition to formal schooling, before academic and social demands increase. While EF is a well-established predictor of academic and social success in neurotypical children (Blair & Raver, 2015; Kuijper et al., 2017), its role in the development of autistic children remains less clear. Further, previous research often lacks a comprehensive, multi-measurement approach to studying EF, highlighting the need for better understanding of how EF influences academic and social outcomes in autistic children, as they transition to school.

Objectives: Using a multimodal approach to EF measurement, we aimed to address the following research questions: (1) Do EF skills relate to current and future reading and math achievement in cognitively able, verbal autistic kindergartners? (2) Are EF skills associated with current and later social skills in autistic kindergartners?

Methods: Participants included 67 autistic kindergartners (18 females, 26.9%) aged 4 to 6 years. All children had an ASD diagnosis confirmed by the ADOS-2 (Lord et al., 2012) and no intellectual disability and used complex sentences. EF was measured through a computerized battery (EF Touch), behavioral observation (Head-Toes-Knees-Shoulders), and parent report (Behavior Rating Inventory of Executive Function). Academic achievement and social skills were assessed using standardized assessments (Woodcock-Johnson III – Tests of Achievement and Penn Interactive Peer Play Scale). All measures were administered at kindergarten-entry and -exit. Multiple regression models were conducted to explore the concurrent and predictive associations of EF with academic/social outcomes, controlling for covariates (e.g., age, sex).

Results: (1) EF, assessed through the computerized battery, was significantly positively associated with concurrent reading and math performance at both kindergarten- and -exit, even when controlling for age, sex, and cognitive ability. Additionally, longitudinal analysis revealed that children with better EF skills at kindergarten-entry had significantly higher math scores by kindergarten-exit (Figure 1). (2) Parent-reported EF difficulties were significantly positively linked to both current and future peer play challenges, suggesting that children with greater daily EF impairments exhibited more aggressive behaviors and reduced social engagement during peer interactions (Figure 2). Together, these findings indicate that different EF measurement approaches provide complementary insights, capturing the diverse range of EF abilities of autistic kindergartners and their role in academic performance and social functioning.

Conclusions: These findings indicate that EF may be critical foundational skills for academic and social development in young autistic children during school transition. Therefore, targeted EF interventions could be a powerful way to maximize school readiness and social skills for autistic children, providing them with the necessary tools to succeed in various domains of their lives. The results also highlight the importance of a multidimensional approach to EF assessment, as it provides a more comprehensive understanding of the broader impact of EF on key developmental outcomes of autistic children.

219.004 Neural Correlates of Cognitive Flexibility Differences in Autistic and Allistic Youth

E. Kang¹, **R. G. McDonald¹**, **R. Ahmad²** and **D. Wallace³**, (1)Department of Psychology, Montclair State University, Montclair, NJ, (2)Montclair State University, Montclair, NJ, (3)Library Administration, Montclair State University, Montclair, NJ

Background: Cognitive flexibility (CF) is a facet of executive function reflecting the ability to shift thoughts and attention according to changing situational demands. Growing body of literature highlights CF differences in autistic individuals and its association with autistic traits (Lage et al., 2023), including patterns of restricted and repetitive behaviors (RRBs; Miller et al., 2015). However, CF is a multifaceted, complex construct, and ecologically-valid measures of everyday CF and performance-based measures likely target distinct CF aspects (Uddin, 2021). Yet, virtually no study has examined CF in autistic youth incorporating across multiple levels of analysis and there is limited understanding of the underlying brain mechanisms. Event-related potentials (ERPs) indexed by electroencephalography (EEG) provide an ideal method for such investigations, as they are closely linked to individual differences in CF and may clarify similarities and distinctions between cognitive processes reflected by these markers.

Objectives: 1) To validate a novel, developmentally-appropriate, computerized CF task in a well-characterized sample of autistic and allistic youth, and demonstrate that the task elicits dissociable ERP indices of CF, and 2) to examine how ERP indices relate to lab-based EF task and everyday EF measures and RRBs.

Methods: Participants included 72 school-aged youth (41 autistic via ADOS-2; 55% male, $M_{age}=10.48$, $SD_{age}=3.07$; $Range_{IQ}=60-140$; 55.4% white; 7.7% Black/African American; 6.1% Asian; 1.5% Native American; 6.2% MENA; 20% multiracial) and their parents. Youth completed a modified version of the Wisconsin Card Sorting Task, while EEG data were recorded. Switch positivity (SwP), indexing set-shifting, and reward positivity (RewP), indexing reinforcement learning, were extracted. Youth were also administered performance-based CF task (D-KEFS Color-Word Interference [CWI], Trails, Design Fluency [DF]; Delis et al., 2001). Parents and youth completed ecologically-valid measures of CF (Flexibility Scale [FS]; Strang et al., 2017; BRIEF-2; Gioia et al., 2015). Parents also completed Repetitive Behavior Scale-Revised (RBS-R; Bodfish et al., 2000).

Results: SwP correlated with CWI_Inhibition/Switching ($r=-.32$, $p=.03$), self-reported FS Special Interests ($r=.39$, $p<.02$), parent-reported FS Transition/Change, FS Generativity, and BRIEF-2 Shift (all $r>.32$, $p<.05$), only in autistic youth. SwP also correlated with RBS-R across several RRB domains, but in opposite directions in autistic ($r>.31$, $p<.05$) and allistic ($r<-.43$, $p<.03$) youth.

RewP correlated with CWI_Inhibition/Switching and DF_Switching ($r<-.55$, $p<.04$), only in the allistic sample.

Conclusions: Our findings demonstrate that a novel CF task elicits distinct ERP indices of CF, such as SwP and RewP in both autistic and allistic youth. Interestingly, SwP and RewP were differentially associated with both lab-based EF tasks and everyday CF measures. In the autistic group, neural marker of set-shifting was related to everyday flexibility around transitions and special interests. Moreover, the differential correlations between SwP and RRBs in autistic versus allistic youth highlight unique brain-behavior relationship, affirming neurodiversity rather than deficit. In contrast, RewP related more strongly to CF task performance only in the allistic group, reflecting possible differences in the neural underpinnings of CF across groups. Overall, this study underscores the importance of multi-level analyses in understanding CF and its neural mechanisms, offering valuable insights into ways to support cognitive flexibility in neurodivergent individuals.

Panel Session

220 - Neural Mechanisms of Bottom-up and Top-Down Influences on Sensory Processing in Autism

May 3rd, 2025, 10:30 AM - 12:30 PM - 6C

Panel Chair: Shulamite Green, *Dept of Psychiatry and Biobehavioral Sciences, UCLA, Los Angeles, CA*

Discussant: Nicolaas Puts, *Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology & Neuroscience, King's College London, London, United Kingdom*

Sensory differences in autism are increasingly recognized as a core feature of the condition, with profound impacts on everyday functioning. While the prevalence and impact of sensory differences in autism are well-established, the underlying mechanisms remain poorly understood. Many studies have focused on individual sensory domains in isolation (e.g., perception, reactivity, subjective measures), without considering how different aspects of sensory processing interact or relate to the complex, context-dependent, lived experiences of autistic individuals. Our panel integrates complex, multi-level, multi-modal approaches to explore how bottom-up differences in sensory encoding and perception interact with top-down differences in executive control to produce the sensory challenges seen in autism. We will also link these multi-level processes to real-world experiences to inform research approaches and potential interventions and support strategies. Dr. Levin will discuss how multi-level extrinsic factors interact with intrinsic brain states to affect sensory processing. Dr. Sapey-Triomphe will integrate behavioral and neural measures to examine associations between basic sensory detection and higher-level affective responsivity. Dr. Green will discuss how top-down processes play a key role in sensory regulation, and can inform varied interventions. Finally, Mrs. Douglas will explore community-relevant approaches to research that integrates understanding of lived experience.

Introduction

N. A. Puts, *Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology & Neuroscience, King's College London, London, United Kingdom*

220.001 A Neurobiological Framework for Understanding Context Dependence in Sensory Processing

A. R. Levin¹, **Y. Braverman²**, **K. Dunham-Carr³**, **L. Jones⁴**, **D. Kranz⁵**, **R. Law⁶**, **C. MacKay²**, **R. M. Mankaryous⁶**, **K. A. McNair⁶**, **G. Parra⁶**, **S. R. Rogers⁶**, **C. Serianni⁶**, **M. Shao⁶**, **K. Szilagyi²** and **K. E. Takach⁷**, *(1)Neurology, Boston Children's Hospital / Harvard Medical School, Brookline, MA, (2)Neurology, Boston Children's Hospital, Brookline, MA, (3)Boston Children's Hospital / Harvard Medical, Boston, MA, (4)Boston Children's Hospital/Harvard University, Boston, MA, (5)Boston Children's Hospital/Harvard Medical School, Boston, MA, (6)Boston Children's Hospital, Boston, MA, (7)Laboratories of Cognitive Neuroscience, Boston Children's Hospital, Boston, MA*

Background: Cortical responses to sensory stimuli depend on the context in which these stimuli occur. Neurodevelopmental conditions such as autism provide a model for considering the neurobiology that supports translation of sensory stimuli into cortical responses and ultimately individual experiences. Electroencephalography (EEG) is a valuable tool for measuring these cortical responses.

Objectives: We propose a model for considering how top-down and bottom-up activity converge to influence context dependence of sensory responsivity. This context includes intrinsic “resting” brain activity, as well as extrinsic factors such as stimulus characteristics (e.g., salience), temporal context (e.g., habituation or facilitation), and spatial context (e.g., simultaneous background noise or distractors). We are developing and testing a series of EEG measures that allow objective assessment of how these factors impact sensory processing in young children with autism spectrum disorder (ASD), their typically developing (TD) counterparts, and a group of children who have sensory processing concerns (SPC) but do not meet criteria for ASD.

Methods: In an ongoing study, thus far we have collected data from children aged 3-4 years with ASD (n=51), SPC (n= 24) and TD (n=42). EEG data are collected at rest (i.e., when no time-locked stimuli are presented), and across multiple context-modulated sensory paradigms. For example, auditory stimuli include a loudness paradigm (tones presented across a range of loudness levels), habituation paradigm (repeated tones), and background noise paradigm (tones presented on top of background white noise). Resting data presented here reflect how often transient beta events occur over electrodes C3 and C4, measured using the Spectral Events Toolbox. Loudness response is measured by interpolated slope of the amplitude of the frontal N2 ERP response between 50 and 80dB. Habituation is measured using the amplitude of the P1 event-related potential. Background noise response is measured by the auditory middle latency response. Clinician observation of behavioral responses to sensory stimuli is measured by the Sensory Assessment of Neurodevelopmental Disorders (SAND), and parent observation is measured by the Sensory Profile 2 (SP2) and SAND.

Results: At rest, transient beta events occur more often in ASD than TD ($p = .02$). Children with ASD have a flattened input-output response curve to the loudness paradigm compared to TD ($p = .005$), but a steeper response curve at high levels of background noise. Habituation is reduced in ASD compared to TD ($p = .014$). Group comparisons with SPC are ongoing. On both the SP2 and SAND, across all diagnostic groups, sensory hyper- and hypo-reactivity are positively correlated (SP2 $r=0.83$, $p < 0.01$).

Conclusions: Our results objectively demonstrate atypical sensory processing in ASD compared to TD on EEG. The intrinsic and extrinsic context in which a sensory stimulus occurs can amplify sensory processing differences in autistic individuals. The proposed framework and associated EEG paradigms provide opportunities for back-translation into animal models (e.g., considering how various activities of inhibitory interneurons may impact context-dependent sensory processing) and forward translation into clinical trials (e.g., biomarker development and consideration of treatments targeting sensory discomfort).

220.002 A Multi-Level Investigation of Visual Sensitivity and Responsivity in Autistic Adults

L. A. Sapey-Triomphe¹, J. Dierckx², S. Vettori³, N. A. Puts⁴ and J. Wagemans³, (1)Lyon Neuroscience Research Center, France, Bron, FRANCE, (2)Department of Brain and Cognition, Leuven Brain Institute, KU Leuven, Leuven, Belgium, (3)Institut des Sciences Cognitives—Marc Jeannerod UMR5229, Centre National de la Recherche Scientifique (CNRS) & Université Claude Bernard Lyon 1, Bron, France, (4)Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology & Neuroscience, King's College London, London, United Kingdom

Background: Atypical sensory processing is a core feature of autism spectrum disorder (ASD), yet measurements of sensory sensitivity in ASD often lack consistency. The terms *sensitivity* and *responsivity* are often used interchangeably, which may contribute to this inconsistency. Here, we define *sensory sensitivity* as the ability to detect a sensory stimulus, and *sensory responsivity* as the degree of discomfort experienced in response to sensory stimuli.

Objectives: We aimed to characterize visual sensitivity and responsivity in autistic adults across three levels: self-reported, behavioral, and neural. Additionally, we sought to explore how atypical sensory processing contributes to intolerance of uncertainty and anxiety. In a subset of participants, we also investigated molecular correlates of visual sensitivity.

Methods: Twenty-five neurotypical and 24 autistic adults, matched for age, gender ratio, and intelligence quotient, participated in this experiment. At the self-reported level, participants completed questionnaires assessing sensory sensitivity (Sensory Perception Quotient – SPQ), sensory responsivity (Sensory Over-Responsivity Scale – SOR), and both (Glasgow Sensory Questionnaire – GSQ). Behavioral tasks were designed to measure detection and responsivity thresholds for contrast and spatial frequency, using contrast-reversing gratings. At the neural level, we recorded electroencephalogram (EEG) signals while participants performed these tasks, using sweep visual evoked potentials to measure implicit detection thresholds. Participants also completed the short Intolerance of Uncertainty Scale and the State-Trait Anxiety Inventory. A subgroup of participants (N = 36, including 20 autistic adults) underwent magnetic resonance spectroscopy to measure Glx (i.e., glutamate and glutamine) and GABA concentrations in the occipital cortex.

Results: At the self-reported level, autistic participants scored higher than neurotypical participants on the GSQ and SOR ($p < .001$), with a marginal group difference on the SPQ visual items ($p = .057$). Behaviorally, no group differences were found in sensitivity or responsivity to contrast. However, the ASD group had significantly higher detection ($p < .01$) and responsivity ($p < .05$) thresholds for spatial frequency than the neurotypical group. Across participants, self-reported measures of sensory sensitivity and responsivity significantly correlated with behavioral measures of both domains. In the ASD group, but not in the neurotypical group, higher self-reported and behavioral sensitivity and responsivity were significantly associated with greater intolerance of uncertainty and anxiety. EEG measures revealed no significant group differences in detection thresholds for contrast or spatial frequency. In both groups, lower Glx/GABA ratios in the occipital cortex predicted lower contrast detection thresholds and higher spatial frequency detection thresholds, as measured by EEG.

Conclusions: In autistic adults, visual sensitivity and responsivity were elevated at the self-reported level, and typical or heightened (depending on the visual feature) at the behavioral level. Neural measures indicated typical sensitivity in ASD. In both autistic and neurotypical adults, lower Glx/GABA ratios in the occipital cortex allowed for better detection of visual inputs at the neural level. This multi-level approach provides new insights into sensory processing in ASD. These heterogeneous results suggest that sensitivity and responsivity per se are not simply increased in ASD, but may be modulated by other factors in daily life, such as predictability.

220.003 Neural Mechanisms of Sensory Regulation and Potential Interventions for Sensory over-Responsivity

S. A. Green¹, A. Than², U. Shah³, M. Dapretto¹, J. Silvers⁴ and M. Iacoboni³, (1)Dept of Psychiatry and Biobehavioral Sciences, UCLA, Los Angeles, CA, (2)Interdepartmental Neuroscience PhD Program, UCLA, Los Angeles, CA, (3)UCLA, Los Angeles, CA, (4)University of California, Los Angeles, Los Angeles, CA

Background: Over the past decade, we have made significant strides in understanding the brain bases of sensory over-responsivity (SOR) in autism spectrum disorders (ASD). Importantly, our prior work has identified that SOR is related to both increased reactivity to sensory stimuli in sensory cortices and limbic regions, as well as atypical top-down regulation of sensory inputs by the prefrontal cortex (e.g., Green et al., 2015; 2019). Importantly, extent of prefrontal engagement during aversive sensory stimulation may explain individual differences in SOR in ASD (Green et al., 2019), as well as age-related improvements in SOR (Cakar et al., 2023). Taken together, these studies suggest that interventions that engage top-down, prefrontal regulatory systems could improve sensory hyper-reactivity and related challenges. Here, I will present data demonstrating the effect of 1) a behavioral and 2) a neuromodulation intervention on engaging prefrontal cortex and reducing neural over-reactivity to sensory information across ages.

Objectives: Test the effect of sensory regulation interventions on neural reactivity to aversive sensory stimuli, including 1) an emotion regulation strategy (reappraisal), in 8-15 year-olds; and 2) transcranial magnetic stimulation (TMS) to the dorsolateral prefrontal cortex (dlPFC) in autistic adults.

Methods: Study 1: Participants were 33 ASD and 28 TD youth, aged 8-17 years. During fMRI, participants were exposed to scratchy tactile stimuli rubbed on their inner wrist, and were instructed to think about how the stimuli made them feel ("Feel" condition) or use a reappraisal strategy of thinking about how they would describe the material objectively ("Reporter" condition). Study 2: Participants were 25 adults with ASD aged 18-30 years, who met criteria for SOR on the Sensory Processing 3-Dimensions self-report questionnaire. Participants completed a baseline fMRI and then 1 month later received excitatory TMS (intermittent theta-burst stimulation; iTBS) to their left dlPFC and immediately thereafter completed the same fMRI paradigm. During fMRI, participants were presented with 6 15-sec blocks each of alternating mildly aversive auditory+tactile (white noise and scratchy sponge) and visual+tactile (flashing checkerboard and scratchy sponge). fMRI data was thresholded at $Z > 2.3$, $p < .05$.

Results: In study 1, both ASD and TD youth showed increases in medial prefrontal cortex in the Reporter compared to Feel condition, suggesting that the reappraisal strategy was successful in engaging prefrontal cortex for all participants. The ASD but not TD youth further showed significant decreases in primary auditory, visual, and tactile cortices in the Reporter compared to Feel condition. In Study 2, participants showed decreases in relevant sensory cortices (sensorimotor and auditory in tactile+auditory condition; sensorimotor and visual in tactile+visual condition) after iTBS compared to at baseline.

Conclusions: Both reappraisal, a behavioral intervention, and TMS, a neuromodulatory intervention, appeared successful at engaging prefrontal cortex and reducing neural sensory hyper-activity across children, adolescents, and young adults with ASD. Taken together, these results are consistent with the hypothesis that top-down processes are important to regulating sensory reactivity. Results will be discussed in terms of the potential for top-down, sensory regulation interventions to provide support for autistic individuals of varied ages and needs.

220.004 Lived Experience of Autistic Sensory Differences

S. Douglas¹, F. Sedgewick² and N. A. Puts³, (1)Bristol, United Kingdom, (2)University of Bristol, Bristol, NA, United Kingdom, (3)Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology & Neuroscience, King's College London, London, United Kingdom

Background:

I am a neurodivergent late diagnosed AuDHD, white, cis, woman. Since my autism dx, I have engaged with the process becoming an autism and neurodivergent research study advisor. As honorary research advisor at Bristol University, an A-Rep on AIMS-2-TRIALS, I use my lived experience in the context of participatory projects and study design (LEANS, STRATA, AASP, VAMHNs). My focus lies on creating a positive impact of participatory research encouraging bridge-building, attitudinal shifts and creates cultural research environments that support and enhance the wellbeing of the research team, the participants and consequently the quality of data collected.

However, we are still a long way from focusing on the priorities of the autistic community that want research that focusses on enhancing our day-to-day wellbeing. Stereotypical and stigmatizing attitudes that monolithically paint autistic people as cold, unempathic loners are both wildly inaccurate and damaging when the reality is that many autistic people thrive when they have the experience of authentic, reciprocal and nurturing relationships in their lives. One of the primary barriers for autistic people to achieve this are sensory challenges. Sensory processing and friendships /relationships both scored highly in the 2024 Stirling survey – the first fully autistic community-based research priority-setting exercise, and it is the interrelationship of these two areas that will be highlighted.

Objectives:

To 1) combine my lived experience of navigating relationships as an autistic person who has numerous sensory challenges, with material from my co-authored accessible academic publication *Understanding Autistic Relationships Across the Lifespan: Family, Friends, Lovers and Others* and 2) Discuss how my conversations with (autistic) researchers have led to co-produced experimental designs to better understand the impact of bottom-up and top-down markers of sensory difficulties.

Methods:

Using qualitative methods, 24 contributors were interviewed and thematically coded within chronological chapters that wove their and my experiences together with existing peer-reviewed research, with an emphasis on the sensory challenges from daily life, merging experimental and lived-experience research. Further, through conversations with autism researchers that I have developed mutually supportive relationships within the AIMS-2-TRIALS Consortium we developed novel, applicable, measures of sensory perception and sensory affections, and aversions (psychophysical and cognitive tasks).

Results:

Thematic findings show that authentic, reciprocal and nurturing relationships are key to autistic thriving, but there are many barriers, including the dynamism of sensory processing differences, to achieving this. The dynamic nature of sensory difference stands out as not currently being addressed by research. Co-production with the autistic community can enhance researchers' understanding of sensory differences. Following consultation, sensory measures were incorporated into the AIMS-2-TRIALS consortium focusing on relevant measures for autistic people (e.g., the ability to filter out sounds in noisy environments). Preliminary findings align with the autistic experience that sensory aversions are highly context-dependent more accurately reflecting the nuanced nature of autistic sensory experiences.

Conclusions:

Understanding the mechanics of autistic sensory processing differences, translating this knowledge into transforming the sensory and relational environment, whilst respecting autistic social and communication culture, will enhance the wellbeing of the autistic community.

Panel Session**221 - Innovations in Training Community Mental Health Providers to Serve Autistic Individuals**

May 3rd, 2025, 10:30 AM - 12:30 PM - 6A

Panel Chair: Allison Nahmias, *AJ Drexel Autism Institute, Drexel University, Philadelphia, PA***Discussant:** Amy Drahota, *Department of Psychology, Michigan State University, Department of Psychology, East Lansing, MI*

Autistic children and adults are more likely than their non-autistic counterparts to have at least one co-occurring mental health diagnosis (Longo et al., 2024; Underwood et al., 2023; Rast et al., 2021). Despite this heightened need for mental health services, autistic individuals report significant difficulty accessing appropriate care, citing practitioners' lack of autism knowledge and inability to adapt modalities for autistic clients (Maddox et al., 2020; Brede et al., 2022; Chiri & Warfield, 2012; Brookman-Frazee et al., 2012). Clinicians highlight a lack of autism-specific training as a key barrier (Ainsworth et al., 2020 and Adams & Young, 2020). Therefore, innovations in community mental health provider training are warranted to increase community capacity to adequately serve the mental health needs of autistic individuals. This symposium will cover four unique models for training community mental health clinicians that vary in their training focus and methods. Outcomes discussed will include changes in putative implementation mechanisms (e.g., provider confidence, presentations 1, 2, and 4) and implementation outcomes (e.g., fidelity, presentations 3 and 4). A senior scholar with expertise in autism mental health services and implementation science will provide an integrative discussion, with a focus on future directions in dissemination, implementation, and service system integration.

Introduction**A. S. Nahmias**, *Psychiatry and Behavioral Sciences, A.J. Drexel Autism Institute, Drexel University, Sacramento, CA***221.001** Extension for Community Healthcare Outcomes As a Model to Increase Mental Health Support for People with Intellectual and Developmental Disabilities**S. Iadarola¹**, **B. Cavanaugh¹**, **C. M. Perez²** and **S. Hochheimer¹**, *(1)University of Rochester Medical Center, Rochester, NY, (2)Developmental and Behavioral Pediatrics, University of Rochester Medical Center, Rochester, NY*

Background: People with intellectual and developmental disabilities (IDD) experience higher rates of mental health distress and risk of self-harm as compared to the general population. Systemic issues within our medical and mental health systems, however, contribute to health inequities for people with IDD. Mental health providers often report feeling unequipped and untrained to welcome people with disabilities into their practices, especially those who do not use fluent spoken language. This is compounded by the already restricted workforce in mental health spaces. Many adults with disabilities experience challenges navigating these complex systems or may have access issues based upon insurance status, location, or transportation. In the context of these barriers, provider education is highlighted as a facilitator of mental healthcare access in the disability population (Whittle et al., 2018). The Extension for Community Healthcare Outcomes (ECHO) model is a promising approach to providing specialty education to community providers. ECHO utilizes subspecialty, interdisciplinary expertise at an institutional "Hub" to engaged community provider "spokes" in a structured and facilitated virtual learning network, through didactics and case presentation discussions. **Objectives:** Evaluate the preliminary efficacy of an ECHO for Mental Health and IDD on the ability of community mental healthcare providers to feel confidence and competence in welcoming disabled patients into their practices.

Methods: We conducted four ECHO cohorts of 10-20 participants across three years. Participants represented community mental health providers including psychologists, licensed mental health counselors, school psychologists, behavior analysts, crisis counselors, and social workers. Each ECHO cohort met either once per week or every other week (depending upon cohort schedules) for 8-10 sessions. Sessions included 1) "spoke" case presentations that were discussed by the full group and 2) "hub" didactic presentations on relevant topics (e.g., risk assessment in IDD, adapting therapy for people with limited spoken language). Participants completed a pre and post-assessments evaluating 1) perceptions of clinical comfort working with the IDD population and 2) disability-related attitudes in mental health care.

Results: 110 participants registered and completed the pre-assessment measures. Approximately 50 participants participated in ECHO, and of these 25 completed the post measures. Pre-ECHO means were 23.09 for Clinical Comfort, as compared to 25.61 post-ECHO, representing a statistically significant increase in perceived comfort working with patients with disabilities ($p=.005$). Pre-ECHO mean was 15 for Disability Attitudes, compared to 16.12 post-ECHO, also representing a statistically significant increase in positive disability attitudes ($p=.03$).

Conclusions: IDD-focused ECHO is a promising strategy to increase the comfort and disability attitudes of community-based mental health providers. Widespread training may help more disabled people with co-occurring IDD received mental health care in the community, as opposed to seeking subspecialty care, which is accompanied by many access barriers. Replication with larger samples is needed, particularly as the pre/post samples were unbalanced. Ongoing IDD and Mental Health ECHO is occurring to provide future data in this area.

**221.002** Evaluating an Online Training Series to Increase Confidence and Competence of Community Mental Health Providers to Use Cognitive Behavioral Therapy Strategies to Treat Autistic Youth and Youth with ID**A. S. Nahmias¹**, **K. Merritt-Gawe¹**, **K. M. Hricak¹**, **B. Jeyanayagam²**, **A. Smith³**, **L. Moskowitz²**, **D. L. Gassner⁴**, **R. Sachs⁴** and **M. D. Lerner¹**, *(1)AJ Drexel Autism Institute, Drexel University, Philadelphia, PA, (2)Department of Psychology, St. John's University, Queens, NY, (3)Department of Psychology, St. John's University, Queens, NY, (4)Spectrum Services, New York, NY*

Background: Despite the increased risk for experiencing mental health disorders and poor mental health outcomes (Rosen et al., 2018), autistic youth are often unable to access *any* mental health treatment, especially evidence-based interventions such as cognitive behavioral therapy (CBT; Adams & Young, 2021). In fact, access to quality mental health care is one of the largest unmet service needs for autistic youth, due in part to the lack of appropriately trained providers (Chiri & Warfield, 2012). Moreover, when care is available, it often neglects crucial lived-experience insights desired by the autistic community to increase relevance, accessibility, and acceptability (Roche et al., 2021; Maddox et al., 2021). The Scalable Psychopathology InteRvention Intensive Training for ID & Autism (SPIRIT) was developed to meet this need, utilizing asynchronous and synchronous online instruction to incorporate neurodiversity-affirming approaches and autistic lived-experience perspectives with training in core CBT skills and evidence-based adaptations for autistic youth and youth with intellectual disabilities (ID). It includes a 6-session Basic instructional series (max n/group = 40), followed by an available Advanced small group case consultation series (once/month for 4 months, max n/group 8), enabling readily scalable and accessible delivery.

Objectives: To assess provider outcomes from participants in the SPIRIT training program.

Methods: Community mental health providers working in state-funded office of mental health settings were invited to enroll in SPIRIT.

Questionnaires were administered to participants pre- and post- Basic training and once a month during (and one month after) SPIRIT Advanced. T-tests were used to compare provider confidence and competence ratings pre- and post- Basic training. Mixed-effects modeling was used to assess SPIRIT Advanced participant-reported frequency and perceived effectiveness of their use of 23 CBT strategies over time. All p-values were Bonferroni-adjusted.

Results: 210 community mental health providers (57.1% social workers, 32% without any prior experience with autism) began SPIRIT Basic training across 6 cohorts, and 40 (22.5% without any prior experience with autism) continued onto SPIRIT Advanced. 69.5% of Basic and 75% of Advanced trainees completed all training activities. Basic participants reported significant improvements in their confidence and competence to treat mental health problems in autistic youth and in youth with ID from pre-to-post training (all $p < .02$). Advanced participants reported significant improvements over time in *both* their frequency and effectiveness for 2 core CBT (e.g., cognitive restructuring, Figure 1) and 4 autism-specific (e.g., visual supports, Figure 2) strategies (p -values $< .02$). They also rated the training as highly acceptable ($M = 4.8$ out of 5) and highly likely to make permanent improvements in their ability to implement, modify, and adapt CBT with autistic youth and/or youth with ID ($M = 4.7$ out of 5).

Conclusions: The SPIRIT training series is a promising, accessible model for increasing the confidence and competence of community mental health providers to use CBT techniques to treat autistic youth and youth with ID. Future research should assess the degree to which provider-reported changes translate to improved access to care and therapeutic outcomes for this population, and utilize experimental designs to compare training models.

221.003 Impact of Internet-Based Self-Directed Training in CBT for Autistic Youth on Clinician's Ratings of Intervention Adherence

J. Wood¹ and **B. McLeod²**, (1)Human Development & Psychology, University of California Los Angeles, Los Angeles, CA, (2)Virginia Commonwealth University, Richmond, VA

Background: Modular EBPs for Youth on the Autism Spectrum (MEYA; meya.ucla.edu) is a free internet-based clinician training and guidance system developed from existing EBPs for autistic youth (e.g., Wood et al., 2020, 2021) distilled into modules that address autism-related clinical needs (e.g., friendship skills) along with concurrent mental health needs (e.g., anxiety; disruptive behavior). Training is provided in brief internet-based self-instruction modules that are pushed out to clinicians just days before an upcoming session. The overarching objective of MEYA is to help community clinicians develop expertise in EBPs by increasing their adherence to specific CBT techniques that are applicable to the highest priority clinical needs of the children and youth they are working with.

Objectives: A multiple baseline study of seven clinicians (e.g., psychologists, MFTs) recruited from several community care settings throughout the United States was conducted to determine if internet-based self-directed training would facilitate an increase in clinician adherence to CBT techniques addressed in MEYA.

Methods: Clinicians were asked to invite a new autistic youth client (aged 6 to 17 years; 3 girls, 4 boys; 5 Caucasian, 2 Latino) and their family to participate in the study as well; once a client (and her/his caregiver) consented/assented, clinicians were randomly assigned to undergo baseline conditions of 2 to 8 weeks in length. During baseline, clinicians used their typical intervention practices. Once online MEYA training commenced, clinicians engaged in algorithm-guided self-instruction in CBT for autistic youth. Participating clinicians videotaped each session (baseline and MEYA) and made self-ratings on an adherence rating scale: the MEYA Fidelity Scale-Clinician Version. The average number of MEYA sessions completed was 11. Trained coders unaware of session number or study hypotheses also used the MEYA Fidelity Scale-Rater Version to rate the therapists' adherence to MEYA practices for each session.

Results: Visual analysis of multiple baseline charts showed that most clinicians significantly increased their self-reported adherence in CBT practices (i.e., MEYA-FS-CV scores) immediately or soon after the end of baseline and beginning of MEYA training. This increase in fidelity was maintained across most subsequent MEYA sessions for these therapists. Multilevel linear models (with sessions nested within therapists) suggested that clinician self-ratings were significantly associated with observer ratings on the MEYA-FS items.

Conclusions: MEYA is a promising free training tool that may help therapists improve their adherence in CBT practices for autistic children and youth. Self-ratings of adherence appeared to be a meaningful tool for examining fidelity to such practices.

221.004 The Impact of Training Community Mental Health Therapists in an Adapted Executive Function Intervention for Autism

K. S. Dickson¹, **T. Holt²**, **L. Anthony³**, **L. Kenworthy⁴** and **L. Brookman-Frazee⁵**, (1)San Diego State University, San Diego, CA, (2)SDSU, San Diego, CA, (3)University of Colorado, Denver, Aurora, CO, (4)Center for Autism Spectrum Disorders, Children's National Hospital, Washington, DC, (5)Psychiatry, University of California, San Diego, La Jolla, CA

Background: As detailed by Maddox and colleagues (2021), there have been significant advances in the understanding of mental health needs and mental health services for autistic individuals, including enhanced understanding of the range of co-occurring mental health conditions experienced and a growing evidence-base for mental health interventions for autism. Yet major barriers to quality mental health services for autistic individuals remain, including limited community mental health workforce capacity to effectively serve autistic individuals. Mental health therapists commonly have limited training, experience and confidence working with autistic individuals, contributing to more limited intentions to use evidence-based interventions with this population (Maddox et al., 2021). Together, this highlights the need for effective autism-focused training models to enhance mental health therapist capacity to work effectively with autistic individuals.

Objectives: The current mixed-methods study examines the impact of training therapists in a clinical intervention training model developed as part of a systematic adaptation of an evidence-based executive function intervention entitled *Unstuck and On Target (Unstuck)* for implementation in community mental health settings.

Methods: As part of our systematic, community-partnered adaptation of *Unstuck* for delivery in community mental health settings, we developed a therapist training model based informed by best-practice methods for effective therapist training (Frank et al., 2020) and existing models shown to promote effective strategy delivery among community providers, including the *Unstuck* (Anthony et al., 2023; Kenworthy et al., 2014) and *AIM HI* (Brookman-Frazee et al., 2019, 2022) training models. As part of a randomized feasibility pilot trial of the adapted version of *Unstuck*, therapists (N=13, 88% female, 38% Hispanic/Latinx, 81% master's level clinician's) received training and delivered *Unstuck* with participating autistic clients (N=20, 60% male, $M_{age}=9.43$, 80% Hispanic/Latino/a). We examined therapist training outcomes, including: therapist training completion, observed therapist *Unstuck* strategy use (fidelity) with participating clients, and therapist-reported changes in knowledge and confidence in addressing executive functioning in their clients. We also gathered therapist perspectives on our training model via corresponding qualitative interviews.

Results: The majority of therapists (92%) successfully completed training and delivered 75% or more of the intervention to participating clients during study participation. Additionally, therapists demonstrated strong use of *Unstuck* strategies ($M [SD] = 4.30 [.51]$ on a 1-5 scale) during delivery with participating autistic clients. Therapists reported significant improvements in knowledge and confidence (Cohen's d effect size range = .44-.84) addressing executive functioning following training. Expanding on this, qualitative themes indicated therapists perceived the feasibility and utility of the training model, particularly in supporting their confidence working with autistic youth.

Conclusions: Our therapist training model was effective in promoting therapist knowledge, confidence, and effective delivery of *Unstuck*. Qualitative themes further underscore the utility and feasibility of this training model for community settings. A strength of the current study is the evaluation of our training model as part of delivery with participating autistic clients. Findings add to the growing literature regarding effective methods to train mental health therapists to effectively work with autistic youth.

Panel Session

222 - Unpacking Social Communication: Conceptualization, Measurement, and Application across the Translational Spectrum

May 3rd, 2025, 10:30 AM - 12:30 PM - 611-614

Panel Chair: Emily Neuhaus, *Department of Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA*

Discussant: Raphael Bernier, *Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA*

Social communication differences represent an influential core diagnostic and theoretical component of autism, but the construct also reflects a broad category of behaviors and abilities that has been inconsistently defined and measured. In this panel, we unpack the construct of social communication to consider novel and nuanced approaches to its assessment, explore applications for support and interventions, examine associations with neural functioning, and consider its utility in understanding genetic influence in neurodevelopment. Speakers will present novel research exploring (1) the development of a change-sensitive tool to capture social communication abilities across development, (2) relationships between social dimensions across measures and over the course of developmentally appropriate intervention, (3) brain-behavior associations during innovative, real-time, ecologically valid dyadic EEG collection, and (4) exploration of social communication alone and in conjunction with other phenotypic features to enhance genetic understanding relevant to autism. As a whole, this panel presents a translational perspective to social communication that bridges implementation of clinically meaningful tools all the way to neural and genetic underpinnings.

Introduction

E. Neuhaus, *Department of Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA*

222.001 Toward a Change-Sensitive Measure of Social Communication: The Developmental Assessment of Social Communication Ability (DASCA)

S. Bishop¹, **A. J. Kaat**², **A. Thurm**³, **C. Farmer**⁴ and **S. Zheng**⁵, (1)*Psychiatry and Behavioral Sciences, University of California, San Francisco, San Francisco, CA*, (2)*Department of Medical Social Sciences, Northwestern University, Chicago, IL*, (3)*Office of the Clinical Director, National Institutes of Health - National Institute of Mental Health, Bethesda, MD*, (4)*National Institute of Mental Health, Bethesda, MD*, (5)*Psychiatry and Behavioral Sciences, The University of Texas at Austin, San Francisco, CA*

Background: Although scientists have long been interested in understanding the typical development of social communication behaviors like joint attention and their foundational importance for language and cognition, in clinical psychology and psychiatry, social communication is most often discussed in diagnostic terms related to autism spectrum disorder (ASD). Thus, social communication tends to be viewed and measured in binary terms (i.e., presence vs. absence of deficit), rather than as a dimension of abilities that evolve over time. Because of the overwhelming focus on evaluating deficits, available measures of social communication are not responsive indices of severity. This hinders meaningful comparisons of social communication ability within or between diagnostic groups, as well as measurement of within-person change in response to treatment.

Objectives: The Developmental Assessment of Social Communication Ability (DASCA) was developed as a clinical outcome measure appropriate for monitoring and longitudinal assessment of change in children with neurodevelopmental disorders.

Methods: Qualitative components of our measure development approach included focus groups and cognitive debriefing interviews. Quantitative components included dimensionality analysis, differential item functioning, and item response theory modeling. The item bank was iteratively refined and field tested with nearly 6000 parents of children under 18 years (approximately 30% were diagnosed with autism or another neurodevelopmental disorder), recruited from several large registries, including OP4G (a market research firm that recruits parents of children unselected for any specific developmental disability), SPARK, and Simons Searchlight.

Results: The final DASCA item bank contains 284 items focused on social communication skills that are typically acquired by early- to middle-childhood. Expressive language was a major factor in determining the appropriateness of some items for different groups of children. Negligible differential item functioning, primarily by age, was observed for some items. However, impact analyses determined that this differential item functioning did not meaningfully impact scores at the test level. Unexpectedly, despite multiple attempts to group items into different “types” of social communication behaviors (e.g., based on form or purpose of initiation or response), models incorporating multiple social communication factors or attributes did not substantially improve the statistical model fit for these data. Thus, we hypothesize that social communication may mirror other domains of development where skills that appear to represent different categories emerge nearly simultaneously (e.g., for expressive language development, young children begin using verbs shortly after first nouns are acquired).

Conclusions: The DASCA item bank represents a significant advancement in measuring caregiver-reported social communication in children with NDDs. Unlike currently available measures, it focuses on the presence of developmentally expected social communication skills rather than lack thereof, potentially allowing for a more responsive measurement of social communication. Ongoing development efforts include creating a computer adaptive test administration to allow for serial assessments using different item sets on a consistent score metric that is sensitive to change.

222.002 Refining Social Communication Domains in Autism: From Better Characterization to Targeted Precision Interventions

A. Y. Hardan¹, L. Chetcuti², E. Spackman³, J. M. Phillips⁴, G. W. Gengoux¹ and M. Uljarevic¹, (1)Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA, (2)Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA, Australia, (3)Psychiatry and Behavioral Sciences, Department of Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA, (4)Psychiatry & Behavioural Sciences, Stanford University, Palo Alto, CA

Background: Social functioning difficulties represent a core diagnostic feature of autism spectrum disorder (ASD) that is complex and multifaceted. Individuals diagnosed with ASD show pronounced heterogeneity with respect to presentation, severity, and the course of specific facets of social functioning. Unfortunately, the majority of widely used scales have poor coverage and representation of distinct constructs of this complex symptom domain. To address this significant limitation, the Stanford Social Dimensions Scale (SSDS) was developed following gold-standard measurement development principles—that span systematic review of the literature and factor analyses of existing instruments, including the Social Responsiveness Scale (SRS-2)—in order to comprehensively characterize fine-grained, biologically-based Research Domain Criteria (RDoC) social constructs and subconstructs: Social Communication (SC), Attachment/Affiliation (AA), and Understanding Mental States (UMS).

Objectives: To better characterize the social functioning profile of children with ASD using novel approaches and examine the usefulness of these strategies in clinical trials.

Methods: Cross-sectional data from a well-characterized sample of 40 children with ASD from an ongoing study were examined to characterize associations between social subdomains captured by the SSDS subscales (social motivation [SM], social affiliation [SA], Expressive Social Communication [ESC], and Social Recognition [SR]) aligning with specific RDoC AA, SC and UMS domains of functioning, and clinical features such as language abilities as measured by the MacArthur-Bates Child Development Inventory (CDI) and restricted repetitive behaviors (RRB) as assessed with the Repetitive Behavior Scale-Revised (RBS-R). Data from a completed trial involving a Developmental Reciprocity Treatment package (DRT-P), a developmentally based intervention, that reported SC benefits will also be examined to identify the subdomains driving the overall improvements.

Results: SM and SA subdomains showed strongest associations with total number of CDI gestures ($R=0.507$, $p<0.001$ and $R=0.529$, $p<0.001$, respectively). Number of words understood from the CDI showed the strongest association with SA ($R=0.321$, $p=0.43$) and SR ($R=0.382$, $p=0.015$). Interestingly, no associations were observed between CDI words produced score and the SSDS social subdomains. Higher levels of RRB were associated with higher difficulties in SM ($R=0.428$, $p=0.013$) and ESC ($R=0.609$, $p<0.001$) subdomains. Regarding the trial, participants in DRT-P showed improvement on the SRS ($F=5.00$; $p=0.034$) with improvement observed in the SC ($F=4.93$; $p=0.035$) but not in the AA and UMS subdomains. Similar analyses will be conducted on data being collected in an ongoing trial in preschoolers with ASD participating in a center-based pivotal response treatment program.

Conclusions: Preliminary findings from the analyses reported here point to the value of examining different social domains in order to increase our understanding of the clinical profile of children with ASD and to further assess the different areas that are benefiting from when receiving a specific intervention. Further research using similar approaches is needed to examine large samples of children and adults with ASD participating in clinical trials, so that additional insights can be gained in the specific domains benefiting from specific treatments.

222.003 Advancing Towards Dyadic, Interactive Neural Measures of Social Perception

C. M. Hudac and C. M. Nelson, Department of Psychology; Carolina Autism and Neurodevelopment (CAN) Research Center, University of South Carolina, Columbia, SC

Background: Social motion perception may reflect the mechanisms by which low-level social communication processes are impacted in autism (Federici et al., 2020; Todorova et al., 2019). Recent studies have utilized biological motion perception as a target of social skills training (Yang et al., 2017) and biomarker development (McPartland et al., 2020; Webb et al., 2020). However, our knowledge of the neural mechanisms of social perception in autism is largely limited to traditional, screen-based research. Because social interactions are naturally dynamic and occur between people, there is an urgent need to examine these processes in an ecologically valid way.

Objectives: Our primary objective is twofold: (1) to evaluate how correlates of social perception vary based upon task (traditional vs interactive) and contingency (real-time vs. pre-recorded) in autistic adolescents; (2) to evaluate how interactive perception relates to individual differences in social communication and social behaviors.

Methods: Participants included autistic and non-autistic adolescents (N=12, aged 10-17 years old) that completed a dyadic electroencephalography (EEG) session with a close friend or stranger. Here, we evaluate neural correlates on two tasks where participants were asked to sit quietly and watch the screen: (1), a traditional motion perception task (Hudac et al., 2015; 2017) with minute-long videos of social motion (person dancing, hands clapping) or nonsocial motion (ball bouncing, tubes swinging); and (2) videos of the participant (Self) or their dyad partner (Other) during real-time (Contingent) or prerecorded (Noncontingent) interactions. We targeted frontal alpha asymmetry (FAA), as it is linked to social communication abilities in autism (Neuhaus et al., 2023). Participants completed a battery of self-report social communication and social behavior measures, including the Conversation Questionnaire (Wilson, 2022), Need to Belong Scale (Leary et al., 2013), and a social connection and loneliness survey (Card & Skakoon-Sparling, 2023).

Results: During the interactive task, FAA did not vary based upon real-time versus pre-recorded conditions, $p = .37$, or relate to autism diagnosis, $p = .85$. As shown in Figure 1, preliminary analyses using Spearman correlations indicated that increased positive FAA ("approach") during interactive motion perception was associated with a trend for increased positive FAA during traditional Biological but not traditional Non-Biological motion. Lastly, interactive FAA values were positively associated with confidence regarding conversation skills ($r = .56$, $p = .039$).

Conclusions: As cognitive neuroscience techniques become more advanced, it is increasingly important to ensure and evaluate the ecological validity of traditional measures and utilize more engaging interactive tasks. Our results indicate that FAA may be a viable biomarker across traditional non-interactive and interactive (e.g., hyperscanning) settings. Importantly, interactive FAA is also associated with autistic self-perception of social communication skills.

222.004 Leveraging Social Motivation to Understand Genetic Influence in Autism

E. Neuhaus¹ and E. E. Eichler², (1)Department of Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (2)Department of Genome Sciences, University of Washington, Seattle, WA

Background: Identification of genetic influences that increase likelihood of autism (ASD) offers tremendous potential to uncover neurobiological mechanisms, delineate genetically-defined subgroups, and enable individualized intervention based on unique etiology. However, large-scale genomic efforts to distinguish genes contributing primarily to ASD (ASDpredominant) versus those contributing to broader neurodevelopmental conditions that may include ASD along with multisystem impairment (e.g., seizures, cardiac concerns) (NDDpredominant) have yielded inconsistent conclusions. This has been attributed to both methodological factors and heterogeneity in phenotype. We suggest that although this heterogeneity poses difficulties for genetic approaches relying on dichotomous classification (presence vs absence of ASD), it represents meaningful variability that has yet to be fully leveraged to understand genetic influences on neurodevelopment. We propose that inclusion of quantitative social phenotypes can aid in these efforts, and "boost the signal" of genomic efforts to understand ASD etiology.

Objectives: We sought to (1) examine social phenotypes across groups with variants in genes hypothesized to associate with ASD versus broader neurodevelopmental conditions, and (2) test the ability of social phenotype alone and in conjunction with medical history and intellectual disability (ID) to distinguish genetically-defined subgroups.

Methods: Phenotypic and genomic data from the Simons Searchlight single-gene cohorts were coded according to ASD specificity as categorized by Satterstrom and colleagues (2020), yielding 32 individuals with variants in "ASDpredominant" genes and 344 with variants in broader "NDD predominant" genes (Fig. 1). General linear models were constructed to compare profiles of social-communication features across the groups, using SRS-2 subscales (Constantino, 2012). Medical history data were extracted and coded for presence of ID, and an index of medical complexity was computed across 12 somatic systems. Logistic regression models were computed to compare the ability of (1) social phenotypes, (2) intellectual disability, and (3) medical complexity, in differentiating between Satterstrom classifications.

Results: Social phenotypes (Fig. 1) differed according to gene group membership, $F(1,2.5)=3.84$, $p=.01$, driven by greater difficulties in social motivation, $p<.001$, and social cognition, $p=.03$, in the ASDpredominant group. While the groups did not differ in likelihood of ID, $\chi^2(1)=2.13$, $p=.14$, the NDDpredominant group had greater medical complexity, $F(1,374)=6.14$, $p=.01$, consistent with broader neurodevelopmental impairment. The logistic regression model containing social phenotypes, ID, and medical complexity was significant, $\chi^2(8)=20.23$, $p=.009$, Nagelkerke $R^2=.14$, and correctly classified 92.2% of cases. Social motivation was the single strongest predictor, $p=.02$, along with medical complexity, $p=.038$, and (marginally) intellectual disability, $p=.079$. Membership in the ASDpredominant gene subgroup corresponded to greater social motivation difficulties, lesser medical complexity, and marginally lower likelihood of ID.

Conclusions: Examination of quantitative social phenotypes, rather than solely dichotomous ASD diagnosis, may uncover information important to understanding genetic influence, especially when considered in conjunction with medical complexity. Social motivation may be a particularly impactful construct in untangling genetic influence, as it uniquely differentiated between subgroups in the current data, tracks with familial history of autism (Marrus et al., 2022), has meaningful variability among individuals on the autism spectrum (Neuhaus et al., 2020), and has long been foundational to etiological theories of neurobiology underpinning autism (Dawson et al., 2005).

Panel Session

223 - Neurodivergence-Affirming and Inclusive Research Practices for Autistic People with High Support Needs

Panel Chairs: Steven Kapp, *School of Psychology, Sport and Health Sciences, University of Portsmouth, Portsmouth, Hampshire, United Kingdom*

Diana Tan, *Macquarie School of Education, Macquarie University, Sydney, NSW, Australia*

Vikram Jaswal, *Psychology, University of Virginia, Charlottesville, VA*

Discussant: Grant Blasko, *self-advocate/ community participatory researcher, Seattle, WA*

Introduction

D. W. Tan, *Macquarie School of Education, Macquarie University, Sydney, NSW, Australia*

223.001 “It's OK to Have Brain Fails”: The Views of Autistic Adults, Including Those with High Support Needs, on Co-Governing the Autism from Menstruation to Menopause Study

A. Grant, *Swansea University, Swansea, Wales, United Kingdom*

Background:

Research on Autistic adults often neglects those with High Support Needs (HSN). However, the neurodiversity paradigm provides a clear justification to not limit Autism research in this way. Moreover, whilst community involvement in Autism research has grown, this involvement has sometimes been described as both tokenistic and superficial. The Autism from Menstruation to Menopause study uses Community Based Participatory Research (CBPR), principles to meaningfully share power as co-researchers, aligned with the neurodiversity-affirming AASPIRE guidelines for participatory research (Nicolaidis et al., 2019; Raymaker, 2020). This included co-developing the grant application and accessible recruitment practices to establish a Community Council, including those with HSN.

Objectives: To describe (i) the approaches used to make the Autism from Menstruation to Menopause Community Council accessible, and (ii) what the Community Council, including Autistic members with HSN, think about it.

Methods:

Twelve Autistic people (including four with HSN; three with intellectual disabilities and one without intellectual disabilities but who is non-speaking and has high care needs) were recruited to a Community Council in ways that prioritised inclusivity. To ensure accessibility, 1-1 conversations about access needs were held when members joined and again a year later. Nine meetings were held to help develop the Autism from Menstruation to Menopause study, and to jointly plan the evaluation of the Council. Accessibility was prioritised in these meetings, for example: providing 1-1 meetings ahead of Council meetings, having reminders focused on inclusivity and a learning culture, paying for or providing 1-1 support workers, and completing payment paperwork for members. In July 2024, all Council members undertook a semi-structured interview or completed a qualitative survey to provide feedback on their experiences of being part of the Council.

Results: After a year, the Council retained 11 members, three with HSN. Council members, including those with HSN, were overwhelmingly positive about their experience taking part in the Council. In particular, Council members with HSN felt their needs were generally met well. Nevertheless, some additional access needs were identified and subsequently implemented (e.g. creating an “easy read” agenda for meetings, using photos alongside words). In addition, Council members with lower support needs valued the accessibility accommodations implemented for those with higher support needs, as these measures made participation more accessible for everyone, including themselves.

Conclusions: All Autism research - and researchers - can benefit from involving the Autistic community, and this should include Autistic people with HSN. Moreover, from a place of social and epistemic justice, research should be done *with* communities. Embedding a neurodiversity-affirming approach throughout our Community Council has resulted in greater accessibility to all members with varying levels of support needs. This has informed our study design and participant-facing materials for the Autism from Menstruation to Menopause study, which has successfully recruited Autistic participants with HSN (10 intellectual disability; 13 semi-speaking). When developing grant applications for autism research studies, sufficient time and funding should be included to allow all aspects of the research process to be informed by the lived experiences of those with HSN.

223.002 Community-Based Participatory Research with Autistic Youth and Adults with Language Impairment

T. M. Girolamo, *School of Speech, Language, & Hearing Sciences, San Diego State University, San Diego, CA*

Background: Community-based participatory research (CBPR) are rare and tend to exclude autistic people with high support needs (HSN), including those with structural language impairment (Chen et al., 2024). Structural language impairment commonly co-occurs in autism and is tied to worse communication outcomes (Boucher, 2012; Johnson et al., 2010). Thus, even with growing attention to CBPR (Fletcher-Watson et al., 2019), it is unclear how researchers could partner with autistic people with different support needs. This study focuses on CBPR with autistic participants who have structural language impairment and diverse nonverbal cognitive abilities.

Objectives:

1. To determine how to enhance the CBPR environment for a study on self-determination in autistic adolescents and adults with structural language impairment;
2. To identify how clinical assessment related to the personal goals of autistic adolescents and adults.

Methods:

To address the first aim, we identified strategies to tailor a self-determination measure for autistic adolescents and adults with structural language impairment and created a novel interview support structure with community partners (5 self-advocates, 3 caregivers, 3 speech-language pathologists, 2 psychologists, 2 special education teachers). To address the second aim, we recruited 73 U.S.-based, English-speaking participants ages 13 to 30 years (55% with structural language impairment; 29% with NVIQ <70 to 84; 16% American Indian, Native American, or Alaska Native, 26% Asian, 52% Black, 36% multiracial and not mutually exclusive with other racial categories, 6% Pacific Islander, 27% white; 12% other and 18% Hispanic/Latine) and caregivers ($N=51$). Participants and caregivers completed questionnaires about self-determination as interviews, services (Newman et al., 2011), and educational and career goals. To address Aim 1, we analyzed interviews using inductive thematic analysis (Braun & Clarke, 2012). To address Aim 2, we compared clinical assessment and person-centered outcomes. To merge data, we interpreted quantitative data in more depth using qualitative data via the constant comparative method (Glaser & Strauss, 1967).

Results: Use of strategies for different language profiles and transparent partnering practices led to 100% partner retention. Partner strategies included planning for multiple synchronous and asynchronous modalities of engagement, including providing agendas with language tailored to each partner, use of visual schedules, and pre-planning to tailor language use (e.g., planning how to rephrase language as needed and how to share information). Practices included adequate compensation and mutual benefit, given partner income restrictions, and balancing sharing technical information about project development (e.g., grant proposals) with individual language and cognitive skills. Interview themes indicated personal perceptions about autonomy shaped self-determination. Also, there was no simple relationship between clinical assessment information (language, NVIQ, autism traits) and person-centered measures (self-determination, personal goals).

Conclusions: Findings supported the feasibility of engaging autistic people with HSN who are the least likely to be part of research, while also honoring their contributions. Using personalized strategies, ensuring partners choose how to represent themselves on the team (including different models of disability), and working to bring benefit to all partners was important. Current projects build upon this approach to CBPR and have implications for partnering with autistic people who have HSN.

223.003 Promoting the Autonomy of Autistic Adults with Intellectual Disabilities in Daily Life Choices: Co-Design of a Neurodiversity-Affirming Toolkit of Practical Resource

J. Ryan, *Rehabilitation Medicine, University of Alberta, Edmonton, AB, Canada*

Background: The neurodiversity movement wants autistic people to exert as much autonomy as possible with the support needed (Kapp, 2023). Autonomy - feeling in control of one's life, making choices, and acting voluntarily - is a fundamental human right regardless of disability and a key component of well-being (Ryan & Deci, 2017). Autistic people with and without intellectual disability (ID) experience decreased autonomy, perhaps due to having few opportunities (e.g. limited by presumed incompetence) and/or little support to act volitionally (Cheak-Zamora et al., 2020).

Objectives:

Co-design a toolkit of practical resources that staff can use to promote autonomy for autistic people with ID in the context of community-based support.

Methods:

We used experience-based co-design (EBCD) to share agency and focus on evidence-informed practice to design a toolkit grounded in the real-world experiences of autistic people and the professionals who support them. Our research team comprised eight people: 4 autistic community partners, 2 with ID; 2 autistic researchers; a non-autistic researcher; and an occupational therapist.

Results:

We recruited 20 participants: 14 autistic people (5 with ID and 2 support workers); and 6 non-autistic clinicians and support workers.

Initial Resource Exploration

We conducted an organized internet search to identify existing tools relevant to supporting autistic individuals. The review highlighted a wide range of resources, categorized as follows:

- In-the-Moment Choice-Making Tools: Supporting immediate decisions.
- Longer-Term Goal-Setting Tools: Aiding in planning and achieving personal goals.
- Training Resources for Staff: Educating support workers and caregivers.
- Training Resources for Autistic People: Empowering individuals in self-advocacy and autonomy.

Workshop 1: Understanding Perspectives

Participants highlighted five critical principles:

- Get to know me: Build an understanding of each individual.
- Don't make assumptions: Avoid preconceived ideas about abilities or preferences.
- Clear communication: Use direct, accessible, and consistent communication.
- Advocate with me: Empower autonomy by standing alongside the individual.
- Always be kind and respectful: Foster empathy- and dignity-based relationships .

Workshop 2: Refining Strategies

To further explore the implementation of strategies using the in-the-moment choice-making tools from our resource exploration.

- Existing tools align with the five themes identified in Workshop 1.
- There was a notable gap: no tools exist specifically for helping supporters communicate clearly with autistic people with ID.

Workshop 3: Pre-User Testing of Prototypes

Participants reviewed and provided feedback on four prototype tools:

1. One-Page Profile: A concise summary of the individual's preferences, needs, and communication style.
2. Communication Chart: A guide for understanding and responding to the individual's communication methods.
3. Personal Environment Preferences: A tool to understand an individual's preferences and needs within environments.
4. Exploring Choice-Making Supports: A resource to help individuals make informed daily choices.

Feedback informed the creation of the final open-access toolkit.

Conclusions: Autistic adults without and with ID, service providers, and caregivers can co-design new resources that address critical gaps. They co-developed a neurodiversity-affirming toolbox of practical resources to equip support staff and caregivers to empower autistic individuals with ID to make choices. It reinforced the importance of trust, clear communication, and mutual respect in promoting autonomy.

223.004 "Communicatively Resourceful, Interpretatively Curious": (mis)Communications in Social Care Settings for Autistic People with High Support Needs.

H. E. Sutherland, Salvesen Mindroom Research Centre, University of Edinburgh, Edinburgh, United Kingdom

Background:

Recent neurodiversity-oriented research has found that nonautistic people can also struggle to understand autistic people (the double empathy problem, or “DEP”; Milton, 2012). However, this research has almost exclusively focused on autistic people with lower support needs (LSN). We wanted to know if and how the neurodiversity paradigm and the DEP could help us understand social communicative interactions between autistic people with higher support needs (HSN) and the practitioners supporting them in support services.

Objectives:

- 1) To characterise the kinds of social and communicative interactions that occur between staff and supported people in support settings.
- 2) To understand staffs’ perspectives on socialising and communicating with autistic people with HSN.
- 3) To consider the findings from (1) and (2) in the context of the neurodiversity paradigm.

Methods: The study took place in the UK, in 2022-2024, in two day-support services for autistic adults with HSN (who needed 24/7 1-to-1 care, often had an intellectual disability, and were often minimally or non-speaking). 12 supported people and 21 staff took part in the study. Data collection occurred on 28 days over the course of a year. We used ethnographic methods, which included participant observation; interviewing of practitioners; analysing documents from the services; and reflexive practice from the ethnographer, HEAS, who is autistic. We used grounded theory as our analytic approach.

Results:

Supported people often had specific communicative difficulties (e.g. articulation issues, long processing time, limited vocabulary), which could make communication with them difficult. However, staff sometimes struggled to understand supported people’s communication instead due to normative expectations (e.g. expecting spoken language, failing to understand stimming, not considering autistic sensory needs). Staff perceptions of risk could also cause misunderstandings, due to increased interactional stress.

Staff often felt responsible for “not understanding” supported people, and rarely framed communication breakdowns as due to supported people “failing to communicate”. Supported people often seemed frustrated at being misunderstood. They also used strategies to accommodate staffs’ difficulties understanding them (e.g. repeating themselves, rephrasing, or changing communication modalities).

Despite these difficulties, practitioners and supported people could have positive social interactions, good communication, and close friendships. Experiences of relational closeness and attunement between staff and supported people often occur when communication was successful.

Successful communication often involved both parties adapting their communication styles to the other party’s needs.

Conclusions: The neurodiversity paradigm and the DEP are useful for understanding autistic people with HSN’s experiences in a support setting. Cross-neurotype communication can be difficult, for a number of reasons. Some of these are seemingly intrinsic to the supported people’s autism and/or intellectual disability; others are relational, and due to the difficulties in overcoming differences in social expectations. Despite this, however, cross-neurotype friendships could still flourish between staff and supported people. This suggests that focusing on mutual cross-neurotype understanding could help improve care provision and outcomes for autistic people with HSN, though more research is needed. These findings point to the value of applying neurodiversity paradigm perspectives to research that includes autistic people with HSN.

Panel Session**224 - From Systems Biology to Drug Targets and Biomarkers in Autism Spectrum Disorder: Bridging the Lab and Clinic**

May 3rd, 2025, 10:30 AM - 12:30 PM - 606-607

Panel Chair: Haitham Amal, *Neurobiology and Neurology, Boston Children's Hospital - Harvard Medical School, Boston, MA, Neurobiology and Neurology, Hebrew University of Jerusalem, Boston, Israel, Neurobiology and Neurology, Boston Children's Hospital - Harvard Medical School, Boston, MA, Neurobiology and Neurology, Hebrew University of Jerusalem, Boston, Israel*

From Systems Biology to Drug Targets and Biomarkers in Autism Spectrum Disorder: Bridging the Lab and Clinic The goals of this session to expose the INSAR community to the extensive work that is done in lab and is translated into clinical studies. The session will emphasize the pre-clinical and IND studies for FDA drug approval as well as diagnostic projects that led to DFA clearance.

Introduction

H. Amal, *Hebrew University of Jerusalem, Israel*

224.001 Using iPSCs to Identify Drug Targets for ASD

S. A. Lipton, *Molecular Medicine, Scripps Research Institute, La Jolla, CA; Neurosciences, UC San Diego, La Jolla, CA*

Background: MEF2C is a transcription factor discovered by the Lipton laboratory that is critical for normal neurodevelopment, and whose loss-of-function mutation in humans results in MEF2C haploinsufficiency syndrome (MCHS), a severe form of autism spectrum disorder (ASD)/intellectual disability (ID). Despite prior animal studies of *MEF2C* heterozygosity to mimic MCHS, MCHS-specific mutations have not been investigated in detail previously, particularly in a human context as patient-derived human induced pluripotent stem cells (hiPSCs) afford. Here, we use patient hiPSC-derived cerebrocortical neurons and cerebral organoids to characterize MCHS deficits, identify new drug targets, and develop a lead drug candidate.

Objectives: To develop a robust, reproducible hiPSC-based model of ASD/ID using 2-dimensional (2D) cultures and 3D cerebral organoids that can be probed both molecularly and electrophysiologically with novel therapeutics.

Methods: We generated MCHS patient-derived hiPSCs and isogenic WT controls using CRISPR/Cas9 technology. We then differentiated the hiPSCs into cerebrocortical neurons in 2D cultures and 3D cerebral organoids. These MCHS mutations manifest varying degrees of haploinsufficiency and are disease specific. This approach allowed us to study human neuronal development and function in the presence of patient-relevant mutations in MEF2C-deficient compared to isogenic control cells. Using these techniques, we have elucidated molecular and electrophysiological mechanisms underlying MCHS pathophysiology. We have also tested novel compounds via a multiomics approach, including single cell RNA-sequencing (scRNA-seq), proteomics, and patch-clamp and multielectrode array (MEA) recordings on WT vs. MCHS neurons and organoids.

Results: We demonstrate network-level hyperexcitability in MCHS neurons, mediated predominantly by excessive extrasynaptic (e)NMDA-type glutamate receptor activity contributing to excitatory/inhibitory (E/I) imbalance. We develop a lead therapeutic candidate, represented by the eNMDA receptor antagonist, NitroSynapsin, with dual functional attributes of open-channel block and redox modulation of NMDA receptor-operated channels, that corrects the aberrant electrical hyperactivity associated with abnormal phenotypes. Additional drug candidates have been identified by a gene expression complementarity approach using the Connectomics Map (Broad Institute). In this technique, we utilize the CMAP/LNC1000 and ReFRAME chemical library databases that identify compounds that correct the expression of differentially expressed genes (DEGs) identified in MCHS vs. isogenic WT neurons and glia using our scRNA-seq database collected on cerebral organoids (Trudler et al. *Mol. Psych.*, 2024).

Conclusions: During neurodevelopment, MEF2C regulates many ASD-associated gene networks, suggesting that treatment of MCHS deficits may possibly help other forms of ASD as well. Here, we identify a lead candidate drug, NitroSynapsin, that corrects E/I imbalance and protects synapses in MCHS hiPSC-derived neurons. We also develop a pipeline of other drugs that correct these abnormal phenotypes using the Connectomics Map and other approaches.

224.002 A Novel Combined Drug Therapy for Autism Spectrum Disorder

H. Amal, Neurobiology and Neurology, Hebrew University of Jerusalem, Boston, Israel

Background: Autism spectrum disorder (ASD) includes various conditions that share a core of behavioral deficits manifested by abnormalities in social interactions and communication, restricted interests, and repetitive behavior. To date, no effective **single drug** treatment has been found for ASD.

Objectives: **Here we developed a novel combo drug to reverse a wide spectrum of ASD phenotypes by targeting three key molecular pathways identified by our unique three-way proteomics platform.**

Methods: Three-way proteomics including global-, phospho-, and S-nitroso-proteomics were conducted on blood samples from kids with low functioning ASD as well as on brain samples from three different mouse models: Shank3, Cntnap2, and Nlgn3. This was followed by biochemical, pharmacological, and behavioral experiments.

Results: Using SNO-proteomics, we found that *de novo* S-nitrosylation (a nitric oxide (NO)-mediated protein modification) of TSC2 causes aberrant activation of the mTOR signaling. Using phosphoproteomics, we found a reduction in GSK-3 β phosphorylation at Ser9, which affects brain development by disrupting the Wnt/ β -catenin signaling pathway. Interestingly, global proteomics revealed an abnormal upregulation of the catalytic subunit of the mitochondrial ATP synthase, which may delay synaptic development via an opening of the mitochondrial permeability transition pore (mPTP). Drugs affecting each of these pathways (NO/mTOR, GSK-3 β /Wnt, and mPTP) attenuated deficits in a specific behavioral phenotype, whereas their combined application showed signs of a synergistic effect.

Conclusions: **The unique approach of this project is to apply a combination of drugs modulating the major pathways to reverse the ASD phenotype. This multidisciplinary work is expected to lead to a breakthrough in ASD therapy and open up the field of neurology to the new concept of combinatorial therapy.**

224.003 De Novo and Somatic Mutations Impacting Autism: Toward Precision Medicine

I. Gozes¹ and L. Gabis², (1)Tel Aviv University, Tel aviv, Israel, (2)Pediatric Neurology and Developmental Disabilities, Tel Aviv University, Tel Aviv, Israel

Background: Discovered in our laboratory, activity-dependent neuroprotective protein (ADNP) is susceptible to de novo mutations as well as somatic mutations causing cognitive impairments/intellectual disabilities, within the autism spectrum disorders, namely the ADNP syndrome (also known as Helsmoortel Van Der Aa syndrome). Davunetide (NAP, CP201 and AL-108) is an investigational drug derived from ADNP that is suggested to protect against deleterious effects of ADNP mutations.

Objectives: We set out to investigate the structure/function relations of ADNP mutations and activities in cell cultures, animal models and affected individuals. We further set out to discover the breadth of davunetide protection in cellular and animal models toward clinical development.

Methods: In silico, genome editing, in vitro, in vivo and patient-related questionnaires were implemented.

Results: Focusing on davunetide (NAP= single amino acid letter code, NAPVSIPQ), we have recently shown that NAPVSIPQQ to NAPVSIPQE de novo point mutation in ADNP causes a mild developmental syndrome, while changing the size of the electrostatic patch on ADNP (1). This finding was further linked with the davunetide sequence being essential for cytoskeletal organization/cellular signaling through interactions with microtubule end binding proteins (EB1 and EB3), association with beta catenin, SH3-domain-containing proteins (like the autism/schizophrenia-linked SHANK3) and with an ADNP zinc finger domain, linked with transcriptional regulation (2). Focusing on ADNP, by a longitudinal genotype-phenotype (Vineland Questionnaire) of 15 ADNP syndrome cases, we highlighted mutated protein length and structural characteristics correlation with communicative abilities, further accentuated in males (3). Our current research surprisingly identified protective inherited ADNP mutations (Gozes et al., in preparation). In contrast, complete ADNP deficiency in mice inhibits neural tube closure and is incompatible with life, while haploinsufficiency predicts and mimics the ADNP syndrome. Truncating ADNP mutations in the nuclear-localization area induced sex-dependent gain of toxic function (4). Mouse model treatment with davunetide ameliorated many of the ADNP haploinsufficiency and mutation-related deficits. Pathologically, and considering ADNP/davunetide critical microtubule/Tau protection, we discovered Alzheimer's like tauopathy in ADNP syndrome patients and mice, which is inhibited by davunetide treatment, in mice.

Conclusions: With our recent clinical results discovering sex differences in the pure tauopathy progressive supranuclear palsy coupled with efficacy for davunetide in women (5) and with davunetide sex-dependently boosting memory in prodromal Alzheimer's disease (6), we are poised for clinical trials in ADNP syndrome, further armed with Orphan Drug Designation and Pediatric Rare Disease Designation (ExoNavis Therapeutics)

224.004 Small Molecule Efficacious Therapeutic Treatment for the Neurodevelopmental Disorder CTNNB1 Syndrome

M. Jacob, Tufts University, Boston, MA

Background: *CTNNB1* is a high-confidence risk gene for intellectual disabilities, autism spectrum disorders and CTNNB1 syndrome. This syndrome is a monogenetic neurodevelopmental disorder characterized by intellectual disabilities, developmental delays, motor disabilities (truncal muscle hypotonia, distal hypertonia, spastic gait), and reduced or no language, as well as autism in a subset of individuals. It is caused by *de novo* heterozygous loss-of-function pathogenic variants in *CTNNB1*, the gene that encodes the protein β -catenin (β -cat). β -cat is essential for proper brain and muscle function, via its dual roles in cadherin-based synaptic adhesion complexes and as a transcription co-activator with LEF/TCF proteins in the canonical Wnt signal transduction pathway. Insufficient levels of this critical protein are the core molecular pathology in CTNNB1 syndrome. The cognitive and motor deficits significantly impact quality of life for affected individuals and their families. Treatment options are currently lacking. We have a unique opportunity to correct this and benefit individuals with CTNNB1 syndrome by capitalizing on our recent identification of a small molecule which significantly normalizes β -cat levels and phenotypes in our preclinical mouse and human cell models, including CTNNB1 patient derived cells.

In addition to *CTNNB1*, several other human gene mutations linked to intellectual disabilities and autism also cause reduced β -cat levels and/or functions. These disorders further highlight the importance of identifying corrective treatments for CTNNB1/ β -cat dysregulation and may benefit from the therapeutic strategies that we are developing for CTNNB1 syndrome.

Objectives: To identify efficacious and safe therapeutic compounds as lead drug candidates to advance the design of clinical trials for this unmet medical need. The goal is to raise the insufficient β -cat protein levels to closely resemble, and not exceed, the normal baseline range of controls, and thereby correct the phenotypes.

Methods: We are testing the therapeutic efficacy of high selectivity small molecule inhibitors of glycogen synthase kinase (GSK)3, the constitutively active endogenous negative regulator of β -cat levels, in preclinical *in vivo* mouse and *in vitro* human cell models, including CTNNB1 syndrome patient derived cells. We assess the phenotypes using quantitative molecular, biochemical, electrophysiological and behavioral analyses.

Results: We have identified an efficacious therapeutic in our preclinical *in vivo* mouse model of *Ctnnb1* germline heterozygosity that displays key features resembling human CTNNB1 syndrome. We show that a small molecule high-selectivity inhibitor of the endogenous negative regulator GSK3 significantly normalizes β -cat levels and molecular, functional, cognitive and motor phenotypes in *Ctnnb1* heterozygote mice, relative to wildtype littermates. The beneficial outcomes were achieved with treatment initiated in symptomatic late adolescent mice. Pilot studies suggest the therapeutic potential extends to human cells by showing significantly improved β -cat levels in human glutamatergic neurons heterozygous for *CTNNB1* and in multiple different CTNNB1 patient derived iPSCs carrying diverse mutations that span the gene. We are now conducting critical tests for therapeutic efficacy and safety in cortical excitatory neurons derived from the CTNNB1 patient iPSCs.

Conclusions: Our data provide new insights into brain molecular and functional changes, and the first evidence for an efficacious treatment with therapeutic potential for individuals with CTNNB1 syndrome.

225 - Beyond Categorical Classifications of Autism: Utilizing Dimensional Approaches to Advance Science and Clinical Practice

May 3rd, 2025, 2:00 PM - 4:00 PM - 6B

Panel Chair: Emily Spackman, *Psychiatry and Behavioral Sciences, Department of Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA*

Discussant: Robert Krueger, *University of Minnesota, University of Minnesota, MN*

Pronounced within-diagnostic heterogeneity and high rates of co-occurrence among neurodevelopmental and neuropsychiatric conditions highlight the limitations of current diagnostic systems. These limitations are particularly prominent with regard to the autism diagnostic criteria. The structure of diagnostic criteria dictates assessment and diagnosis, measure development, support provision, and research yield. Therefore, utilizing dimensional approaches to develop empirically-informed diagnostic criteria is crucial for advancing autism research and clinical practice. This panel aims to (i) compare the DSM-5 structure of restricted and repetitive behaviors to empirically-derived alternatives, evaluating the placement of sensory features within diagnostic criteria, (ii) validate a novel and comprehensive measure of the social motivation domains outlined in the National Institute of Health's Research Domain Criteria (RDoC) to advance the characterization of autism features and facilitate transdiagnostic research, and, finally, to characterize structural relationships between autism features and broader neurodevelopmental and neuropsychiatric symptoms utilizing (iii) state-of-the-art psychometric approaches and (iv) the Hierarchical Taxonomy of Psychopathology (HiTOP), as a novel, evidence-based nosology. By integrating reviews of current diagnostic criteria alongside applications of dimensional approaches (i.e., RDoC and HiTOP) in research and clinical practice, the proposed panel holds promise for facilitating a timely discussion around the future of autism assessment and diagnosis.

Introduction

E. Spackman, *Department of Psychiatry and Behavioral Sciences, Stanford University*

225.001 Are Sensory Features a Subdomain of Restricted and Repetitive Behaviors? Evaluating Empirical Support for the DSM-5 Conceptualisation of Repetitive Behaviors

E. Spackman¹, **L. Chetcuti**², **E. K. Baker**³, **T. W. Frazier**⁴, **A. Y. Hardan**³ and **M. Uljarevic**³, (1)*Psychiatry and Behavioral Sciences, Department of Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA*, (2)*Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA*, (3)*Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA*, (4)*Psychology, John Carroll University, Cleveland, OH*

Background: Following calls to formally recognise sensory differences in the autism diagnostic criteria, the DSM-5 introduced sensory features as a fourth subdomain of restricted and repetitive behaviours (RRBs), alongside (1) stereotyped movement and speech, (2) insistence on sameness, and (3) intense interests. However, this categorisation was developed based on expert consensus, rather being empirically derived and subsequent psychometric investigations have shown only mixed support. More specifically, sensory features encompass a wide range of different behaviours, many of which are neither restricted nor repetitive in nature, raising concerns over their conceptualisation under RRBs and as a unidimensional domain. Similarly, repetitive motor behaviours (RMB) and repetitive language (RL) have also emerged as distinct factors in several factor analytic investigations of RRB measures and likely have distinct trajectories and correlates, despite comprising a unidimensional subdomain in the DSM-5. Finally, intense interests in common topics (restricted interests [RI]) and in topics generally not salient outside of autism (unusual interests [UI]) have also been suggested to represent distinct domains, showing opposite patterns of association with age, IQ, and social motivation. The structure outlined in diagnostic systems has far reaching implications for assessment and diagnosis, measure development, support provision, and/or the yield of research across the autism field. Therefore, drawing on structural evidence to establish robust criteria is essential.

Objectives: To compare the DSM-5 model of RRBs against empirically derived alternatives, evaluating whether sensory features are better conceptualised as a part of RRBs or their own unique domain.

Methods: Cross-measure confirmatory application of exploratory structural equation modelling was used to compare empirical support for different proposed latent RRB structures in a large sample of 1368 autistic children and adolescents ($M_{age}=10.78$, $SD_{age}=4.14$; 301 females; 24% intellectual disability). Four correlated factor models and eight bifactor models were compared to evaluate the lower- and higher-order latent structure of RRBs. Sensory features were assessed using the Sensory Experiences Questionnaire (SEQ-3) and RRBs using the Dimensional Assessment of Restricted/Repetitive Behaviours (DARB). Findings were then replicated using the Repetitive Behaviour Scale – Revised (RBS-R).

Results: The four-factor DSM-5 model consistently demonstrated poorest fit across models (CFI= 0.881 to 0.895; RMSEA= .028 to .026). The model comprising 10 distinct subdomains (RMB, RL, IS, RI, UI, obsessive-compulsive behaviour, self-injurious behaviour, sensory hypersensitivity, sensory hyposensitivity and sensory seeking) showed the best fit amongst correlated models (CFI=0.940; RMSEA= .021).

Comparison of higher-order latent structures found that models with distinct General RRB and General Sensory factors showed better fit (CFI= 0.940 to 0.950; RMSEA= .021 to .019) than models consisting of a combined General RRB/sensory factor (CFI= .895 to .945; RMSEA= .026 to .020). A similar pattern of findings was observed in RBS-R replications.

Conclusions: Findings indicate a need to revise the RRB structure outlined in the DSM-5. More specifically, sensory features should be recognised as a multidimensional construct, consisting of at least three subdomains and may be better characterized as a distinct domain to RRBs.

Additionally, RMB and RL, as well as RI and UI, should be recognized as distinct subdomains.

225.002 Advancing a Biologically-Grounded Taxonomy of Social Motivation

L. Chetcuti^{1,2}, **A. Y. Hardan**¹, **J. M. Phillips**³, **T. W. Frazier**⁴ and **M. Uljarevic**³, (1)*Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA*, (2)*Telethon Kids Institute, University of Western Australia, Perth, Western Australia, Australia*, (3)*Psychology, John Carroll University, Cleveland, OH*

Background: Differences in social motivation are a prominent feature of autism and may contribute to its etiology. However, the DSM-5's operationalization of these differences, outlined in Criterion A3 ('deficits in developing, maintaining, and understanding relationships') and Criterion A1 ('deficits in social-emotional reciprocity'), lacks precision, factorial evidence, and alignment with underlying biological mechanisms. The National Institute of Health's Research Domain Criteria (RDoC) proposes a nosological shift toward describing clinical phenomenology through scientifically validated biobehavioral dimensions of human functioning. In autism, this shift requires reconceptualizing diagnostic criteria to address more granular processes underlying social motivation. A reward processing framework emphasizes the roles of orienting, wanting, pursuing, liking, and learning in responsiveness to both social and nonsocial stimuli. Adopting this framework could aid in identifying converging and diverging functional profiles within and across diagnostic populations, informing personalized interventions. However, a major challenge remains the lack of measurement tools capable of capturing individual differences in social motivation at the level of these reward-based processes.

Objectives: To conduct an initial psychometric validation of the Stanford Social Dimensions Scale-2 (SSDS-2), an informant-report measure aimed at overcoming the limitations of existing instruments by comprehensively characterizing individual variability in reward-driven processes that are essential for understanding social motivation differences.

Methods: SSDS-2 items were developed to capture each of the five identified social motivation processes and were refined through an iterative process guided by the NIH Patient-Reported Outcome Measurement Information System framework, which included a systematic review of existing literature, factor analyses of existing instruments, and stakeholder engagement. Parents of 943 children diagnosed with autism, aged 5-to-17 years ($M [SD]=11.23 [3.56]$; 76% male) recruited from the SPARK (Simons Foundation Powering Autism Research for Knowledge) research match, completed the SSDS-2. Confirmatory application of exploratory structural equation modeling (ESEM) tested the a priori five-factor structure of the SSDS-2. Model fit was evaluated using the comparative fit index (CFI), Tucker–Lewis index (TLI), root mean square error of approximation (RMSEA), and its 95% confidence interval. The stability of the final factor solution was examined across subsamples based on sex, age, and cognitive level. Convergent and divergent validity were established against the Social Responsiveness Scale-2nd Edition (SRS-2), Child Social Preference Scale (CSPS), and Strengths and Difficulties Questionnaire (SDQ).

Results: Analyses indicated strong model fit for the a priori-specified model, comprising separate orienting, wanting, pursuing, liking, and learning factors ($CFI=0.93$, $TLI=0.92$, $RMSEA=0.06$ [90% CI: 0.06, 0.06], $SRMR=0.04$). SSDS-2 items demonstrated robust (>0.40) and statistically significant loadings on their hypothesized factors, with minimal cross-loadings on non-hypothesized factors. All factors showed significant correlations with each other ($p<.05$), ranging from weak (learning-wanting, $r=.04$) to strong (wanting-pursuing, $r=.64$). The factor solution demonstrated stability across sex, age, and cognitive level subgroups. Significant positive correlations were observed between SSDS-2 subscales and corresponding subscales of the SRS-2, CSPS, and SDQ.

Conclusions: These results underscore a multidimensional conceptualization of social motivation and highlight the utility of the SSDS-2 in providing more nuanced and biologically valid clinical descriptors and diagnostic criteria for autism, in accordance with RDoC principles.

225.003 Towards Identifying an Accurate Model of Internalizing Symptoms in Autism: The Importance of Incorporating Autistic Traits within a Transdiagnostic Model

T. Rosen^{1,2}, C. Rodriguez-seijas³, K. D. Gadow⁴ and M. D. Lerner⁵, (1)St. Christopher's Hospital for Children, Philadelphia, PA, (2)Department of Psychiatry, Drexel University College of Medicine, Philadelphia, PA, (3)Department of Psychology, University of Michigan, Ann Arbor, MI, (4)Department of Psychiatry, Stony Brook University, Stony Brook, NY, (5)AJ Drexel Autism Institute, Drexel University, Philadelphia, PA

Background: Autistic youth are at increased risk for experiencing co-occurring internalizing symptoms (e.g., van Steensel et al., 2011). Some presentations are consistent with standard diagnostic (e.g., *DSM*) criteria, yet others suggest distinct, altered symptom presentation resulting from overlap with – or influence of – autism traits (e.g., Kerns et al., 2014). Additionally, there is emerging evidence that a transdiagnostic internalizing factor explains the co-occurrence of anxiety and depression in autism (Rodriguez-Seijas et al., 2019). The influence of autism traits on previous factor models of internalizing symptoms remains to be explored.

Objectives: The current examination sought to identify an improved model of internalizing symptoms by examining a broader, transdiagnostic model of internalizing symptoms that allowed internalizing symptoms to load with autistic traits.

Methods: Participants were ages 6-18, diagnosed with autism in an outpatient clinic ($N=280$; $M_{age}=10.7$, $SD_{age}=3.4$) or referred to a psychiatry outpatient clinic with no autism diagnosis ($N=1195$; $M_{age}=12.1$, $SD_{age}=3.4$). Internalizing symptoms and autism traits were measured using the parent CASI-4R (Gadow & Sprafkin, 2008), a *DSM*-referenced rating scale. Following confirmatory factor analysis (CFA: Table 1), an exploratory factor analysis (EFA) of anxiety and depression symptoms, and autism traits, was conducted. Fit indices from a CFA of the CASI-4R (e.g., *DSM*) structure of these symptoms and traits were then compared against fit indices from the EFA-derived model.

Results: Fit indices from the baseline CFA showed poorer fit of *DSM* internalizing symptoms in the autistic compared to non-autistic sample (see Table 1). Several revisions were made to improve the baseline model, though fit indices were still insufficient. A 3-factor EFA model of internalizing and autism traits was parameterized with factors representing (1) broad internalizing symptoms (anxiety and depression), (2) social anxiety symptoms, and (3) autism traits (Table 2). The EFA model demonstrated better fit compared to the *DSM* model (Table 1), though fit indices were still inadequate.

Conclusions: Results from the baseline CFAs suggest that the *DSM* structure of internalizing symptoms may not adequately capture these symptoms in autism. It may be that allowing depression and anxiety symptoms to covary in the EFA helped improve model fit, consistent with previous applications of a transdiagnostic approach in other populations. Results also highlight the importance of accounting for autism traits when modeling co-occurring internalizing symptoms, given that both internalizing factors (e.g., factors 1 and 2) included autism traits. This finding is consistent with theories that internalizing symptoms are influenced and perhaps even altered by autism traits (e.g., Wood & Gadow, 2010). In addition, findings are consistent with previously-validated autism-influenced presentations of anxiety, and are the first to identify models consistent with autism-influenced depression and autism-influenced internalizing symptoms more broadly. Although fit indices were improved for the EFA, it nonetheless exhibited inadequate fit indices. Overall, findings highlight the importance of developing more comprehensive, transdiagnostic internalizing models of distinct symptom presentation in autism. Towards this end, it will be important to consider additional relevant constructs, such as sensory differences, emotion regulation challenges, and externalizing symptoms while incorporating autism traits into these models.

225.004 Where Do Autistic Traits Fit in Transdiagnostic Psychiatric Frameworks? New Insights from Transdiagnostic Research
G. Michelin¹, **W. Liao¹**, **C. Caserini¹**, **T. Eley²**, **M. Malanchini¹**, **K. Rimfeld³** and **S. Wilson⁴**, (1)School of Biological & Behavioural Sciences, Queen Mary University of London, Bethnal Green, London, United Kingdom, (2)Department of Behavioural Genetics, Kings College London, London, United Kingdom, (3)Royal Holloway University of London, Egham, Surrey, United Kingdom, (4)Institute of Child Development & Department of Psychology, University of Minnesota, Minneapolis, MN

Background: Autism and other neurodevelopmental conditions, including attention-deficit/hyperactivity disorder (ADHD) and learning and intellectual disabilities, are grouped together in the DSM-5 and ICD-11 to reflect their common co-occurrence and shared characteristics. Yet, reliance on categorical diagnoses poses significant challenges in both research and clinical settings (e.g., arbitrary diagnostic boundaries, high heterogeneity). Taking a transdiagnostic dimensional approach provides a useful alternative for addressing these limitations and characterizing the common co-occurrence and developmental continuity between autism and other neurodevelopmental and mental health conditions. Yet, autistic and other neurodevelopmental traits have not been adequately considered in current transdiagnostic frameworks (e.g., Hierarchical taxonomy of Psychopathology, HiTOP), even though doing so would have fundamental research and clinical implications.

Objectives: This presentation aims to (1) review recent evidence indicating that autistic and other neurodevelopmental traits belong to a novel transdiagnostic “neurodevelopmental spectrum”, reflecting their dimensional nature and high co-occurrence; (2) present new data on the structure of the neurodevelopmental spectrum across development and its association with key predictors and outcomes in a UK nationally-representative longitudinal study.

Methods: (1) We developed a conceptual framework based on comprehensive review of studies supporting the structure, validity, and predictive utility of the neurodevelopmental spectrum. (2) Parents of children from the Twins Early Development Study (TEDS) reported on a broad range of neurodevelopmental traits and mental health problems at age 7 (N=15,668; 51% female), 12 (N=12,465, 52% female), and 16 (N=10,261; 55% female). Hierarchical exploratory factor analysis of items collected at each wave delineated a neurodevelopmental factor alongside other transdiagnostic factors (e.g., internalizing, externalizing) across development. Linear mixed models tested the association of the neurodevelopmental factor at ages 7-16 with early environmental/developmental predictors and with current and later cognitive, educational, and mental health outcomes.

Results: (1) A large body of work, spanning studies on covariation and phenotypic structure, shared biological, cognitive and neural profiles, similar developmental course, and predictive and clinical utility, support the inclusion of autistic and other neurodevelopmental traits into a neurodevelopmental spectrum. (2) In TEDS, a neurodevelopmental factor capturing autistic traits, inattention, hyperactivity, and learning difficulties emerged across development, alongside externalizing (impulsivity, oppositionality, and callousness) and internalizing (anxiety and depression) factors. Higher neurodevelopmental factor scores at ages 7-16 were associated with low birth weight ($\beta=-.05/-0.10$, $p<.001$) and age-3 language and cognitive difficulties ($\beta=-.11/-0.29$, $p<.001$). Furthermore, higher neurodevelopmental factor scores predicted worse cognitive, educational, and mental health outcomes both concurrently and longitudinally to a greater extent than DSM autism diagnoses.

Conclusions: Our literature review and new data show that assessing autistic traits within a transdiagnostic neurodevelopmental spectrum can further our understanding of its developmental pathways and is useful for predicting clinically relevant outcomes across development. Based on this body of work, we argue that incorporating a new neurodevelopmental spectrum into transdiagnostic frameworks has considerable potential for transforming our understanding, classification, assessment, and clinical practices around autism and other neurodevelopmental and mental health conditions.

Panel Session

226 - Trials of Caregiver-Focused Interventions in Diverse Settings: Results and Key Learnings

May 3rd, 2025, 2:00 PM - 4:00 PM - 6C

Panel Chair: Jonathan Green, University of Manchester, Manchester, United Kingdom

Discussant: Alexia Rattazzi, PANAACEA, Buenos Aires, ARGENTINA

Proactive stepped-care provision for autistic children entails supporting caregivers at the earliest opportunity to understand their child, parent them in an attuned way, support their development, and feel resilient and adaptable in the face of parenting complexities and external stressors. Caregiver-focussed approaches have potential not only to improve caregiver wellbeing and empowerment, but to ensure a responsive and nurturing goodness-of-fit around the child. Such interventions must respond to the needs of caregivers within the context in which they will be implemented, be culturally sensitive, and scalable. Moreover, they must be supported by rigorous evidence of acceptability, feasibility of implementation, and effectiveness. This panel brings together results and key learnings from rigorously-designed and -conducted studies of innovative caregiver-focussed approaches evaluated in diverse international settings. This includes two well-powered clinical effectiveness trials – the COMPASS trial of non-specialist-delivered social communication intervention in India and the REACH-ASD trial of a post-diagnostic psycho-educational and psycho-therapeutic programme in the UK, along with a feasibility trial of an intervention promoting sensitive responsiveness in caregivers of children with higher likelihood of autism in India (LiL'STEPS), and an evaluation of a multiphase platform to increase access to the WHO Caregiver Skills Training programme in community settings in Canada.

Introduction

A. Rattazzi, PANAACEA, Buenos Aires, ARGENTINA

226.001 Preliminary Outcomes from a Parallel and Single-Blind Feasibility Randomized Controlled Trial in India of a Novel Caregiver Mediated Intervention, LiL' STEPS, for Infants at Elevated Likelihood for Autism

S. S. Meera¹, **P. P. Vasuki²**, **M. Srikanth³**, **D. Swaminathan⁴**, **R. Raju⁵**, **R. Johnson⁶**, **S. Volme⁷**, **J. V. S. Kommu⁸**, **L. R. Watson⁹** and **D. B. Nair¹⁰**, (1)National Institute of Mental Health and Neurosciences (NIMHANS), Bangalore, Karnataka, India, (2)National Institute of Mental Health and Neurosciences (NIMHANS), Bangalore, India, (3)National Institute of Mental Health and Neurosciences (NIMHANS), Bangalore, India, (4)National Institute of Mental Health and Neuro Sciences (NIMHANS), Bangalore, Karnataka, India, (5)National Institute of Mental Health and Neuro Sciences (NIMHANS), Bangalore, India, (6)Department of Health Sciences, University of North Carolina at Chapel Hill, Chapel Hill, NC, (7)CommuniVerse India, Mumbai, India

Background: About 40-50% of infant siblings of autistic children are at elevated likelihood for autism or other neurodevelopmental delays (EL-A).¹ Preliminary evidence suggests very early support be given to these infants through caregiver-mediated approaches.² One such program for EL-A infants in India is LiL' STEPS— Supporting Early Social Communication and Language by Promoting Caregiver Sensitive Responsiveness (STEPS), developed by the Language Development & Intervention Lab (LiL'). While the program's feasibility and acceptability have been established,³ its preliminary efficacy in improving caregiver and infant outcomes has yet to be evaluated. This evaluation is critical before progressing to a resource-intensive definitive randomized controlled trial (RCT).

Objectives: We aimed to evaluate the preliminary utility of the LiL' STEPS program for EL-A infants by examining changes from baseline to post-intervention in caregiver sensitive responsiveness (primary outcome), and a range of caregiver and infant measures, compared to care-as-usual (CAU).

Methods:

Families of 36 EL-A infants were randomized (2:1 ratio) into LiL' STEPS (n=24, age:11.62±1.99 months, 8F) and CAU (n=12, age:11.73±2.32, 7F). Fig-1 contains the CONSORT diagram. Participants were primary caregivers of 9-15-month infants with an older autistic sibling. Caregivers spoke either Kannada, Hindi or English and had access to basic technology including smartphones and internet connectivity. LiL' STEPS, a manualized caregiver-mediated early support program, was delivered via Zoom using video feedback and live demonstrations for 12 weeks comprising 14 sessions. It is based on NDBI principles, focusing on caregiver sensitive responsiveness, infant social-communication and language. Outcomes were assessed at baseline (before group allocation- T1) and post intervention (T2). The primary outcome, caregiver sensitive responsiveness, was a blinded assessor-rated video coded measure on the MACI. Secondary outcomes included a range of caregiver reported and video coded measures assessing infant social-communication and language (e.g., MCDI, CSBS). See Table-1. Additionally, parent stress was evaluated using the parent stress scale. Trial registration: CTRI-REF/2022/06/055249.

ANCOVAs, adjusting for infant age at T2, and corresponding pre-randomization baseline variables was used to measure pre-to-post intervention outcomes. For MCDI, Quade's ANCOVA adjusting for age and baseline values was used as the data did not meet the assumptions.

Results: Groups were matched on key demographic variables (age: $t=-0.14, p=0.884$; sex: $\chi^2=2.06, p=0.151$; parental education $t=0.26, p=0.941$). Post-intervention, there were significant differences between groups on sensitive responsiveness ($F=13.03, p=.001$, effect size $\eta^2=.31$, 95%CI=0.06-0.52), psychological stimulation ($p=.047$), dyadic mutuality ($p=.014$), and infant attentiveness ($p=.016$) on the MACI. See Table-1 for complete analysis. These findings suggest preliminary utility of LiL' STEPS in EL-A consistent with previous studies^{4,5}

Conclusions: LiL' STEPS is the first manualized program for EL-A infants in India, and this feasibility RCT has clearly demonstrated significant positive impacts on both caregiver and dyadic outcomes with some difference in infant outcomes, highlighting a need for video coded measures. These promising results, along with findings from a recent in-depth study of the program's feasibility and acceptability through parental interviews,³ underscore the potential of LiL' STEPS to address critical developmental needs. A future definitive RCT is strongly recommended to further validate these outcomes and expand the program's reach.

226.002 Clinical Effectiveness of a Post-Diagnostic Psycho-Educational and Psycho-Therapeutic Programme for Caregivers of Children Newly Diagnosed As Autistic: A United Kingdom Parallel, Single-Blind Randomised Controlled Trial (REACH-ASD Trial)

K. Leadbitter¹, S. Langhorne², R. Smallman³, P. Chu⁴, C. Ellis⁵, L. Harrison⁶, C. Butter⁷, C. Goldie⁸, K. James⁹, L. Hackett¹⁰, A. Dunkerley¹¹, P. Bee¹², G. Shields¹⁰, R. Emsley¹¹, J. Green¹ and T. Reach-ASD Team¹², (1)University of Manchester, Manchester, UNITED KINGDOM, (2)Division of Psychology and Mental Health, University of Manchester, Manchester, Manchester, United Kingdom, (3)University of Manchester, Manchester, United Kingdom, (4)King's College London, London, United Kingdom, (5)University of Manchester, MANCHESTER, Lancs, United Kingdom, (6)King's College London, London, London, United Kingdom, (7)Manchester University NHS Foundation Trust, Manchester, Manchester, United Kingdom, (8)Manchester University NHS Foundation Trust, Manchester, United Kingdom, United Kingdom, (9)University of Manchester, Manchester, Manchester, United Kingdom, (10)Division of Population Health, Health Services Research, and Primary Care, University of Manchester, Manchester, United Kingdom, (11)Department of Biostatistics & Health Informatics, Kings College, London, United Kingdom, (12)Manchester University NHS Foundation Trust, Manchester, United Kingdom

Background:

Caregivers can experience significant challenges following their child's autism diagnosis and often seek informational, relational and emotional support (Legg & Tickle, 2019). They can experience poor mental health within the post-diagnostic period and on an ongoing basis. UK best practice guidelines recommend post-diagnostic family support. However, provision is patchy, largely unevidenced, and a source of dissatisfaction for families and professionals. Empower-Autism is a new group-based, manualised, post-diagnostic programme combining autism psycho-education and psycho-therapeutic components based on Acceptance and Commitment Therapy to support the mental health, wellbeing, and adjustment of caregivers of newly diagnosed autistic children.

Objectives:

To evaluate the clinical effectiveness of the Empower-Autism programme over usual care on caregiver mental health (primary outcome) and a range of other caregiver, family and child secondary outcomes

Methods:

We conducted a pre-registered (ISRCTN 45412843) prospective multi-centre two-parallel-group randomised controlled superiority trial (REACH-ASD Trial) of the Empower-Autism programme plus treatment-as-usual versus the usual local post-diagnostic offer plus treatment-as-usual. Empower-Autism consisted of five 3-hour group-based sessions delivered via videoconferencing. Treatment-as-usual was any locally-available group-based post-diagnostic psycho-education offer. Participants were recruited from 11 North-West England autism diagnostic/intervention centres and were primary caregivers of children aged 2-15 years given an autism diagnosis within last 12 months. Exclusion criteria: insufficient English, significant learning disability, hearing/visual impairment or psychiatric condition in caregiver; significant current family safeguarding concerns. Individual randomisation with 2:1 ratio (intervention/TAU) and stratification by centre. Primary outcome was caregiver mental health (General Health Questionnaire-30) at 52-weeks. Secondary caregiver-focussed outcomes included autism knowledge, wellbeing, adjustment, parenting stress and self-efficacy, and psychological flexibility at 12-, 26- and 52-week follow-up. Secondary family and child outcomes including parent-child relationships, family wellbeing and child functioning and emotional and behavioural difficulties at 52-week endpoint. Investigators were masked to group assignment; participants were not. Adverse events were monitored. Primary analysis followed intention-to-treat principles using linear mixed models with random intercepts for group membership and repeated measures.

Results:

The CONSORT diagram (Figure 1) presents the numbers referred, eligible, consented, randomised, and retained. 379 participants were recruited between September 2020 and April 2022 (255 intervention/124 treatment-as-usual; 88% female; 83% White). In the available case analysis (n=319), participants randomised to Empower-Autism had improved mental health at 52 weeks compared to TAU (mean difference -4.95 [95% CI: -8.21, -1.68], p=0.003). We also observed significant improvements in secondary outcomes of caregiver wellbeing (mean difference 2.66 [95% CI: 0.7, 4.62], p=0.008), adjustment (0.1 [95% CI: 0.02, 0.17], p=0.016), autism knowledge (0.74 [95% CI: 0.01, 1.46], p=0.046) and family wellbeing (-4.97 [95% CI: -8.75, -1.19], p=0.01). Other secondary outcomes showed no clear difference between arms. Figure 2 shows a forest plot of effect estimates on available data at 52-week endpoint. 181 adverse events (116 intervention/65 TAU) and 15 serious adverse events (9/6) were reported; none related to the study intervention.

Conclusions:

This is the first fully-powered randomised trial to show a statistically- and clinically-significant effect on mental health and wellbeing in caregivers of autistic children. We recommend programmes like this to clinical teams and policymakers.

226.003 A Randomised Controlled Trial of the PASS Plus Intervention for Young Children with Autism Spectrum Disorder in New Delhi, India: Findings from the COMPASS Trial.

G. Divan¹, R. Roy², K. Leadbitter³, G. Shields⁴, C. A. Taylor⁵, M. Juneja⁶, C. Aldred⁷, S. Gulati⁸, V. Vajaratkar⁹, R. Emsley¹⁰, V. Patel¹¹ and J. Green³, (1)Child Development Group, Sangath India, New Delhi, India, (2)COMPASS, Sangath India, New Delhi, Delhi, India, (3)University of Manchester, Manchester, UNITED KINGDOM, (4)Division of Population Health, Health Services Research, and Primary Care, University of Manchester, Manchester, United Kingdom, (5)University of Manchester, Manchester, United Kingdom, (6)Maulana Azad Medical College, New Delhi, India, (7)University of Manchester, Manchester, United Kingdom of Great Britain and Northern Ireland, (8)Centre of Excellence and Advanced Research for Childhood Neurodevelopmental Disorders, Child Neurology Division, Department of Pediatrics, Ansari Nagar, New Delhi, India, (9)Sangath, New Delhi, India, (10)Department of Biostatistics & Health Informatics, Kings College, London, United Kingdom, (11)Harvard Medical School, Boston, MA

Background: Autism Spectrum Disorders (ASD) affects at least 5 million children in South Asia. The vast majority of these children are without access to evidence-based care which is restricted to urban child development centres and delivered by specialists. To address barriers to care, we systematically adapted and expanded the UK Pre-school Autism Communication Therapy (PACT) for non-specialist provider delivery in community settings and piloted the resulting 'Parent-mediated Autism Social Communication Intervention for non-Specialists Plus' (PASS Plus). This presentation will share the results of a definitive randomized controlled evaluation of PASS Plus (the COMPASS trial) in New Delhi, India. **Objectives:** To evaluate the effectiveness of a non-specialist community-based delivery of a parent-mediated intervention for ASD in an urban setting in India.

Methods: The Communication-centred Parent-mediated treatment for Autism Spectrum Disorder in South Asia (COMPASS) trial was a pre-registered two centre, two arm single (rater) blinded random allocation parallel group study of the PASS Plus intervention in addition to treatment as usual (TAU) compared to TAU alone embedded in the India health system (ISRCTN ID: 21454676). Recruitment was from two tertiary care government hospitals in New Delhi, India. 7 Accredited Social Health Activists, health system frontline workers were trained through a task-sharing model to deliver the PASS Plus intervention at home. They were supported by 10 project based non-specialists with similar characteristics to ensure trial timelines were met.

Results: 261 parent-child dyads were recruited into the trial with 130 randomised into the intervention arm. 18% of children were female and 48% minimally verbal. 98 sessions were evaluated for treatment fidelity of which 90% passed. Retention rates for the primary endpoint evaluated at 9 months was 83% and 84% for the follow-up at 15 months. The primary outcome is autism symptom severity measured through the Brief Observation of Social Communication Change (BOSCC). Secondary outcomes include parent-child communication and dyadic change, child adaptation, quality of life and parental wellbeing. Primary analysis will follow intention-to-treat principles and will be presented to the Trial Steering Committee in December 2024. Figure 1 illustrates the CONSORT for COMPASS

Conclusions:

COMPASS is the largest trial to date for ASD in a low-and-middle income country setting, with several innovations: the systematic adaptation of an evidence-based intervention developed in a high income setting for delivery by frontline health workers with no prior exposure to autism; an adaptation process which retained all the key mechanistic underpinnings of the original intervention; and the delivery of the intervention in the community, supporting families to overcome barriers of access. If found to be clinically effective, even in comparison to the highest quality of care available for children with ASD in India, this trial will offer evidence on the scaling up of a low-cost intervention for ASD.

226.004 CST Canada: Evaluation of a Multiphase Platform to Increase Access to Early Intervention in Community Settings

M. Elsabbagh¹, A. Yusuf¹, M. Ghanadzade², **M. Habra³**, N. J. Wright⁴, R. Bedford⁵, K. Hudry⁶, E. O'Connor⁷, J. L. Scora⁸, S. Y. Shire⁹, P. Dixon¹⁰ and T. W. CST Team¹⁰, (1)Neurology and Neurosurgery, McGill University, Montreal, QC, Canada, (2)McGill University, Montreal, QC, Canada, (3)RI-MUHC, Montreal, QC, Canada, (4)Department of Psychology, Manchester Metropolitan University, Manchester, United Kingdom, (5)University of Bath, Bath, United Kingdom, (6)Department of Psychology, Counselling and Therapy, La Trobe University, Melbourne, VIC, AUSTRALIA, (7)La Trobe University, Melbourne, Australia, (8)Special Education and Clinical Sciences, University of Oregon, Eugene, OR, (9)Autism Speaks, Washington D.C., MD, (10)Department of Mental Health and Substance Abuse, World Health Organization, Geneva, Switzerland

Background: WHO Caregiver Skills Training is a manualized, caregiver-mediated, evidence-informed intervention that integrates active ingredients of early intervention with a validated and scalable delivery mechanism. Its delivery through the Cascade Training Model ensures scalability across diverse settings, including resource-limited settings. In 2017, our research team introduced CST to Canada by launching the CST-Canada platform, a multiphase initiative aimed to overcome long-standing challenges in equitable access to early intervention. This abstract presents the outcomes of this platform, which supports the phased adaptation, implementation, and evaluation of CST in Canadian communities, positioning it for national scale-up.

Objectives: We report findings across three phases of the CST-Canada platform: (1) translation and adaptation of CST to the Canadian context through co-design with key stakeholders, (2) establishment of a national network of Master Trainers (MT) and capacity-building through professional training, and (3) implementation of a pragmatic feasibility RCT to evaluate CST delivery.

Methods: Each phase leveraged the CST-Canada platform's integrated approach to tailor methods and outcome measures. In the formative Phase 1, focus groups (clinicians, decision makers, and caregivers) informed the contextual, cultural, and linguistic adaptations of CST for Canada. In Phase 2, the platform facilitated capacity-building by training 26 professionals while engaging decision-makers in programme implementation and evaluation. Feasibility metrics focused on programme acceptability, participant retention, and fidelity of delivery. In Phase 3, the platform enabled the national delivery of CST to caregivers of children with suspected or diagnosed autism or other neurodevelopmental conditions, as part of a feasibility RCT (ISRCTN58638141).

Results: **Phase 1:** Key themes from focus groups will highlight the acceptability of CST, with adaptations ensuring relevance within the Canadian context. **Phase 2:** Of the 26 professionals (demographics) participating in the MT training, 17 (65%) completed the program. Moderate reliability in fidelity was achieved for 56% of participants, with additional fidelity data to be reported. Fidelity challenges and their implications for future training iterations will be discussed. **Phase 3:** Five community service providers across five sites formally partnered on the feasibility RCT, facilitating recruitment and CST delivery. Preliminary findings focused on key feasibility indicators, including recruitment of a representative sample, engagement of all sites in the recruitment process, retention of families, and adherence to the intervention. Analysis of primary outcomes from 80 families enrolled in the RCT is ongoing.

Conclusions: Our phased implementation of CST in Canada through the CST-Canada platform demonstrates that engagement, partnership, and the integration of research can drive both scalability and knowledge building. Our findings indicate that the CST-Canada platform holds promise for reaching under-served families and demonstrating promise CST as a scalable community-based program. With ongoing feasibility analyses and plans for a fully powered RCT, the CST-Canada platform has the potential to transform early intervention delivery at a national scale.

Panel Session

227 - Translational Bridges across the Autism Spectrum: Multi-Level Approaches to Understanding Heterogeneity across the Lifespan and Range of Functioning

Panel Chair: Karen Pierce, *Autism Center of Excellence, Department of Neurosciences, University of California San Diego, San Diego, CA*

Discussant: Alison Singer, *Autism Science Foundation, New York, NY*

Autism Spectrum Disorder (ASD) is characterized by significant heterogeneity at both behavioral and biological levels. Despite this variability, autism research and standard treatment often overlook the need to establish subtype profiles a priori to optimize interpretation of findings and intervention outcomes. Precision medicine approaches—interventions tailored to individual subtypes—could represent a critical advancement for individuals with ASD, yet such strategies have not yet materialized. Achieving this goal requires a comprehensive understanding of autism's diversity across multiple biological and behavioral dimensions and developmental periods, along with clarity on how subtypes overlap but are also distinct. This panel features four unique presentations that address this challenge head on by presenting data that connects to dots from computational to animal and in-vitro modeling to direct tests at large-scale starting from early development. The panel integrates work across a wide range of multidisciplinary approaches that includes longitudinal clinical, eye tracking, genomics, neuroimaging, and cortical organoid studies.

Introduction

227.001 Molecular and Neural Biology Underlying Profound, Moderate, and Mild Autism Social Subtypes: Embryonic Beginnings and Toddler Age Outcomes

E. Courchesne¹, J. Zahir², K. Pierce³, V. Taluja⁴ and K. Duan⁵, (1)Neuroscience, Eric Courchesne, San Diego, CA, (2)Autism Center of Excellence, UCSD, San Diego, CA, (3)Autism Center of Excellence, Department of Neurosciences, University of California San Diego, San Diego, CA, (4)Neurosciences Graduate Program, UC San Diego Autism Center of Excellence, La Jolla, CA, (5)UC San Diego, La Jolla, CA

Background:

Social affective and communication symptoms are central to ASD, yet their severity differs across ASD toddlers: Some with mild autism display improving abilities across early-ages and develop good language skills and social relationships, while others with profound autism have persistently low social, cognitive and adaptive skills, may be minimally-verbal, and require lifelong care. How these opposite social subtypes and developmental trajectories differ at a biological level is unknown but is essential to know if the field is to develop effective interventions. The biology of those with severe autism begins in embryonic life, and it is therefore particularly important to study their biology at the earliest ages, leveraging technologies such as brain cortical organoids (BCO methodologies modelling developing cerebral cortex).

Objectives:

- Identify embryonic autism BCO subtypes and their relationships to toddler-age phenotypes
- Discover replicable early-age autism social subtypes by leveraging multimodal data
- Determine whether profound, moderate, and mild autism social-biological subtypes occur at both embryonic and toddlers ages and across cellular, molecular, social anatomic, social functional, social behavioral and social clinical levels
- examine clinical change over time in discovered subtypes

Methods:

We conducted five studies totaling 2,126 ASD, typical and delayed 1 to 3-year-olds. Study 1 analyzed molecular, cellular and growth of embryonic BCOs from 10 ASD and 6 controls and replicated findings. N=4,910 BCOs were measured in total, averaging 196 BCOs/child. BCO relationships to toddler phenotypes utilized N=266 to N=1,902 ASD and typical normative data values. To gain further foundational biological knowledge of multi-level autism subtypes, four data-driven multimodality subtyping studies used Similarity Network Fusion that combined **within-child** social and language clinical scores with biological measures: embryonic gene pathway activity (n=363, Study 2), social fMRI activation (n=179, Study 3), social eye tracking (1,259, Study 4), and social MRI anatomy (n=309, Study 5, not in Fig 1). Subtyping results were statistically validated using multiple methods such as examination of subtype separation followed by t-tests for statistical significance.

Results:

Results revealed consistently found three autism subtypes: profound, moderate, and mild autism social-biological subtypes. These were present across different cohorts and modalities and span embryonic, gene expression pathways, social cortex anatomy, social brain activation, social eye tracking, and social clinical (**Figure 1**). Compared to mild autism, profound autism displayed enlarged embryonic brain cortical organoids correlated with severe social symptoms (**Figure 2**); disrupted cell proliferation and differentiation; dysregulation in gene pathways controlling proliferation and differentiation; reduced social brain responses; reduced social attention; severely reduced cognitive, language and social IQ, and enlarged social and language cortices.

Conclusions:

Collectively, our results suggest social deficits and profound, moderate, and mild subtypes in autism begin with embryonic dysregulation of cell proliferation, differentiation, and migration. These embryonic dysregulations cause a cascade of progressive multi-level disruptions running through social cortical to social neurofunction to social attention to clinical social, language and cognitive development. Temporal and occipital cortices are dysfunction epicenters. Profound autism is distinctive because its embryonic origins, which are predictive of later social symptom severity, involve the most extreme molecular and cellular dysregulations.

227.002 Eye Tracking Derived Subtypes Reveal Associations with Clinical Phenotype and Early Brain Development Profiles

K. Pierce¹, E. Lunkova², V. Taluja³, V. H. Warnakulasooriya Fernando⁴ and E. Courchesne⁵, (1)Autism Center of Excellence, Department of Neurosciences, University of California San Diego, San Diego, CA, (2)Neurosciences, UC San Diego, La Jolla, CA, (3)Neurosciences Graduate Program, UC San Diego Autism Center of Excellence, La Jolla, CA, (4)California State University San Marcos, San Marcos, CA, (5)Neuroscience, Eric Courchesne, San Diego, CA

Background:

What a toddler chooses to look at and listen to influences early brain development through experience-dependent mechanisms. While difficulties in attending to and reacting to the social world are common in ASD, symptoms vary widely in nature and degree. Attempts at quantifying social heterogeneity at the time of first diagnosis and understanding the impact – both on clinical phenotype and brain development- of children with vastly different social attention profiles is lacking. Eye tracking (ET) technology offers objective, quantitative metrics of social visual and auditory attention. Using our novel battery of five ET tests, we have demonstrated that levels of social attention can accurately predict diagnosis in toddlers with ASD, achieving PPV and specificity between 81-100%. Here, we advance the use of ET technology to characterize heterogeneity in social attention.

Objectives:

(1) Leverage ET as a tool to quantify social attention levels and to examine consistency of responding across different eye tracking tests; (2) examine relationships between levels of social attention and clinical phenotype and brain function

Methods:

Using the *Get SET Early* model as the recruitment strategy, 2,489 toddlers (N=1,191 ASD; 616 TD; 682 non-ASD delays) participated in 1- 5 visual and/or auditory social attention ET tests (**Figure 1**), clinical testing (ADOS, Mullen and Vineland) and some (~400) participated in fMRI and were exposed to child-friendly stories through headphones during natural sleep. 223 toddlers (169 ASD; 54 Non-ASD) completed all 5 ET tests and consistency of social attention levels examined. Areas of Interest (AOIs) were created to calculate the percentage fixation on social AOIs across each ET paradigm. Within the sample of 223 toddlers, 19 toddlers with ASD also participated in fMRI and % signal change in frontal and temporal regions calculated. Associations with clinical phenotype and fMRI activation analyzed.

Results:

Preliminary analyses revealed that within the larger sample of 1,191 ASD toddlers, clinical test scores such as Mullen expressive language subscale were significantly correlated with social attention levels ($r = .27-.42$ depending on the test, all $p < .05$). Among the 169 toddlers with ASD who completed all 5 ET tests, three distinct social attention profiles were revealed: (1) Low social attention - fixation on social images $< 50\%$ across all tests; (2) Best social attention - fixation on social images $> 50\%$ on all tests; and (3) Mixed social attention. ASD toddlers in the Low Social Attention subtype had the most severe social symptoms and lowest language and adaptive scores compared to other subtypes (all $p < .05$). A significant correlation with levels of percent signal change in frontal ($r = .48$), and a trend in temporal cortex ($r = .33$) was also found, underscoring possible social attention-brain development mechanisms. **Figure 2.** Analyses with the larger dataset are ongoing.

Conclusions:

Eye tracking is a technology that objectively quantifies social attention levels. Because it can be implemented quickly and requires minimal training, it has significant potential to transform ASD clinical understanding and care. Combined with social fMRI activation, eye tracking results enhance our understanding of ASD social-biological subtypes, paving the way for precision medicine—interventions tailored to each individual child.

227.003 Electrophysiologically-Defined Excitation-Inhibition Autism Neurosubtypes

M. V. Lombardo¹ and N. Bertelsen², (1)Laboratory for Autism and Neurodevelopmental Disorders, Italian Institute of Technology, Rovereto, Trento, Italy, (2)Center for Neuroscience and Cognitive Systems, Laboratory for Autism and Neurodevelopmental Disorders, Istituto Italiano di Tecnologia, Rovereto, Italy

Background:

Excitation-inhibition (E:I) imbalance has long been considered one of the primary neurobiological theories explaining autism. However, the theory has been bolstered heavily by research on high-penetrance genetic mechanisms which are only found in a small proportion of the autism population and can manifest with potentially different directionality. Thus, a natural extension of this theory would be to test the theory and whether it manifests in a heterogeneous manner in the larger population of idiopathic autistic individuals.

Objectives:

To derive an EEG-based biomarker that is sensitive to underlying E:I imbalance and then apply the biomarker to EEG data on autism for the purpose of neurosubtyping.

Methods:

To derive an EEG-based biomarker sensitive to E:I imbalance, we first employed *in-silico* modeling of a leaky integrate-and-fire point neuron network that has recurrently connected excitatory (E) and inhibitory (I) neuronal populations. We systematically manipulated ground truth synaptic conductances (*g*) in the model over a range E:I ratios and then synthesized realistic EEG and local field potential (LFP) data as output. From the simulated LFP and EEG data we computed a statistical descriptor of fractal long-memory characteristics of the neural time-series, known as the Hurst exponent (*H*). We then evaluated how *H* behaved over the systematic manipulations of synaptic E:I conductance *g*. Directional predictions from these *in-silico* simulations were then tested and validated on *H* computed from LFP data measured from *in-vivo* causal chemogenetic DREADD experiments that manipulated E:I balance in mice. Scaling up to human patients, we also evaluated *H* computed from resting state EEG data measured in male idiopathic autistic patients (*n*=286, 5-21 years) from the Child Mind Institute Healthy Brain Network (CMI-HBN) dataset. Stability-based relative clustering validation was used on EEG *H* data to test whether replicable E:I-derived subtypes could be identified. Subtypes were compared to a typically-developing (TD) age-matched group of males from CMI-HBN (*n*=123). Partial least squares analysis (PLS) was used to test for brain-behavioral associations between *H* and age, FIQ, SRS, and ASSQ phenotypic measures.

Results:

In-silico simulations show that synaptic E:I imbalance scales with firing rate of the network and *H* - as excitability increases, firing rate increases while *H* decreases. *In-vivo* chemogenetic DREADD experiments in mice validate *in-silico* simulation predictions - increasing excitability increases firing rates while *H* decreases. Subtyping autistic males by EEG-derived *H*, we find evidence of 2 E:I neurosubtypes that generalize in new data with 92% accuracy. Around 45% of autistic males are in subtype 1 and characterized by decreased E:I (higher *H*) than the TD group (Cohen's *d* = 0.5). In contrast, the remaining 55% of autistic males are in subtype 2, characterized by increased E:I (lower *H*) than the TD group (Cohen's *d* = 0.7). Autism E:I neurosubtypes also show differential relationships between *H* and behavioral and demographic variables consisting of age, intelligence, and autism symptomatology.

Conclusions:

This work establishes causal evidence for interpreting changes in EEG-derived *H* as an E:I-relevant biomarker and suggests that idiopathic autistic males can be characterized by opposing types of E:I imbalance with differential phenotypic relevance.

227.004 Structural Correlates of Empathy and Empathising-Systemising: Effects of Sex, Autism, and Age

M. A. Radecki^{1,2}, **L. Cecchetti**¹ and **S. Baron-Cohen**², (1)Social and Affective Neuroscience Group, IMT School for Advanced Studies Lucca, Lucca, LU, Italy, (2)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, Cambridgeshire, United Kingdom

Background: It is unknown whether the relationship between brain structure and empathy – understanding others' mental states (cognitive empathy) and responding to them with an appropriate emotion (affective empathy) – can comprehensively describe differences by sex, autism diagnosis, and age. It is further unknown whether additional insights are offered by empathising-systemising (E-S), operationalised as the “D-score” or difference between systemising (understanding and creating rules) and empathy.

Objectives: Development of a comprehensive theoretical framework for individual, sex, autistic, and age differences in empathy, E-S, and their structural correlates.

Methods: We used five datasets: (1) CCC (*N* = 117, non-autistic, 18-48 years); (2) LEAP (*N* = 558, autistic and non-autistic, 6-30 years); (3) AIMS (*N* = 122, autistic and non-autistic, 18-49 years); (4) HCP (*N* = 1,096, non-autistic, 22-37 years); and (5) AOMIC (*N* = 926, non-autistic, 19-26 years). Robust linear regression across pooled datasets modelled differences in empathy (measured by the 40-item Empathy Quotient; EQ), D-score (measured by the EQ and 75-item Systemising Quotient-Revised), and brain structure (i.e. MRI-derived cortical thickness [CT] and surface area [SA] across 360 regions). Structural variables of interest were defined based on meta-analytic empathy clusters (cognitive and affective) and canonical functional networks (Fig. 1A). IQ and site were controlled for in all analyses and total intracranial volume additionally in SA analyses.

Results: Regarding individual differences in non-autistic adults across CCC, LEAP, and AIMS (*N* = 283), SA but not CT within a meta-analytic affective-empathy cluster was related to both empathy (negatively) and the D-score (positively) (Fig. 1D), mirroring the effects of somatomotor and ventral-attention SA. Regarding sex differences, females compared to males had higher empathy and a lower D-score, reflected in a larger absolute difference between empathy and systemising. Secondly, affective-empathy SA differed by sex (*F* < *M*), and this was replicated in the thousands across HCP and AOMIC (*N* = 2,022). Thirdly, affective-empathy SA mediated both behavioural sex differences. Regarding autistic differences in adults across LEAP and AIMS (*N* = 358), autistic individuals compared to non-autistic individuals had lower empathy and a higher D-score, reflected in a smaller absolute difference between empathy and systemising (Fig. 2B). Secondly, while affective-empathy SA did not differ by diagnosis, it interacted with diagnosis in relation to both behavioural variables, where the brain-behaviour relationship in autism was not present or went in the opposite direction (Fig. 2C). Thirdly, both behavioural variables but not affective-empathy SA had a sex-by-diagnosis interaction, where the sex difference in autism was not present or went in the opposite direction (Fig. 2D). Finally, regarding age differences in LEAP (*N* = 558), the D-score but not empathy had an age-by-diagnosis interaction, where the autistic difference became smaller from childhood to adulthood. Secondly, affective-empathy SA interacted with age and diagnosis in relation to both behavioural variables, where the brain-behaviour relationship changed direction with age depending on diagnosis.

Conclusions: Empathy, E-S, and their structural correlates differ by and/or interact with sex, autism diagnosis, and age. These findings should be replicated and built upon in larger and more diverse populations.

228 - Beyond Infant Siblings: Understanding the Emergence of Autism in Infants with Early Medical Risk Factors

May 3rd, 2025, 2:00 PM - 4:00 PM - 611-614

Panel Chair: Nicole McDonald, *UCLA Center for Autism Research and Treatment, Los Angeles, CA*

Discussant: Shafali Jeste, *Children's Hospital Los Angeles, Los Angeles, CA*

Much of what we know about the early emergence of autism comes from prospective studies of the infant siblings of autistic children. To extend our knowledge of how autism unfolds over the first years of life, we must expand our perspective to include infants with other factors known to increase the likelihood of autism and related neurodevelopmental conditions. The current panel focuses on infants with early medical risk factors, including infants who experienced extended NICU hospitalizations, were born preterm, and who had a low birthweight. We present data from prospective studies conducted at three independent sites across the United States that include neurophysiological (EEG) and behavioral methods to understand neurodevelopmental outcomes and developmental trajectories in infants with early medical risk, with a focus on autism outcomes. Presentations will review both parallels with infant siblings (e.g., increased rates of autism and social-communication delays), as well as unique areas of vulnerability (e.g., global developmental delays) in infants with significant medical histories.

Introduction

S. Jeste, *Children's Hospital Los Angeles, Los Angeles, CA*

228.001 Neurodevelopmental Outcomes in High-Risk NICU Graduates at Age 2

N. M. McDonald¹, **C. Ferrario²**, **S. Iyer³**, **A. H. Dickinson³** and **S. Jeste⁴**, (1)*UCLA Center for Autism Research and Treatment, Los Angeles, CA*, (2)*UCLA, Los Angeles, CA*, (3)*University of California, Los Angeles, Los Angeles, CA*, (4)*Children's Hospital Los Angeles, Los Angeles, CA*

Background: Much of our understanding of early development in autism comes from studies of infants with a family history of autism. Extending this knowledge to infants with medical histories that make autism and other neurodevelopmental concerns more likely can broaden our understanding of autism as it first emerges. This study followed children who experienced extended neonatal intensive care unit (NICU) hospitalizations and qualified for the state High-Risk Infant Follow-Up (HRIF) Program (e.g., born <32 weeks, birthweight <1500g, neurological and/or cardiovascular concerns) from ages 6-24 months.

Objectives: To better understand and explain variability in neurodevelopmental outcomes in high-risk NICU graduates, we first describe 24-month outcomes, then compare outcome groups based on earlier behavioral and brain-based data.

Methods: All infants were enrolled by 6 months, with subsequent visits at 9, 12, and 24 months (adjusted age for preterm). The current sample includes 43 infants who qualified for HRIF and had 24mo outcome data available (see Table). Measures include: Vineland Adaptive Behavior Scales-3rd Edition (Vineland-3; all ages), Mullen Scales of Early Learning (MSEL; 12mo, 24mo), and frontal alpha power (resting-state EEG; 12mo).

Results: Nearly half (48.8%) of participants were neurotypical, 32.6% had developmental concerns (e.g., developmental delays, subclinical autism), and 18.6% had autism. Outcome groups did not differ demographically (though boys marginally less likely to be neurotypical). Groups were similar across birthweight and gestational age, but infants with developmental concerns had longer NICU stays than neurotypical, $p<.001$, and autistic participants, $p<.01$. Developmental trajectories were compared across groups using Vineland-3 data. For communication ($p=.02$), daily living ($p<.001$), and socialization ($p=.04$), differential trajectories were identified by outcome, with the neurotypical group staying relatively stable, while the autism and developmental concerns groups showed greater deviations from the norm over this period (see Figure). Motor skills were more stable over time, with the developmental concerns group showing consistently lower scores ($p=.002$). Verbal skills on the MSEL were consistently lower in the developmental concerns and autism groups from 12-24 months, $p<.001$, while nonverbal skills diverged from the neurotypical group over this period, $p<.03$. Neurotypical children had higher 12mo frontal alpha power than those with developmental concerns, $p<.05$. The autism group had lower mean 12mo frontal alpha power than the neurotypical group, but this did not reach significance. Brain-behavior correlations were mostly non-significant, with the exception of higher frontal alpha power being associated with higher gross motor scores on the MSEL, $r(38)=.34$, $p=.03$.

Conclusions: Nearly 1 in 5 children with outcome data in our sample of high-risk NICU graduates met diagnostic criteria for autism by age 2. This rate is higher than in prior studies in similar groups (e.g., preterm) and is comparable to recurrence rates in infant siblings. While these results should be replicated in a larger sample, they suggest that autism may be under-identified in prior studies of medical-risk infants that focused less closely on autism. In line with infant sibling studies, we also observed a gradual divergence from typical expectations over the first two years, suggesting a window of opportunity for early intervention.

228.002 The Preterm Autism Phenotype: Examining Developmental Patterns Among Autism Siblings and Preterm Infants

A. Acosta, **K. Everhart** and **J. Bradshaw**, *University of South Carolina, Columbia, SC*

Background: The rate of ASD in preterm populations is approximately 4-9%, which is 2-3x higher than the general population (Angrawal et al., 2018). Approximately 20% of preterm infants exhibit the “preterm behavioral phenotype” (Johnson & Marlow, 2011), which describes behavioral, sensory, social, and attention difficulties in later childhood. Similarly, ASD siblings are at an elevated likelihood for ASD (~20%) and the broader autism phenotype (~30%). Despite similarities between the preterm behavioral phenotype and autism siblings, very few studies have compared early developmental trajectories among the two groups.

Objectives: This prospective longitudinal study compares developmental trajectories of preterm (PT) infants and infants at elevated (EL) and low (LL) genetic likelihood for ASD across the first two years of life.

Methods: Participants (N=102, n=46 female) include EL (n=26), LL (n=50), and PT (n=26; GA: 26-36 weeks) infants who were followed from birth-24 months and who received an outcome diagnosis of ASD (EL-ASD,PT-ASD) or typical development (EL-TD,LL-TD,PT-TD). At 12, 18, and 24 months, assessments of social communication (CSBS Behavior Sample; Wetherby & Prizant, 2002), early ASD features (Systematic Observation Ratings of Features of ASD, SORF; Wetherby et al., 2016), and sensory profiles (TSP-2; Dunn, 2014) were completed. Linear mixed-effects models were used to analyze the effect of age, group, and age x group interactions for each developmental domain.

Results: Of the 102 participants, 24.5% were diagnosed with ASD at outcome, including n=16 ELs (EL-ASD) and n=9 PTs (PT-ASD). CSBS models revealed a main effect of age for the CSBS-Social ($F(1,147.56)=9.26, p=0.002$) and CSBS-Speech ($F(1,154.25)=14.92, p<0.001$), but not CSBS-Symbolic ($p>0.05$), and a main effect of group for CSBS-Speech ($F(4,170.45)=2.46, p=0.04$; [EL-ASD and PT-ASD < EL-TD,LL-TD,PT-TD]). There was a significant age*group interaction for all CSBS composites, with TDs showing greater score increases compared to both ASD groups (Fig 1). EL-ASDs and EL-TDs were largely similar at 12 months, but significantly different by 24 months. SORF models showed no main effects (all $p>0.05$), but a significant age*group interaction was present for the social communication domain ($F(4,79.55)=3.09, p=0.02$) and overall composite ($F(4,82.05)=3.34, p=0.01$), with EL-TDs showing ASD features similar to that of EL-ASD and PT-ASD at 12 months, but not at 18 and 24 (Fig 2). Models of sensory responsivity resulted in a main effect of age for increasing sensory registration ($F(4,121.48)=5.52, p=0.02$) and avoiding ($F(1,116.86)=29.38, p<0.001$) over time and an age*group interaction for sensory avoiding ($F(4,115.41)=2.98, p=0.02$), with the PT-ASD showing more sensory registration and avoiding than the other groups by 24 months of age (Fig 3).

Conclusions: Findings reveal strikingly similar developmental trajectories of EL-ASD and PT-ASD, as well as LL-TD and PT-TD, infants from 12-24 months. Interestingly, EL-ASD and EL-TD infants were inconsistently similar at 12 months, but diverged thereafter, across developmental domains. PT-ASD was distinguished from EL-ASD only by sensory responsivity, showing more sensory avoidance by 24 months. Together, these data suggest that the preterm behavioral phenotype may largely describe PTs with ASD. Further research with larger sample sizes and on specific ASD features within the ASD groups may be useful in understanding the unique profile of ASD in PT infants.

228.003 EEG As a Predictor of Neurodevelopmental Outcomes in Infants with Low Birth Weight or Family History of Autism

V. Arutunian¹, M. Santhosh¹, C. Tompkins², K. Macdonald³, S. Corrigan⁴, K. J. Dommer¹, F. Shic¹ and S. J. Webb¹, (1)Center for Child Health, Behavior and Development, Seattle Children's Research Institute, Seattle, WA, (2)Institute of Human Development and Disability, University of Washington, Seattle, WA, (3)Child Health, Behavior, and Development, Seattle Children's Research Institute, Seattle, WA, (4)Seattle Children's Hospital and Research Institute, Seattle, WA, (5)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA

Background: Little is known about generalizability of infant neuromarkers related to increased likelihood of autism or other neurodevelopmental delays based on different risk factors such as medical complexity or familial history. Electroencephalography (EEG) is one of the promising tools for developing prognostic biomarkers related to early autism behaviors or behavioral delays as it is well tolerated by infants and appropriate for measuring both stimulus-induced and resting-state brain activity.

Objectives: To examine if EEG-based early neural markers are altered in infants with low-birth-weight medical complexity (LBW) or familial history of autism (FH) in comparison to those without elevated likelihood of neurodevelopmental concerns. We also examined if EEG markers in the first year were related to early diagnostic concerns broadly and communicative and social adaptive skills specifically.

Methods: We included infants with elevated likelihood for developing ASD and/or developmental delay based on LBW (less than 2400g) or familial history (an older sibling with a diagnosis of ASD) at 6 and 12 months of age. High density EEG was recorded while the infants watched videos with social and nonsocial stimuli. Power spectral density (PSD) at 18 channels based on the 10-20 system was calculated using the Harvard Automated Preprocessing Pipeline for EEG. At 24 months, neurodevelopmental disorder (NDD) outcomes were based on the Brief Observation of Symptoms of Autism (total score) and Mullen Scales of Early Learning (≤ 2 SD). Adaptive skills were measured with the Vineland Adaptive Behavior Scales communication and socialization standard scores. (1) We fitted a linear mixed-effects model with PSD as a dependent variable, risk group, timepoint, experimental condition (stimuli with social vs. nonsocial content), and interaction as fixed effects, and participants as a random intercept. (2) We then used similar linear mixed-effects models to examine outcome groups (NDD vs. noNDD). Correlations were used to explore relations between PSD and social and communication behaviors.

Results: See Table 1 for sample demographics, 24-month characteristics, and outcome groups. (1) Gamma power was elevated in the first year in the LBW and FH groups at central (C3/C4, $ps<.01$) and parietal (P3/P4, $ps<.06$) electrodes. (2) However, infants with 24-month NDD (compared to those without) did not have significantly enhanced gamma power ($ps=NS$), although gamma power in the NDD group was associated with communication skills at left electrodes (e.g., C3 $r=-.31$; P3 $r=-.30$).

Conclusions: Abnormal gamma power has been reported in previous studies in infants with autism family history and children with ASD and/or developmental delays (e.g., Gabard-Durnam et al., 2019; Manyukhina et al., 2022). Increased gamma power has been suggested as a metric of altered excitatory > inhibitory activity (Rubenstein & Merzenich, 2003; Sohal & Rubenstein, 2019). Our next step will be to conduct sensitivity analyses that compare gamma responses between LBW group and FH groups, and cluster-based analysis (using EEG and behavior) that may identify a bio-profile of infants with altered gamma and communicative delays. These preliminary results suggest that neural markers of NDD can be identified in the first year of life, with high frequency EEG power a promising prognostic marker.

228.004 Developmental Trajectories and Autism Outcomes in Low Birthweight Infants

K. J. Dommer^a, M. Reninger^a, H. Willis^a, S. Corrigan^a, E. Olson^a, K. Michener^a, J. Skytta^a, D. Christakis^a, S. J. Webb^a and F. Shic^a, (1)Center for Child Health, Behavior and Development, Seattle Children's Research Institute, Seattle, WA, (2)Child Health, Behavior & Development, Seattle Children's Research Institute University of Washington, Seattle, WA, (3)Seattle Children's Hospital and Research Institute, Seattle, WA, (4)University of Washington, Seattle, WA, (5)University of Washington School of Medicine, Seattle, WA, (6)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA

Background: Children born preterm and very low birthweight may have distinct developmental trajectories (Caravale et al, 2005; Wolfe et al, 2002), including increased rates of autism (Lampi et al, 2012) compared to peers born at term. Parsing out developmental differences in this complex population could help hone screening tools and lead to more precision interventions.

Objectives: Evaluate developmental trajectories of children born with or without elevated likelihood of neurodevelopmental conditions including autism, with a specific probe into whether autistic or non-autistic children show different trajectories depending on their likelihood group at birth.

Methods: Data were collected from 257 children as part of a longitudinal study at roughly 6-, 12-, 24-, and 36-months-old. Recruitment groups included children with low likelihood of developmental concerns (LL), or elevated likelihood (EL) based on being born LBW (EL-LBW, <2400g) or having an older autistic sibling (EL-Sib). Diagnostic outcomes and developmental assessments including the Brief Observation of Symptoms of Autism (BOSA; total score), Mullen Scales of Early Learning (Receptive Language and Visual Reception subscales), and Vineland Adaptive Behavior Scales – 3rd Edition (Social, Communication, Daily Living Skills, and Motor subscales) were analyzed. Linear mixed models of each outcome predicted by recruitment group, diagnostic outcome (ASD vs nASD), and age were analyzed using repeated measures ANOVA.

Results: Chi-square tests evaluating diagnostic outcome by group showed significantly higher rates of ASD in EL-Sibs than EL-LBW and LL groups ($p < .001$) with no difference between EL-LBW and LL. To better appreciate the nuance of developmental outcomes, we also evaluated atypical non-ASD outcomes, and only found that EL-LBW trended towards higher outcomes of atypical non-ASD diagnoses than LR ($p = .057$) (Table 1).

All models showed significant age and diagnosis*age effects ($p < .05$) (Figure 1). Autistic children most often differed from non-autistic ($p < .05$) at 24-months and older. BOSA scores were lower (fewer symptoms) in the LBW-nASD children than LL-nASD at 28-months but were higher for LBW-ASD than LL-ASD at 39-months-old ($p < .05$). Broad trends emerged of LBW-nASD scoring lower on developmental measures than LL-nASD, especially at older timepoints. Among varied significant differences on the Vineland-3, the Sib-ASD group scored lower than LL-ASD—and occasionally LBW-ASD—at various ages in Social, Communication, and Daily Living Skills ($p < .05$), and LBW-ASD scored significantly higher than LL-ASD in the Social subscale at 14-months.

Conclusions: Amid myriad significant differences between recruitment and diagnostic groups across ages, a pattern emerges where non-autistic EL-LBW children show pervasive vulnerability to developmental deficits by 28-months-old compared to non-autistic LL children; however, they do demonstrate lower levels of autism symptoms than LL-nASD peers at 2-years-old. This pattern may suggest that children born LBW who do not receive an autism diagnosis have a developmental trajectory that lags slightly behind other non-autistic peers, but may specifically demonstrate fewer autistic traits. EL-LBW children who do receive an ASD diagnosis also show select resiliencies compared to LL-ASD peers in the social domain, but have greater autism symptom scores by 3-years-old. Autistic children with an autistic sibling show significant patterns of greater developmental deficit than low birthweight or low-likelihood autistic children.

**Panel Session****229 - Sensory Processing in Autism: From Brainstem to Environmental Context**

May 3rd, 2025, 2:00 PM - 4:00 PM - 608-609

Panel Chair: Ryan Stevenson, *University of Western Ontario, London, ON, Canada*

Discussant: Zachary Williams, *Vanderbilt University, Nashville, TN*

The study of sensory processing in Autism has exploded in the past decade after being incorporated into diagnostic criteria. The importance of sensory processing as a fundamental building block upon which most, if not all, cognitive functions rely has become apparent. Sensory differences in autism have now empirically been shown to have a cascading impact on multiple facets of Autism, including both social communication and restricted interests and repetitive behaviours. This panel will present groundbreaking research across the hierarchy of sensory processing levels, from auditory processing in the brainstem, EEG responses to speech stimuli in infants at high risk for developing autism, and from behavioural measures of audiovisual integration to examining the role that environmental context (i.e. location, who you are with, control) has on the perceptual experience of sensory information and the responses to sensory inputs using ecological momentary assessments and qualitative measures. At each level of analysis, we will relate these sensory characteristics to the development of cognitive processes impacted by Autism, including speech and language abilities and development. This panel will highlight the ubiquity of sensory differences across the processing hierarchy and across development, and the cascading downstream effects of sensory differences at each processing level.

Introduction

229.001 Brainstem Mediated Physiological and Behavioral Measures of Responsivity across Development in Autism

A. Seif^a, R. Guerville^a, M. S. Rajab^a, K. Schaaf^a, C. Marceau-Linhares^a, S. Schmid^a and R. A. Stevenson^a, (1)University of Western Ontario, London, ON, Canada, (2)Anatomy and Cell Biology, University of Western Ontario, London, ON, Canada

Background:

Autistic children and adults experience a range of sensory differences including hyper- and hypo-responsivity. We have hypothesized that auditory sensory issues may be related to delays in auditory brainstem maturation in autism, which has been structurally observed by neuroimaging and post-mortem analysis. Functionally, this delay is measured through the auditory brainstem responses (ABR), an auditory evoked potential recorded through electrodes on the scalp. Alterations in ABR latencies indicate a reduced sound sensitivity which seems counterintuitive given the increased sensory sensitivities reported by autistic individuals. Therefore, we also used a behavior measure of brainstem-mediated sensory reactivity; the acoustic startle reflex (ASR) which is an evolutionary conserved protective response to sudden auditory stimuli. It is typically quantified as the strength of an eyeblink response measured using electromyography.

Objectives:

To investigate the link between brainstem responsivity indexed via ABR and sensory issues using ASR across development.

Methods:

Autistic (n=44 kids; n= 21 adults) and non-autistic (n=57 kids; n= 26 adults) completed a hearing evaluation, an ABR recording session, and an ASR paradigm. The hearing evaluation consisted of a visual inspection using an otoscope, tympanometry (226Hz probe), and audiogram (250-8kHz). The ABR paradigm consisted of a slow click-rate (19.1clicks/second) and a fast click-rate (59.1clicks/second), and acoustic stimuli at 80 dBnHL intensity across both ears. The ASR test included responses to white noise acoustic stimuli in the range of 65–105 dB with 5 dB increments. Participants listened passively while watching a silent video.

We conducted three-way, mixed-model, repeated-measure ANOVAs with within-subject factors stimulus type (click-rate for ABR and dB level for ASR), and between-subject factors of diagnostic group and sex. Absolute latencies and amplitudes of peaks I, III and V were evaluated for the ABR.

Results:

The overall ABR waveform showed a trend towards prolongation in the autistic children relative to the non-autistic children in both click-rates (figure 1). Peak I and peak V latencies had a sex-by-group interaction in which girls had a delay in latencies. The overall ABR waveform had lower peaks for the autistic participants with more prominent differences for the autistic kids. Autistic adults had increased behavioral reactivity (figure 2).

Conclusions:

Autistic children showed a prolonged ABR waveform with increased latency of peaks I, III, and V, which is indicative of reduced speed of neural conduction. This was combined with reduced peak amplitudes meaning they have reduced neural responsivity. The differences were more severe for the autistic girls compared to the boys. In addition, they did not display any behavioral increase in acoustic reactivity. Their behavioral and physiological responses align. Their ascending auditory pathway is less responsive to sounds and there seems to be a perceptual adaptive gain to counteract the reduced responsivity.

In contrast, autistic adults have a relatively typical ABR response indicating that ascending auditory pathway development normalizes by adulthood. It is combined with increased sound reactivity as measured with ASR. This could be due to the perceptual adaptive gain in childhood becoming maladaptive as the neural responsivity of the brainstem normalizes by adulthood.

229.002 Audiovisual Multisensory Integration in Autistic and Non-Autistic Youth: Links with Language and Core Autistic Features

J. I. Feldman¹, G. Pulliam², M. Cassidy³, J. G. Conrad³, Y. Liu⁴, W. Kuang³, D. M. Simon², E. Tschaikowsky⁴, A. Tu³, M. T. Wallace³ and T. G. Wojnaroski¹. (1)Department of Hearing and Speech Sciences, Vanderbilt University Medical Center, Nashville, TN, (2)Vanderbilt Brain Institute, Vanderbilt University, Nashville, TN, (3)Vanderbilt University, Nashville, TN, (4)Frist Center for Autism and Innovation in the Workplace, Vanderbilt University, Nashville, TN

Background: Sensory differences, particularly those in audiovisual integration, have been well studied in autistic children and are hypothesized to underly core- and related-features of autism, such as language, social communication, and restricted interests and repetitive behaviors (RRBs). However, the extant literature is limited by a lack of studies that (a) compare audiovisual integration in autistic versus non-autistic youth across levels of stimulus complexity (i.e., social and nonsocial) and (b) evaluate whether links between metrics of audiovisual integration and standardized clinical assessments are moderated by diagnostic group.

Objectives: This study sought to investigate multisensory integration in autistic children using a comprehensive battery of psychophysical tasks and to relate those abilities to an extensive neuropsychological battery characterizing core and related features of autism (i.e., social communication, RRBs, language).

Methods: Participants were 120 youth (62 autistic, 58 non-autistic) well-matched on gender identity and chronological age. Participants completed a psychophysical battery assessing audiovisual integration: a speech simultaneity judgment task (participants were shown the syllable "ba" with the auditory and visual tracks separated by various stimulus onset asynchronies), a task assessing perception of the McGurk illusion (participants are presented with an audio "pa" dubbed onto a visual "ka", which elicits an illusory percept of "ta" or "ha" upon integration), and a task assessing perception of the sound-induced flash illusion (SIFI; participants were shown one visual flash presented with two auditory beeps, which elicits an illusory flash percept upon integration, at a range of stimulus onset asynchronies). Participants also completed a battery of clinical assessments tapping aspects of language, social communication, and RRBs.

Results: Results of a MANOVA indicated that groups differed in their audiovisual integration, Pillai's trace = 0.173, $F(4, 115) = 6.02$, $p < .001$.

These differences were specific to perception of the McGurk illusion, ANOVA $F(1, 118) = 1.96$, $p < .001$, such that non-autistic comparison participants reported the illusion significantly more often than autistic participants, but not on any of the metrics of audiovisual integration assessed. Across groups, perception of the McGurk effect was associated with expressive language ($r = .485$, $p < .001$), receptive language ($r = .452$, $p < .001$), social communication skill ($r = .325$, $p = .005$), and the presence of RRBs ($r = .347$, $p = .003$); these correlations were robust to controlling for nonverbal IQ and correcting for multiple comparisons. None of the correlations between metrics of multisensory integration and clinical features were significantly moderated by group after correcting for multiple comparisons.

Conclusions: This study was the most comprehensive assessment of audiovisual multisensory integration and its links with clinical features in autism conducted to date. Perception of the McGurk illusion was the only metric of audiovisual integration that distinguished groups, and it was strongly linked with language and the core features of autism (e.g., social communication, RRBs) across groups.

229.003 Looking Behavior and Neural Responses to Audiovisual Speech Contribute to Language Development in Infants at Increased Likelihood for Autism

K. Dunham-Carr¹, B. Keceli-Kaysili², P. Santapuram³, J. E. Markfeld⁴, G. Pulliam⁵, S. M. Clark⁶, K. McClurkin³, A. Schwartz³, D. Agojci³, J. I. Feldman⁴ and T. G. Woynaroski¹, (1)Boston Children's Hospital / Harvard Medical, Boston, MA, (2)Hearing and Speech Sciences, Vanderbilt University Medical Center, Nashville, TN, (3)Vanderbilt University, Nashville, TN, (4)Department of Hearing and Speech Sciences, Vanderbilt University Medical Center, Nashville, TN, (5)Vanderbilt Brain Institute, Vanderbilt University, Nashville, TN, (6)Vanderbilt University Medical Center, Nashville, TN

Background: Differences in sensory processing, including looking to and processing of audiovisual speech, may cascade onto heterogeneity in language development in autistic children. Neurotypical infants have been found to predominantly look to the mouth of communication partners during the first year of life, presumably to access audiovisual cues that facilitate speech processing and language learning. Empirical support for audiovisual speech cues facilitating speech processing in children has been provided by evidence from event-related potentials (ERPs), specifically via ERP amplitude suppression in response to audiovisual versus auditory-only speech that has been linked with vocabulary in school-aged autistic and non-autistic children.

Objectives: This study evaluated the role of audiovisual speech processing in early development by determining: (a) if visual cues increase efficiency of speech processing as indexed by ERPs in infants, (b) if infants at increased familial likelihood for autism (infant siblings of children with autism; Sibs-Autism) display a lesser boost in speech processing efficiency with access to multisensory versus unisensory cues compared to infants at general population-level likelihood for autism (infant siblings of non-autistic children; Sibs-NA), and (c) if individual differences in audiovisual speech processing efficiency covary with looking to visual speech cues and emerging language ability.

Methods: Fifty-four 12-18 month old infants (28 Sibs-Autism; 26 Sibs-NA matched on sex and chronological age) viewed videos of a female speaking syllables in audiovisual (auditory speech + synchronous visual mouth movements) and auditory-only (auditory speech + still image of the face) conditions while EEG data were collected using NetStation and a 128-channel Geodesic sensor net (Net Amps 400 amplifier, Hydrocel GSN 128 EEG cap, EGI Systems Inc.). The amplitudes of the P1 and N2 components (defined a priori as occurring between 100-200 ms and 350-500 ms poststimulus, respectively) as measured at Cz were extracted from the average ERP of each participant. Participants also completed a previously developed and validated eye tracking task using an SMI Redn Scientific Eye Tracker, wherein they watched a video of a woman speaking in infant-directed speech. The proportion of looking time to the eyes and mouth were derived for analyses. Receptive and expressive language aggregates were created using the Vineland Adaptive Behavior Scales, the Mullen Scales of Early Learning, and the MacArthur Bates Communicative Development Inventory, following z score transformation.

Results: On average, infants displayed more negative N2 amplitudes in response to audiovisual versus auditory-only speech, $F(1,52) = 4.26, p = .042, \eta^2 = .040$. There were no significant group differences in ERP amplitudes (Figure 1); however, there was considerable individual variability in the degree of P1 and N2 amplitude effects in response to audiovisual speech observed. Links between looking to audiovisual speech, ERP amplitude effects, and language aggregate scores were moderated by sibling group, chronological age, and biological sex (Figure 2).

Conclusions: These findings suggest that access to audiovisual cues increases the efficiency of speech processing early in life across infants at high and low likelihood for autism. Looking to and processing of audiovisual speech may, however, differentially influence language development in these populations.

**229.004** A Mixed-Method Analysis of Contextual Factors Impacting Sensory Processing in Autistic Adults

M. M. Luszczowski¹, S. E. Schulz², G. Czichrak¹, T. Rowe¹ and R. A. Stevenson², (1)Western University, London, ON, Canada, (2)University of Western Ontario, London, ON, Canada

Background:

Autistic individuals often report negative experiences with particular sensory stimuli, commonly described as atypical sensory processing. There is a high level of heterogeneity in responses to sensory stimuli, both between individuals, but also within individuals across different contexts. While some previous research has sought to determine the contextual factors that influence sensory processing in autistic individuals, a number of methodological issues have led to inconsistent results, specifically the lack of ecological validity in many lab-based studies and recall bias in qualitative and questionnaire studies.

Objectives:

The purpose of this study was to determine the contextual factors that impact sensory processing in autistic individuals using ecological momentary assessment, an in-the-moment measure of participants' experiences, and to collect both quantitative and qualitative data on autistic individuals' sensory experiences.

Methods:

We prompted participants to complete a survey of their current sensory environment and experiences on their cellphones three times per day over the course of two weeks. The survey focused on participants' current activities, surroundings, mood, and sensory experiences. We predicted that contextual factors such as the participants' level of control over their environment, mood, and the sensory stimuli involved would affect their sensory processing. Additionally, participants completed two measures of autistic traits, the Sensory Profile and the Social Responsiveness Scale.

Results:

41 autistic adults participated in the study. Results indicated significant associations between participants' positive, negative, and neutral sensory experiences and their surroundings and other contextual factors. In particular, we found that location, being with other people, and feelings of control over the environment, good mood, fatigue, physically unwell, and anxiety/overwhelmed impacted the sensory experiences reported by participants (Figure 1). Qualitative analyses of participants' responses to open-ended questions in the daily survey revealed themes related to descriptions of their sensory experiences, their reactions to these experiences, and any coping mechanisms they used. We found no significant relationship between these experiences and their scores on standardized measures of autistic traits (Table 1).

Conclusions:

Factors such as mood, surroundings, and the modality of the sensory stimuli all contributed to differences in autistic individuals' sensory experiences. Differences were found both between and within individual reports of sensory experiences, which is consistent with previous findings. The lack of correlations between the standardized questionnaires and the proportion of sensory experiences reported as negative was unexpected and suggests a potential discrepancy between measures of sensory sensitivity and sensory reactivity. These findings help acknowledge the role that context plays in autistic individuals' sensory experiences and can have implications for creating supportive environments by controlling for different contextual factors. These findings also have implications for helping autistic individuals develop coping strategies for dealing with these experiences, such as deep breathing or wearing headphones to help reduce feelings of anxiety in situations where they have little control over their environment.

**Panel Session****230 - EEG As an Outcome Measure in the Arbaclofen Clinical Trial in ASD and the 16p11.2 Deletion.**

May 3rd, 2025, 2:00 PM - 4:00 PM - 606-607

Panel Chair: Sarah Lippe, *Neurosciences of Early Development Lab, CHU Sainte-Justine University of Montreal, Montreal, QC, Canada*

Discussant: Grainne McAlonan, *NIHR-Biomedical Research Centre for Mental Health at the Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, UNITED KINGDOM*

This panel brings together international teams to explore the sensitivity and specificity of EEG in assessing the efficacy of Arbaclofen treatment for autism spectrum disorder (ASD) and 16p11.2 deletion, a genetic condition associated with psychiatric and neurodevelopmental disorders. Featuring four presentations, the panel integrates findings from three clinical trials conducted across the USA, Canada, and Europe, where identical EEG tasks were used as exploratory outcome measures. The speakers will discuss how resting-state conditions, auditory steady-state responses, and face event-related potentials (ERPs) are modified by Arbaclofen treatment in ASD and 16p11.2, and how specific EEG features—or combinations of features—predict behavioral changes. Attendees will gain deeper insights into how various EEG features converge or diverge as treatment-sensitive markers in these conditions, and how diverse statistical modeling approaches contribute to the development of efficient pipelines for enhancing the success of clinical trials.

Introduction

S. Lippe, *Neurosciences of Early Development Lab, CHU Sainte-Justine University of Montreal, Montreal, QC, Canada*

230.001 EEG Neural Functioning in Youth with the 16p11.2 Deletion: Targeting Auditory Processing and Learning with Arbaclofen

S. J. Webb¹, **S. Lippe²**, **S. Faja³**, **M. Santhosh⁴**, **C. Tompkins⁵**, **V. Arutiunian⁶**, **S. Jacquemont⁷**, **I. S. Knoth⁸**, **P. Vandana⁹**, **R. P. Goin-Kochel¹⁰**, **L. A. Prock¹¹**, **J. Veenstra-VanderWeele¹¹** and **P. Wang¹²**, (1)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (2)Neurosciences of Early Development Lab, CHU Sainte-Justine University of Montreal, Montreal, QC, Canada, (3)Boston Children's Hospital, Harvard, Boston, MA, (4)Center for Child Health, Behavior and Development, Seattle Children's Research Institute, Seattle, WA, (5)Institute of Human Development and Disability, University of Washington, Seattle, WA, (6)Department of Pediatrics, University of Montreal, Montréal, QC, Canada, (7)CHU Sainte-Justine Research Center, Neuroscience of Early Development lab, Montreal, QC, Canada, (8)Columbia University Irving Medical Center/NYSPI, White Plains, NY, (9)Baylor College of Medicine, Houston, TX, (10)Division of Developmental Medicine, Boston Children's Hospital, Boston, MA, (11)Columbia University, New York, NY, (12)Simons Foundation, New York, NY

Background:

Approximately 1% of youth with ASD have 16p11.2 BP4 and BP5 deletion syndrome (Fernandez et al., 2010). From individuals diagnosed clinically with the 16p11.2 deletion, the most common profile is impaired speech and language (~70%), with about 25% also having ASD, and most having lower IQ compared to unaffected family members (Chung et al., 2020; Männik et al. 2015). Affected individuals also have atypical white matter maturation (measured through DTI; Chang et al., 2016) and response delays in auditory cortex signaling (measured through MEG; Jenkins et al., 2016).

The L16HTHOUSE Study (NCT04271332) aims to evaluate the safety, tolerability, and effectiveness of arbaclofen in children and adolescents with the 16p11.2 deletion. This is a phase 2 double-blind placebo trial of arbaclofen with a similar protocol structure as ARBA and AIMS-2-TRIALS-CT1. L16HTHOUSE targets articulation as the primary endpoint with exploratory endpoints in EEG biomarkers that assess inhibitory and excitatory (E/I) balance during general neural functioning and auditory processing.

Objectives:

To examine EEG metrics of E/I balance in individuals with 16p11.2 deletion obtained from the Genetique des Familles Montreal research project or L16HTHOUSE clinical trial. We first examined baseline responses in the two groups to better understand neural processing in youth with 16p11.2 deletion syndrome. For L16HTHOUSE, we hypothesized that arbaclofen would increase neural inhibition reflected by decreased power in higher frequency bands (gamma), decreased aperiodic slope, and increased aperiodic offset, in line with hypotheses from AIMS-2-TRIALS-CT1.

Methods:

Youth with 16p11.2 deletion syndrome were enrolled in (A) Genetique des Familles project (n=21) or (B) L16HTHOUSE (n=29) with EEG acquired at baseline, day 36 and day 113 (n=18). In both, EEG was acquired using a 128 channel system. The Genetique des Familles project included resting state (passive movie viewing) and auditory oddball. L16HTHOUSE included resting state EEG (passive screen-saver viewing), auditory oddball, auditory steady state, and social/nonsocial videos. We matched EEG post-processing pipelines. Absolute power was extracted across the frequency range as well aperiodic offset and slope.

Results:

(A) In the Genetique des Familles project, resting state EEG of 16p11.2 del (n=21) compared to controls (n=42) included reduced gamma power on the periodic spectra ($p < .001$), but increased power on the aperiodic spectra ($p = .027$). Aperiodic offset did not differ from controls, but the exponent was significantly lower ($p = .019$). (B) L16HTHOUSE is closed to enrollment and data lock is expected Jan 2025, with analysis conducted in Feb-May 2025.

Conclusions:

Alignment of biomarker studies and clinical trial protocols in ASD with those being conducted in rare genetic syndromes with phenotypic overlap, allows for increased rigor and reproducibility of findings as well as examination of disorder specificity. On alignment the L16HTHOUSE EEG protocol with the Genetique des Familles, ARBA, and AIMS-2-TRIALS-CT1 protocols allows for comparison to comparison or larger samples of youth, assessment of neural systems that are related to behavioral heterogeneity within and across groups (e.g., auditory processing), generalizability of the arbaclofen EEG treatment response, and the unique primary behavioral treatment outcomes for each trial.

230.002 Predict Arbaclofen-Induced Behavioral Changes in Individuals with ASD Using EEG

S. Lippe¹, R. Bucksner², S. Davoudi³, E. Anagnostou⁴ and I. S. Knoch⁵, (1)Neurosciences of Early Development Lab, CHU Sainte-Justine University of Montreal, Montreal, QC, Canada, (2)CHU Sainte-Justine, Montreal, QC, Canada, (3)University of Montreal, Montreal, QC, Canada, (4)Bloorview Research Institute, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (5)CHU Sainte-Justine Research Center, Neuroscience of Early Development lab, Montreal, QC, Canada

Background:

The ARBA Study (NCT03887676) is a double-blind, randomized clinical trial that aims to determine whether a 16-week treatment with Arbaclofen can ameliorate behavioral symptoms and alter EEG signals in children and adolescents with ASD. Participants in the ARBA-EEG study of the Canadian arm of the international trial completed EEG and clinical interviews at a baseline visit and a follow-up visit 16 weeks after starting arbaclofen treatment or a placebo. The sample used for the present analysis includes 60 participants from two research sites in Toronto and Kingston, Ontario, comprising the full EEG sample and approximately two-thirds of the data collected by the Canadian arm of the ARBA study.

Objectives:

Test if EEG can predict treatment related behavioral improvements.

Methods:

We extracted a total of 144 features from RS-EEG data, capturing elements of power spectra and signal complexity. Power features included Alpha, Beta, Theta, Low-Gamma, and High-Gamma bands and Alpha Peak Frequency (APF). Complexity measures included Low-Scale, High-Scale, and total complexity interval (CI); Hurst Exponent (Hurst); Higuchi Fractal Dimension (HFD); Katz Fractal Dimension (KFD); and Sample Entropy (SE). We also included FOOOF, which characterizes aperiodic activity in the signal in addition to periodic power spectra. FOOOF features included Exponent, Offset, Center Frequency (CF), Power (PW), and Bandwidth (BW).

With 60 subjects in our analysis, a regression model containing all EEG features would be severely underdetermined. Thus, we first conducted feature selection by applying a bootstrapped least absolute shrinkage and selection operator (BOLASSO). Following the feature selection phase, we used forward-backward stepwise regression to find a final predictive GLM for each behavioral measure. Terms from the ranked list were added to or subtracted from a base model containing treatment, sex, age, and FSIQ as predictors and DScore as the outcome. The final model was the one with the lowest Bayesian Information Coefficient (BIC).

Results:

We identified 19 measures in which models showed a significant ($p < .05$) relationship between Treatment and DScore, indicating that a treatment-dependent change in behavior could be predicted from a combination of EEG features. These included ABC Hyperactivity, Inappropriate Speech, Irritability, and Total Score; AIM Atypical Behavior, Communication, Repetitive Behavior, Repetitive Language, and Total Score; SEQ Nonsocial Context, Social Context, EP, Hyposensitivity, SIRS, Visual Modality, and Total Score; and Vineland-3 Coping Skills, IPR, and Socialization.

The number of EEG features within each model ranged from one to 12, with a median of three features per model across the four stimuli. Features were distributed across all ROIs and included APF; High-Scale, Low-Scale, and total CI; HFD; KFD; FOOOF Exponent; FOOOF Offset; Hurst; SE; and PSD in Alpha, Beta, Delta, High-Gamma, Low-Gamma, and Theta bands.

Conclusions:

We demonstrate that combinations of features extracted from RS-EEG signal at baseline can predict significant changes in behavioral symptoms. Our approach of selecting a subset of maximally predictive features from a large and diverse feature set reveals that a combination of linear and non-linear factors across multiple ROIs can serve as a highly predictive indicator of change in multiple symptom domains after a clinical intervention.

230.003 A Phase II Randomised, Double Blind, Placebo-Controlled Study of Effects of GABA Modulation on Spontaneous Neural Oscillations in Autistic Children and Adolescents

R. Haartsen¹, T. Del Bianco¹, L. Mason², A. San Jose Caceres³, L. Colomar², D. Ilyka², C. Arango⁴, M. Parellada⁵, S. Lippe², D. Murphy⁶, E. Jones¹ and T. AIMS-2-TRIALS-CT1 Group⁷, (1)Centre for Brain and Cognitive Development, Birkbeck University of London, London, United Kingdom, (2)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (3)Hospital General Universitario Gregorio Marañón, Madrid, Spain, (4)Psychiatry, Institute of Psychiatry and Mental Health, Hospital General Universitario Gregorio Marañón, CIBERSAM, IsBGM, UCM, Madrid, Spain, (5)Neurosciences of Early Development Lab, CHU Sainte-Justine University of Montreal, Montreal, QC, Canada, (6)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, UNITED KINGDOM, (7)Instituto de Investigación Sanitaria Gregorio Marañón, Madrid, Spain, Spain

Background:

Increasing evidence from rodent and human studies suggests the balance between excitatory (glutamatergic) and inhibitory (GABAergic) neural activity (E/I balance) is a potential biological system for autism. This E/I balance can be measured with electroencephalography (EEG), using spectral power, aperiodic metrics, and connectivity. We need increased understanding how EEG markers shift under pharmacological interventions that target E/I balance for advancing treatment development.

Objectives:

We aimed to identify the effects of the GABA_A receptor agonist arbaclofen on E/I EEG proxies in one of the first randomised controlled trials using EEG measures. We hypothesised the treatment group would show a) decreased power in higher frequencies, b) decreased aperiodic slope and increased aperiodic offset, and c) increased connectivity between timepoints compared to the placebo group (pre-registration: <https://osf.io/tbgz9>).

Methods:

123 autistic children aged 5-17 years with fluent speech were recruited into a randomised, double blind, placebo-controlled trial across several European sites (ClinicalTrials.gov ID: NCT03682978). The treatment group received arbaclofen 3 times a day (15/20mg depending on age) for 16 weeks after a 5-week titration period while placebo group received a placebo tablet at identical frequency and duration. Randomisation was stratified 1:1 with the Interactive Web Response System.

EEG was recorded before treatment and at week 16. Children passively watched 4 stimuli: videos of women singing nursery rhymes, spinning toys, abstract shapes, and a fixation cross. Absolute power was extracted across lower (6-12Hz), and higher frequencies (15-100Hz). Aperiodic offset and slope were obtained across 3-28Hz (from human studies), and 1-120Hz (from rodent studies). Global connectivity (theta and alpha) was calculated as the debiased weighted phase lag index. For each of these variables, we ran a mixed model with their difference between timepoints as outcome, with treatment as predictor, stimulus, age and normalised baseline as covariates, with stimulus and participant as varying slopes and intercepts, respectively.

Results:

The treatment group (N = 42 out of 60 randomised) displayed a significant decrease in power from baseline in the lower frequencies (Coefficient = -0.54, SE = 0.16, $p = 0.001$), whereas the placebo group (N = 47 out of 63 randomised) showed no change. Aperiodic offset and slope both increased between timepoints, but the active treatment group showed smaller increases (Offset: Coef. = 0.37, SE = 0.11, $p = 0.001$; Slope: Coef. = 0.23, SE = 0.11, $p = 0.03$) compared to the placebo group (Offset: Coef. = 0.44, SE = 0.10, $p = 0.0001$; Slope: Coef. = 0.27, SE = 0.10, $p = 0.009$). Theta connectivity decreased between timepoints in the treatment group only (Coef. = -0.007, SE = 0.003, $p = 0.04$).

Conclusions:

Our findings demonstrate that arbaclofen affects periodic oscillations in lower frequencies, aperiodic neural oscillations and connectivity in autistic children and adolescents. For the aperiodic metrics, arbaclofen resulted in smaller changes across time than the placebo. This may result from arbaclofen impacting inhibitory activity from parvalbumin (PV) interneurons – with downstream changes in neuronal activity and circuits. Future research should focus on relation to behavioural changes and potential use for treatment development.

230.004 What a GABA-B Agonist Does (and Doesn't) Do to Face Processing: Insights from a Clinical Trial in Autism

E. Broggi¹, D. Ilyka¹, T. Del Bianco², R. Haartsen², A. San Jose Caceres³, L. Colomar⁴, B. Oakley⁴, E. Loth⁴, E. Jones², M. Parellada³, C. Arango⁵, D. Murphy⁶ and L. Mason¹, (1)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (2)Centre for Brain and Cognitive Development, Birkbeck University of London, London, United Kingdom, (3)Hospital General Universitario Gregorio Marañón, Madrid, Spain, (4)Department of Forensic and Neurodevelopmental Sciences, Flat 2, 116, South Hill Park, London, London, United Kingdom, (5)Psychiatry, Institute of Psychiatry and Mental Health, Hospital General Universitario Gregorio Marañón, CIBERSAM, IsBGM, UCM, Madrid, Spain, (6)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, UNITED KINGDOM

Background: Social difficulties are a core diagnostic criterion of autism spectrum disorder (ASD), and can significantly affect the quality of life and adaptive functioning of autistic people. Face processing is critical for social interaction. N170 latency (N170L), an electroencephalography (EEG) index of face processing, is delayed in some autistic individuals and may reflect differences in neural processing during social interactions. Slower N170L is associated with greater social challenges. One proposed mechanism contributing to social differences in autism is an imbalance between excitation and inhibition (E-I) in the brain. The role of E-I balance in face processing remains unclear. Arbaclofen, a GABA-B agonist, may help restore E-I balance in autism, potentially supporting adaptive and social functioning.

Objectives: To explore 1) how N170L responds to arbaclofen, and 2) whether N170L predicts treatment response on clinical markers of social function in ASD.

Methods: In this phase II, randomised, double-blind, placebo-controlled trial, 123 autistic children and adolescents (aged 5–17) were administered arbaclofen or placebo for 16 weeks (ClinicalTrials.gov ID: NCT03682978). EEG data were recorded as an exploratory measure while participants viewed static upright faces at weeks 1 (pre-treatment; N=96) and 16 (post-treatment; N=87). We filtered, segmented, cleaned, and averaged EEG data from each trial to extract N170L. Parents provided VABS-3, SRS-2, AIM, ABC-C, and clinician-assessed CGI-I and CGI-S measures.

Hypotheses were preregistered on the Open Science Framework (OSF)[1] and tested using linear mixed models.

Results: N170L did not differ between the arbaclofen and placebo groups ($p=0.72$), and baseline N170L did not predict clinical change on any measure. In the placebo group, changes in N170L were significantly associated with changes in SRS-Social Cognition ($r=0.34$, $p=0.028$), AIM-Peer Interaction ($r=0.39$, $p=0.018$), and CGI-Improvement scores ($r=-0.51$, $p<0.001$), with slower N170L associated with greater social challenges. In the arbaclofen group, these associations were decoupled, with N170L no longer relating to clinical changes (all p -values>.075). See Figure 1 for scatterplots and boxplot.

Conclusions: N170L is not sensitive to arbaclofen over 16 weeks, nor does baseline N170L predict clinical treatment response. However, in the placebo group, changes in N170L correlate with increased social challenges, suggesting N170L potential as a marker of social functioning in ASD over short timescales. The decoupling of this association under arbaclofen may indicate that expertise in face processing, as indexed by N170L, is acquired over longer treatment durations, or through mechanisms not directly impacted by GABA-B modulation.

Poster Session**435 - Digital Health Research or Technology Demonstration I**

May 3rd, 2025, 10:30 AM - 1:00 PM - 6E

Supporting Autistic Adults through a Gamified Educational App*A. McGuire, K. Chapman, J. C. Xing and X. Page, Computer Science, Brigham Young University, Provo, UT*

Background: For many autistic individuals with substantial support needs, the transitional years of young adulthood (18-29) can be difficult due to reduced access to resources such as education. Coupled with limited access to transportation (Lubin, 2016) and employment (Chen, 2015), many individuals in this population may not be able to easily attend traditional educational venues. As such, it is important to understand how to better support this population in receiving an education for low cost, asynchronously, and self-paced. Prior research has found that gamification can be a beneficial mechanism for encouraging self-paced participation in various learning tasks (Camargo, 2019). However, the vast majority of the work done on education, autism, and gamification has focused solely on autistic children (Mubin, 2019).

Objectives: To develop an educational gamified platform which encourages self-paced, asynchronous learning for autistic young adults.

Methods: In order to better understand gamification mechanisms preferred by autistic emerging adults with substantial support needs, we first ran participatory design sessions with 3 autistic young adults (ages 18-29) residing at a residential facility. During these participatory design sessions, participants were exposed to common gamification styles (determined from the top games in the app store) and asked to explain why they did or did not like each one. We then deployed a survey with 6 autistic young adults (ages 18-29) also with substantial support needs at the residential facility. We used the survey to gauge their preferred user interface aesthetic (also determined from the most popular games in the app store).

Based on the game style preferred by our participants, we designed and developed an educational app. Furthermore, we designed elements to support the user experience given characteristics of our target population. This includes helping with executive functioning by avoiding multiple-step directions - the home screen displays step-by-step directives on the current educational activity. We also offer audio for all screens to assist those who may struggle or become tired of reading the content. Colors used are minimized, avoiding superfluous visuals. Also, as users complete each learning activity, they receive game rewards as an external motivator to engage with the content. The app can collect data about the student's performance which is displayed in a teacher dashboard.

Results: From our participatory design sessions we found that our participants had a preference for virtual pet and badge collection style games. These games include having a 'pet' that participants can care for, accessorize, and earn badges as the user progresses. For each educational module, participants receive an animal which they can grow as they progress in the module. At the end, they can engage in extra practice problems which allows them to collect additional accessories for that animal. Students can also retake quizzes to improve their score, earning incentives as they do. We are testing this app with a social media safety curriculum and will present this version for attendees to use at the conference.

Conclusions: This introduces a self-directed and self-motivated educational platform that can be used for emerging autistic adults.

**Integrating the Application of Cognitive Behavioral Therapy, Social Skills, and Virtual Reality for Adults with Autism and Social Anxiety**

G. I. Esteve^{1,2}, K. A. Loveland³, A. F. Pagàn⁴ and A. K. Izuno-Garcia⁴, (1)Counseling Education, Sam Houston State University, Huntsville, TX, (2)Department of Psychiatry and Behavioral Sciences, University of Texas Health, Houston, TX, (3)Louis A Faillace, MD, Department of Psychiatry and Behavioral Sciences, McGovern Medical School, University of Texas McGovern Medical School, Houston, TX, (4)University of Texas Health Science Center, Houston, TX

Background:

Social anxiety is one of the most prevalent comorbidities in individuals with autism, with an estimated 17-49% developing a social anxiety disorder. The literature indicates that this comorbidity predicts poorer treatment outcomes than either condition alone (Briot et al., 2020; Stark et al., 2022). Cognitive Behavioral Therapy (CBT) is a more recent treatment applied to individuals with autism and social anxiety (Bemmer et al., 2021; Ekman & Hiltunen, 2015; Factor et al., 2022; Wang et al., 2021). With the expansion of new technologies, therapists have incorporated advancements such as virtual reality (VR) and telehealth (Botella et al., 2000, 2007). VR has been recently utilized to treat several mental health conditions, including anxiety disorders (Castro et al., 2014). However, even with multiple treatment modalities available, individuals with autism and social anxiety face difficulties accessing programs that meet their unique needs.

Objectives:

The goal of this study was to create an adapted CBT/Social Skills/VR treatment tailored to the needs of adults with autism and social anxiety. Although research and resources have primarily focused on children, there are limited resources for adults with autism, especially those from minority groups (Maenner et al., 2020; S. White et al., 2016). Enhanced services are necessary to provide appropriate diagnostic, treatment, research, and support services for all impacted by these conditions.

Methods:

A quantitative, exploratory, two-group repeated measures design was used to assess the clinical impact of the treatment on social anxiety traits. Post-intervention measures of acceptability, feasibility, and appropriateness of the intervention were also used to evaluate the intervention and its adaptation. Adults with social anxiety face multiple barriers to accessing services, and those with autism experience lifelong challenges that exacerbate their difficulties, often leading to additional mental health conditions such as depression. Adapted treatment that addresses this population's unique needs could reduce social anxiety symptoms, positively impacting their participation in social situations. The treatment consisted of a modular program of 12 sessions, including CBT-psychoeducation, emotional awareness, social skills training, and virtual reality exposure. The virtual reality exposure was conducted using a novel virtual communicator tool using avatars and virtual scenarios.

Results:

Results indicated high levels of acceptability, appropriateness, and feasibility among participants ($n = 10$). Additionally, repeated measures ANOVA showed a reduction on social anxiety across different measures of social anxiety used before, during, and after the treatment. A total of five Liebowitz Social Anxiety Scale (LSAS) measures across treatment modules indicated a slight reduction -but not statistically significant- of social anxiety scores. In contrast, five measures of the Social Interaction Anxiety Scale (SIAS) signaled a preliminary statistically significant reduction in social anxiety scores across treatment modules.

Conclusions:

The integration of technological advancements such as virtual reality and telehealth services, combined with evidence-based practices in a culturally adapted treatment, can be accepted, appropriate, and feasible while contributing to the reduction of social anxiety symptoms in this population.

A Community Trial of Holly™ for Pediatric Populations in Naturalistic Settings

J. Carbone, M. M. Vandewouw, H. Bokadia, T. Paul, A. Kushki, K. Niroomand and A. Walji, Bloorview Research Institute, Autism Research Centre, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada

Background: Emotion dysregulation refers to difficulties with managing the intensity and duration of feelings. Emotion dysregulation can be highly disabling for many neurodivergent children, negatively impacting opportunities for participation and inclusion, and long term physical and mental health. An important aspect of effective emotion regulation is awareness of internal states to allow for timely de-escalation of intense emotional states. To support children with awareness, we have developed holly™, a patented algorithm that uses real-time heart rate measurements from smart watches to characterize and provide a visual display of emotional arousal levels. The intended use of holly™ is as an informational tool that can increase awareness of emotional arousal states, and help children and caregivers support effective and timely emotion regulation. The holly™ algorithm has been tested in controlled laboratory conditions, demonstrating high accuracy. Furthermore, a small randomized controlled trial provided early evidence that holly can improve self-awareness of emotional states. However, it is unclear how these results translate to real-world environments.

Objectives: To evaluate the implementation of holly™ in community settings with pediatric populations.

Methods: Children, aged 4-21 with parent reported difficulties with emotion regulation, were provided a smartwatch with the holly™ app and instructed to wear it as often as they wanted to for three weeks. Parents were provided with a smartphone allowing them to review the data collected from holly™ and receive alerts indicating their child was experiencing strong emotions (high arousal level). Parents were asked to complete questionnaires after the use of holly™ to characterize usability (System Usability Scale (SUS; range: 0-100), Post-Study Usability Questionnaire (PSSUQ; range: 1-7), and a custom questionnaire), acceptance (Client Satisfaction Questionnaire (CSQ-8); range: 8-32), appropriateness (Barriers to Treatment Participation Scale (BTTPS); 44 items with 5-point Likert scale), and adoption (custom questionnaire). Descriptive statistics were computed.

Results: Of 168 families assessed for eligibility, 126 families enrolled and 70 completed the trial ($n=14$ withdrew, $n=42$ incomplete). The sample consisted of children with a mean age of 11.9 (SD=3.49 years), 65% male. Most families found it easy to learn and use the holly system (SUS mean [SD] = 66.9 [17.2]; and PSSUQ system usefulness: 3.0 [1.6]; information quality: 3.4 [1.5]; interface quality: 3.5 [1.7]). Most children found holly™ comfortable to wear (64%), liked the device (58%), and indicated they would wear holly again (57%). Themes of usability challenges identified included timeliness of data due to difficulties with wireless connectivity, difficulties with device initiation due to movement, and difficulties with interpreting arousal levels due to valence confounders. Acceptance was high (mean CSQ-8 score of 27.1 [4.4]). In terms of adoption, most families responded they would use holly™ again (56% strongly agree or agree, 26% neutral, 17% disagree or strongly disagree). Finally, most families deemed holly™ appropriate across all questions of the BTTPS (mean [SD] across items: 61% [15%] strongly appropriate, 16% [5%] appropriate, 11% [8%] neutral, 9% [5%] inappropriate, 2% [2%] strongly inappropriate).

Conclusions: The results of this community trial indicated high satisfaction and acceptability of holly™, although usability challenges were identified.

Beating the Music: How a Digital Game Protocol “Seriously” Enhanced Sensorimotor and Executive Functioning in Children with Autism

K. Jamey¹, S. Dalla Bella², S. Rigoulot², H. Laflamme² and N. Foster², (1)International Laboratory of Brain, Music and Sound Research (BRAMS), University of Montreal, Montreal, QC, Canada, (2)University of Montreal, Montreal, QC, Canada

Background:

Children on the autism spectrum display sensorimotor and executive functioning difficulties (i.e., inhibition control, cognitive flexibility), which may be linked to co-occurring timing impairments and symptom severity (social awareness, repetitive behaviors, and restricted interests). Emerging perspectives suggesting that deficits in timing may trigger a cascade of effects, influencing motor skills, repetitive behaviors, and broader social interactions in individuals with autism. “Serious games,” designed with objectives beyond mere entertainment, have gained prominence across various fields, including education, healthcare, and social awareness. These games harness the engaging nature of gameplay to facilitate learning, training, therapy, and behavioral change.

Objectives:

We validated an adaptation in autistic children of the existing *Rhythm Workers* (RW) “serious game” (previously validated in adults with Parkinson’s). We examined if rhythm-based training improves sensorimotor and executive functioning in children on the autism spectrum and how improvements related to training duration and symptom severity.

Methods:

We invited children with autism (7-13 years; n = 26) and to complete a remote longitudinal protocol. They were randomly assigned to RW or a control game with similar auditory-motor demands without beat-synchronization (active control condition). Participants played the game for 300 minutes over 2 weeks. We collected data (self-reported and logged on the device) on several feasibility measures (enjoyment, perceived difficulty) as well as social symptom severity (SRS-II). Additionally, we tested children’s rhythmic abilities with the BAASTA battery and executive functioning tasks (inhibition control, cognitive flexibility).

Results:

Our findings show high compliance with the protocol using RW and the control game (the training duration target was met), and that participants enjoyed playing both games. Those who played RW improved more in sensorimotor synchronization (Beat Tracking Index - BAASTA) and executive functioning compared to the control game. Training duration and symptom severity (SRS-II - social awareness, repetitive behaviors, and restricted interests) were strongly related to improvement in both outcomes.

Conclusions:

We validated that both the experimental and control games are well-matched and that the rhythmic game can selectively improve sensorimotor and executive functioning in children on the autism spectrum. We support more extensive training on a wider range of measures in a larger randomized control trial design. Neuro-imaging paradigms would help to examine mechanistic and longitudinal effects.

Joint Attention and 3D Motion and Depth Perception Using Virtual and Augmented Reality Techniques

A. Samantaray¹, C. Majumder², T. K. Gandhi¹, **S. Gulati³**, S. Khan⁴ and G. Kamila⁵, (1)Electrical Engineering, Indian Institute of Technology Delhi, New Delhi, India, (2)Department of Electrical Engineering, Indian Institute of Technology, New Delhi, India, (3)Centre of Excellence and Advanced Research for Childhood Neurodevelopmental Disorders, Child Neurology Division, Department of Pediatrics, Ansari Nagar, New Delhi, India, (4)Child Neurology Division, Department of Pediatrics, All India Institute of Medical Sciences, New Delhi, New Delhi, India, (5)Centre of Excellence and Advanced Research for Childhood Neurodevelopmental Disorders, Child Neurology Division, Department of Pediatrics, All India Institute of Medical Sciences, New Delhi, New Delhi, India

Background: Individuals with Autism Spectrum Disorder (ASD) encounter a range of challenges related to perceptual, social, motor, and cognitive skills. The development of social and communication abilities is often closely linked to the enhancement of Joint Attention (JA) skills. Additionally, many individuals diagnosed with ASD struggle with motion and depth perception, which can significantly affect their daily lives. Traditionally, various human intervention methods have been used to address these challenges. However, recent advancements in computing technology have transformed this field, introducing digital mediums as innovative intervention strategies. Notably, the combination of Virtual Reality (VR) and Augmented Reality (AR) technologies presents exciting opportunities for improved therapeutic interventions.

Objectives:

The primary objectives of this research study are twofold. First, it seeks to evaluate the feasibility of an AR and VR JA training platform designed to effectively train individuals diagnosed with ASD. Second, the study aims to explore eye-tracking data concerning the 3D motion and depth perception capabilities of participants with ASD. The research focuses on children aged 6 to 13 years. Utilizing avatar-mediated digital platforms delivered via AR and VR headsets, this study employs visual cues to enhance joint attention and subsequently compares the responses of participants with ASD to those of their neurotypical (NT) peers.

Methods:

This study comprised 19 participants diagnosed with ASD and 13 NT control participants, all aged between 6 and 13 years. All participants were in good health, and the severity of autism in the ASD group was evaluated using the Social Responsiveness Scale (SRS) and the Social Communication Questionnaire (SCQ). Each participant utilized AR and VR headsets during experimental sessions that lasted approximately 20 minutes.

The AR and VR head-mounted displays (HMDs) employed in this study are equipped with eye-tracking technology. The JA training platform features a virtual avatar alongside two objects positioned on either side. This avatar is programmed to deliver visual cues that guide participant's attention toward the virtual objects. The application records and monitors the participant's eye movements, enabling researchers to determine gaze fixations and assess whether participants are successfully focusing on the designated target objects.

Results:

In the JA study, participants with ASD demonstrated notably slower response times compared to their NT counterparts, who quickly responded to cues and maintained eye contact with a virtual avatar. Additionally, NT participants exhibited superior motion and depth perception skills, allowing them to track stimulus movement more effectively.

Conclusions:

This study evaluates the feasibility of a VR and AR training platform designed for children with ASD. It also investigates the motion and depth perception differences between participants with ASD and their NT counterparts. The findings reveal significant disparities in performance metrics between the two groups, highlighting the distinct perceptual characteristics associated with ASD.

Igait: A Smartphone-Accessible Early Screening Tool of Autism Spectrum Disorder for Children Using Video-Based Gait Analysis
Z. Wang¹, J. White², M. Sensenbrenner², M. Raju², S. Onal³, A. Gladfelter⁴ and M. Buac⁴, (1)Industrial and Systems Engineering, Northern Illinois University, DeKalb, IL, (2)Northern Illinois University, DeKalb, IL, (3)Industrial Engineering, Southern Illinois University, Edwardsville, Edwardsville, IL, (4)Speech-Language Pathology, Northern Illinois University, DeKalb, IL

Background: Although children show clinical signs of autism early in their development, many children are not diagnosed until well into preschool years, and children from minority, low-income, and rural backgrounds are diagnosed at an even later age. Moreover, current practices designed to detect autism rely solely on parent reports and clinician observations. There is a critical need for accessible, innovative, less subjective, and more inclusive tools for early detection of autism.

Objectives: The objective of this research is to develop an easily accessible early autism screening web-based application to objectively assess children's walking gait to provide an autism index. The research is not intended to replace current diagnostic practices, but rather to offer a cost-effective, readily accessible way to screen for autism.

Methods: We created a mobile-friendly website where a user (for instance, parent of the child being screened) can upload phone-recorded videos of the child walking, along with basic demographic information, and will receive an autism likelihood index, with an interpretation guide and suggested actions, as output. We developed a machine learning (ML) model that predicts the child's score on Social Responsiveness Scale-2nd edition (SRS-2) as an index indicating the likelihood of autism, based on the child's demographic information (age, gender, height, weight, ethnicity) and several key kinematic parameters describing the child's walking gait, extracted from the 2D videos. We recruited 16 autistic, and 25 non-autistic children aged 5-12 years to collect data for training and validating the ML model, with more participants being recruited for further tests.

Gait parameters were chosen as predictors to leverage research-based evidence of significant differences between autistic and non-autistic children. OpenPose, an open-source software for posture modeling, was used to extract gait parameters from 2D videos. The ML model was built upon the Long Short-Term Memory model, a type of recurrent neural network.

Results: A prototype of the tool, called *iGAIT*, has been developed. The website is freely accessible from any mobile device and only requires a short video of the child walking, making it user-friendly for non-speaking children, multilingual children, or children showing differences in language development. By including demographic information and culture-related factors, the website can be more culturally responsive, addressing an urgent need to consider culture when assessing the development of gait in autistic children. The website can generate the autism likelihood index within 1 minute, allowing for fast screening requests from a large number of users. It also offers a visualized summary of historic records for further reference by the user and healthcare professionals. The ML model shows satisfactory accuracy on preliminary validation. Further tests and model enhancement are in progress. Figure 1 shows the user interface and the back end of the website.

Conclusions: This research has demonstrated the feasibility of early screening of autism in a fast, cost-effective, easily accessible, minimally invasive, and less subjective way. The tool lowers the barrier to autism screening services for low-income families, helping to raise autism acceptance and reduce delays in diagnosis. The research also advances gait-based health evaluation technology.

A Virtual Dental Office Experience for Children with Autism – a Randomized Controlled Trial

T. Paul¹, M. Friedman², A. Dupuis³, H. Bokadia⁴, M. Penner⁴ and A. Kushki¹, (1)Bloorview Research Institute, Autism Research Centre, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (2)Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (3)Biostatistics, University of Toronto, Dalla Lana School of Public Health, Toronto, ON, Canada, (4)Autism Research Centre, Bloorview Research Institute, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada

Background: Dental visits can be stressful, especially for autistic children, due to sensory sensitivities and unfamiliar environments, often leading to anxiety. Traditional tools like social stories help prepare children, but they have mixed results. Virtual reality (VR), which provides immersive experiences, can provide a relatively inexpensive way to learn and practice skills in a personalized, controlled, and safe setting.

Objectives: This randomized controlled trial (RCT) aimed to evaluate the effectiveness of a VR-based intervention (360° Video) compared to a social story approach in reducing pre-visit anxiety and improving dental visit completeness in children with autism at the Holland Bloorview dental office.

Methods: The 360° Video was co-created in partnership with Holland Bloorview clients and families, clinicians, industry partner (Wellwave), and dental office and research staff. A total of 146 children with autism, ages 4–12, were randomly assigned to either the 360° Video or social story intervention group prior to their dental visits. The attending clinician assessed dental visit completeness using a five-step checklist and participant behaviour on the Frankl behaviour rating scale. The primary outcome, visit completeness, was analyzed using a log-rank test to compare the two groups. The hazard ratio (HR) and 95% confidence interval (CI) were reported to assess the relative likelihood of visit completion. Pre-visit anxiety was measured using the State-Trait Anxiety Inventory for Children (STAI-CH), as filled out by the parents. Groups were compared using independent sample t-tests and the Wilcoxon Rank Sum test.

Results: A total of 130 participants (65 in each group) completed the study. Participants had a mean age of 7.0 (SD=2.3), with 32 girls (24.6%) and majority non-white participants (n=104, 86%). The group difference in visit completion rates was not statistically significant (Hazard Ratio: 1.35, 95% CI [0.86, 2.09], $p = 0.195$). There was no statistically significant difference in the pre-visit anxiety scores between the two groups ($p = 0.74$). The difference between groups on the Frankl scale approached statistical significance ($t = 1.81$, $p = 0.072$), suggesting a trend toward more positive behavior in the 360° video group. Parents of children in the 360° group reported higher satisfaction with the tablet experience ($p = 0.006$), though not significantly different for the children ($p = 0.12$).

Conclusions: This research introduces a new tool to prepare for clinic visits and contributes to the growing evidence on the use of VR in healthcare by exploring its role in preparing autistic children for dental visits. While both 360° video and social stories showed comparable outcomes in visit completeness and anxiety reduction, VR demonstrated a trend toward more positive behaviour, suggesting potential benefits that warrant further investigation. The positive feedback from parents in the 360° group suggests that the tool is well-received and appreciated as a useful resource. This can help foster better outcomes, improving the overall healthcare experience for autistic children and their families.

ClinicalTrials.gov ID NCT05196230

Community-Based Participatory Approach to Developing a Gamified Mobile Health Intervention for Increasing Physical Activity and Reducing Sedentary Behavior in Autistic Adults

L. K. McNulty¹, S. Kathiravan², M. L. Mauriello³, A. N. Bhat⁴, V. Vasudevan⁵, I. Obrusnikova³, R. R. Suminski¹ and D. Lee⁶, (1)Department of Health Behavior and Nutrition Sciences, University of Delaware, Newark, DE, (2)Physical Therapy, University of Delaware, Newark, DE, (3)University of Delaware, Newark, DE, (4)Department of Physical Therapy, University of Delaware, Newark, DE, (5)Autism Speaks, Gainesville, FL, (6)Health Behavior and Nutrition Sciences, University of Delaware, Newark, DE

Background: Despite the recognized importance of regular PA for overall health, a large proportion of autistic adults remain insufficiently active. Current research on strategies to enhance PA and reduce sedentary behavior (SB) in this population is limited and often lacks methodological rigor in the intervention design process. Gamified mHealth interventions offer a promising avenue for PA promotion, leveraging autistic individuals' strengths in visuospatial learning and predilection for digital gaming. Although the commercially available gamified apps show preliminary effectiveness in general populations, their long-term impact on PA and SB changes in autistic adults remains uncertain. Understanding the adoption challenges and transferability of mHealth interventions in real-world settings is essential to improve preventive health behaviors in this community.

Objectives: (1) To formulate gamification and behavior change techniques for PuzzleWalk app using a community-based participatory approach. (2) To assess the feasibility and acceptability of PuzzleWalk app in increasing PA and reducing SB among autistic adults, including those with mild intellectual disabilities (ID) in real-world settings.

Methods: Weekly participatory design workshops with seven autistic adults, one parent of an autistic adult child, and one speech therapist were conducted for 2-month to guide the development of PuzzleWalk app. Remote workshop sessions, including individual interviews and online surveys, evaluated the preferences and patterns of mobile technology use, applicable gamification and behavior change strategies to enhance user engagement and adherence, and the app's previous and current prototypes. Interview and survey findings were analyzed and incorporated into the PuzzleWalk system, followed by compatibility testing on various iPhone models. Thirty autistic adults (Mage 33.1±10.1; 80% females) recruited from the SPARK Research Match are currently participating in the 8-week field deployment study to assess the effects of PuzzleWalk app on increasing PA and reducing SB in real-world settings. Sedentary time, step counts, light PA, and moderate-to-vigorous PA are measured by ActiGraph Centropoint Insight Watches (Pensacola, FL) and user engagement (e.g., number of app login sessions and time for app use) is tracked via data server logs. Repeated measures ANCOVA will be used to examine the changes in participants' objective levels of PA and sedentary time before, during, and after the PuzzleWalk intervention.

Results: Usability beta testing revealed that nine participatory design workshop participants highly valued the app's step-tracking feature, leaderboard, and visual design, which boosted their motivation for PA engagement and fostered competition among users. Most participants felt the app helped increase PA, reduce SB, and provide a sense of achievement. Autistic traits like perfectionism and competitiveness influenced the level of engagement, sometimes enhancing motivation but also causing discouragement due to difficulty of puzzle games. Overall, the app was viewed as potentially beneficial for promoting PA and reducing SB in autistic adults. The results of the field deployment study will be provided with the live demo.

Conclusions: The PuzzleWalk app shows promise as an effective tool for enhancing both PA motivation and intervention engagement through tailored gamification and behavior change strategies. Ongoing field deployment results will further clarify the app's effectiveness and real-world applicability.

Examining Temporal Patterns of Physiologic Markers and Self-Reported Stress in Autistic Children and Their Parents in Daily Life
Z. Yu¹, S. Iadarola², K. Buettner², S. Daley³, K. Shamlan² and Z. Zheng¹, (1)University of Notre Dame, South Bend, IN, (2)University of Rochester Medical Center, Rochester, NY, (3)University of Rochester, Rochester, NY

Background:

Autistic children are prone to experiencing negative mental health outcomes, including stress. Their parents often experience greater stress compared to those raising children without disabilities. Parenting stress negatively affects families, increasing risks of physical ailments (e.g., cardiovascular disease) and mental health issues (e.g., depression). The temporal dynamics of children's stress and parents' stress in daily life are complex and remain largely unexplored. Mobile applications have been widely used to track daily activities and psychological health. Non-invasive wearable sensors have proven effective for ongoing physiological signal recording that may be used to extract stress markers. We proposed a data collection method using both technologies to explore the temporal pattern of both physiologic and psychological stress in autistic children and their parents in their daily lives. Understanding how these types of stress interact provides a reference for early stress detection and management, potentially mitigating physical and behavioral health risks.

Objectives:

This study aimed to 1) evaluate the feasibility of a self-reported stress data collection method by parents during daily interactions with their autistic children, and 2) explore the temporal stress pattern in autistic children and their parents.

Methods:

Figure 1 shows the framework of the proposed data collection method, with arrows indicating information flow. The framework consists of three modules:

1. Module I collects physiological data simultaneously from both the child and the parent using wearable sensors (e.g., Empatica E4 wristband).
2. Module II allows parents to report stress via a custom mobile application, securely uploading data to a database.
3. Module III synchronizes physiological signals with self-reported stress events, enabling temporal analyses.

Participating families wore the E4 wristband and recorded data for at least four days. Parents were encouraged to report stress using Module II during daily interactions.

Results:

Fourteen families participated and twelve of them completed data collection. The parents included 11 females and one male (Age (years): Avg = 44.3; SD = 6.96). All 12 autistic children were boys (Age (years): Avg = 9.33; SD = 1.96). Physiological signal analysis showed that the standard deviation of heart rate variability of both autistic children ($p = 0.04$) and their parents ($p = 0.04$) was significantly higher in periods when parents reported stressful events (Wilcoxon signed-rank test). Meanwhile, the temporal distributions of physiological stress markers in children and parents were coupled, as shown in Figure 2. While parents tended to have greater numbers of segments indicating physiological stress throughout most of the day and particularly during the mid-day period, the overall patterns and peaks tend to be synchronized. This pattern may stem from heightened arousal states associated with externalizing behavior and the emotional or physical strain on parents when managing these episodes.

Conclusions:

Our preliminary findings demonstrated the feasibility of the proposed data collection method in tracking stress in autistic children and their parents during daily life. The temporal stress patterns in children and parents seemed synchronized, revealing the importance of further analysis on the reciprocal dynamics of stress between children and their parents.

“Heels 2 Participation” Elearning Modules Toward Improving Community Participation in Young Adults with ID: Demonstration and Lessons Learned

D. V. Chan¹, H. Loeb², A. Marx², W. Morgan³ and B. Tomaszewski⁴, (1)Allied Health Sciences, University of North Carolina at Chapel Hill, Chapel Hill, NC, (2)Psychiatry, UNC TEACCH Autism Program, Chapel Hill, NC, (3)Psychiatry, UNC Frank Porter Graham Child Development Institute, Chapel Hill, NC, (4)University of North Carolina at Chapel Hill, Chapel Hill, NC

Background:

Adults with intellectual disabilities (ID), and autistic individuals with and without ID, have lower rates of vocational, recreational, and social activity after exiting the school system that endures into adulthood (Weiss et al., 2021; White & Forrester-Jones, 2020; Windsor et al., 2021). A significant barrier to improving participation outcomes for young adults with ID is the inability to scale up intervention programs that have shown success (Amado et al., 2013; Tint et al., 2017; Verdonschot et al., 2009) and the need for technology-driven interventions (Valencia et al., 2019). To bridge this gap, we translated our on-campus “Higher Education, Employment, and Living Success (HEELS) 2 Transition” curriculum targeting key areas of the transition to adulthood of self-management/goal setting, daily living, community safety, career, and mental health skills into web-based eLearning modules and a downloadable resource toolkit termed HEELS 2 Participation (H2P). H2P is designed to support community participation for young adults with ID, including autism, in an interactive, adaptive, and accessible web-based format that features narrative storytelling and gaming elements.

Objectives:

This technology demonstration will present the prototype for our H2P eLearning tool. Findings from qualitative research on pilot testing of H2P with young adults with ID and their care partners that informed design decisions, including functionality, usability, challenges, and content preferences will also be shared.

Methods:

Semi-structured virtual or in-person interviews were conducted with 15 dyads of young adults with ID, most (67%) who had co-occurring autism, and one care partner (a parent or family member) as part of prototyping the H2P eLearning tool to inform design decisions further. Study team members analyzed transcribed interviews to identify content preferences, acceptability, feasibility and usability (i.e., barriers and facilitators), and other emergent themes.

Results:

85.7% of young adults and 100% of care partners enjoyed using H2P. All young adults (100%) felt specific tools for goal planning and time management were helpful, most care partners did as well (92.3% and 83.3%, respectively). Preferences for eLearning content are seen in Figure 1, and show greater young adult preferences for life skills, self-management/goal setting, and mental health content compared to care partners, who reported community safety, interpersonal relationships, sexual health education and career development as priorities. Analysis of challenges in usability involved the need for speech-to-text function tools, more visual cues, and the importance of social and/or coaching support components in the learning process. Most participants liked the visuals, videos, virtual tools, and not relying on handwriting for learning. Care partners appreciated the interactivity, engaging graphics, potential for participants to return to materials and continual skill development, and the opportunity for participants to dream big for their goals.

Conclusions:

H2P is designed for use by young adults with ID, instructors, and supports to encourage attainment of individualized goals toward improved community participation. Findings from the pilot study suggest positive engagement in the eLearning modules and tools from participants and care partners, but points to continued development to improve functionality and usability. Plans for future testing will incorporate these design changes.

**Pressing Forward: Measuring Effort with a Progressive Ratio Task to Activate Music and Bubbles in Early Childhood**

M. McEllin, Y. C. Kuo, S. Agurcia, J. Kaste, J. Savino and C. C. Clements, University of Notre Dame, South Bend, IN

Background: The social motivation hypothesis of Autism Spectrum Disorder (ASD) posits that behaviors involving diminished attention to social stimuli (e.g., reduced eye contact, response to social sounds), commonly displayed by autistic individuals, lead to less motivation for and response to social learning opportunities (Chevallier et al., 2012). Early interventions for ASD to support learning rely on motivation for social and tangible rewards to shape behavior. However, many autistic children show modest gains after early intervention, perhaps due to individual differences in motivation. The developmental model of reward processing (Clements, Asuncion, and Nelson, 2023) deconstructs motivation and reward processing into six components, including effort, response, anticipation, and more. Effort can be studied behaviorally using the progressive ratio task (PRT), which requires progressively more input to receive rewarding output (e.g., mice pressing a lever 1, 2, 4, then 6 times to receive milk (Hodos, 1961)). We combined the progressive ratio with the classic infant mobile paradigm (Rovee et al., 1969) to create a developmentally appropriate PRT in which children press a button progressively more times to activate music and bubbles. PressMORE (pressing Measure Of Rewarded Effort) is an innovative infant- and child-friendly PRT designed to measure individual differences in effort to receive a reward. PressMORE is intended for repeat measurement in longitudinal studies to assess the development of effort, a key missing piece of the social motivation hypothesis with applications to early intervention.

Objectives: Develop a behavioral task to assess individual differences in effort in infants and children with varying abilities.

Methods: PressMORE was completed by children ages 3 to 5 years with typical development (n=29) and developmental concerns (n=9), which ranged from genetic conditions to ADHD and suspected autism. PressMORE tasks children with pressing a large red button with increasing amounts of effort (1, 2, 4, 6 presses and so on) to receive a display of bubbles and music. Effort is measured by the “breakpoint,” or the highest threshold (i.e., number of button presses) completed by the child. Caregivers completed the Social Responsiveness Scale (SRS-2 Preschool) to measure autistic traits in their child.

Results: All enrolled participants successfully completed PressMORE. A trend was observed such that for all participants, increasing age was correlated with increasing breakpoint ($r=0.28$, $p=0.09$), and this relationship appeared more pronounced in the small developmental concerns group ($r=0.63$, $p=0.06$; Figure 1). In contrast to our hypothesis, no relationship emerged between breakpoint and SRS-2 Preschool score ($r=0.0008$, $p=0.996$). Data collection is ongoing and PressMORE breakpoint data in additional autistic children will be available by April 2025.

Conclusions: PressMORE assesses, for the first time, individual differences in effort in early childhood with applications to understanding how reward processing develops and the social motivation hypothesis of autism. PressMORE demonstrated feasibility in 3-5-year-olds. Breakpoint may correlate with age and does not appear to correlate with autistic traits. Future directions include exploration of the relationship between breakpoint and developmental level, and validation of PressMORE with other hypothesized measures of effort, such as the Child Behavior Questionnaire.

The Impact of Stress on Autism: Exploring Self-Efficacy and Wellbeing with SAM the Stress Autism Mate

Y. Roke, Emerhese, ggz centraal, Almere, Flevoland, Netherlands

Background:

Autistic adults often experience higher stress levels compared to neurotypical adults, likely due to environmental changes and social pressures, which can impair daily functioning. They frequently employ passive coping strategies like avoidance or focusing on emotions, which may exacerbate their stress. Effective coping strategies are essential for stress reduction to improve mental and physical well-being. Current treatment approaches for autistic adults typically include psychoeducation, psychosocial counseling, and stress-signaling plans. However, these plans are often not suitable due to difficulties autistic individuals have in recognizing stress. To address this gap, the Stress Autism Mate (SAM) app was developed by GGz Centraal to assist autistic adults in recognizing stress and managing it through personalized coping strategies.

Objectives:

This study aimed to qualitatively explore the experiences of autistic individuals using the SAM app and evaluate its effect on their coping strategies. The research sought to answer two main questions: (1) What are the positive and negative experiences of autistic individuals using SAM? (2) How does SAM influence their coping skills?

Methods:

A phenomenological qualitative approach was employed through in-depth interviews with autistic adults aged 16 and older who used SAM for at least four weeks. Participants were selected from the autism expertise center of GGz Centraal (Emerhese) and Karakter, an academic center for child and adolescent psychiatry. Inclusion criteria included a formal diagnosis of Autism Spectrum Disorder, treatment at one of the centers, and the ability to reflect on their SAM experience. Ten participants (six women, four men, ages 17 to 63) were interviewed either digitally or in-person. Interviews were transcribed and analyzed using thematic analysis according to Braun and Clarke's six-step framework, with coding conducted using Atlas.ti software.

Results:

Participants generally reported higher stress awareness through SAM, noting that its regular questionnaires helped them identify stress triggers and gain insight into their stress patterns. SAM's visual stress gauge and personalized coping strategies were viewed as helpful in actively managing stress. Users described feeling more in control and disciplined due to the app's structured approach. Four main coping strategies were identified through SAM use: problem-focused coping, cognitive coping, distraction, and seeking social support. Positive feedback highlighted SAM as a neutral, supportive tool that facilitated stress recognition and provided actionable advice. However, several challenges were reported. Some participants found the frequency of the questionnaires overwhelming, leading to non-completion. Technical issues, were sources of frustration.

Conclusions:

SAM appears to be an effective tool for increasing stress awareness and promoting active coping strategies among autistic individuals. The app's structured approach helps users recognize stress and apply coping mechanisms more consistently. To maximize SAM's effectiveness, future developments should focus on improving the app's personalization features, addressing technical issues, and integrating its use more seamlessly into clinical practice. Further qualitative research with a broader participant base is recommended to refine SAM and explore its applicability to other populations. SAM is freely available in 33 countries and 7 languages.

www.stressautismmate.nl

A Full-Fledged Robotic Intervention, Robot for Autism Behavioral Intervention (RABI), to Enhance the Social and Emotional Well-Being of School-Age Autistic Children

W. C. So, Educational Psychology, The Chinese University of Hong Kong, Hong Kong, NA, Hong Kong (China)

Background:

Autism is characterized by difficulties with social interaction and communication. Treatment success lies in behavioral support, which is limited and carries high costs for families. Autistic children also have difficulty handling social stimuli, engaging with people and maintaining social relationships (social motivation theory of autism; Chevallier et al., 2012), and tend to have excessive reactivity to sensory stimulation from human-to-human interactions due to a particular form of brain hypertrophy (intense world theory; Markram & Markram, 2010). The intensity of sensory processing may be so overwhelming that these children may actively avoid interacting with humans, and instead focus on predictable features in their surrounding environment. Unlike humans, robots are operated in a predictable manner (Empathising-Systemising Theory, Baron-Cohen, 2009).

Objectives: This project develops a full-fledged robotic intervention, called Robot for Autism Behavioral Intervention (RABI), that aims to strengthen the social and behavioral skills of autistic individuals and facilitate their societal inclusion by applying science and technology. The RABI programme deploys the social robot “HUMANE”, which can communicate interactively in multiple languages, including English, Chinese, and Japanese, with facial expressions.

Methods: HUMANE is installed with RABI curriculum, which involves 12 modules, including selfcare, daily-use vocabularies, prosocial behaviors, basic and advanced emotional understanding and expression, basic and advanced conversation, narration, sexual education, anti-bullying, resilience, and vocational training. During each lesson, two social robots roleplay dramas and demonstrate appropriate social skills to learners. Children are then invited to engage in roleplay with the robots to practice the social skills. Empowered by Artificial Intelligence, the robots are programmed to respond to the learners spontaneously. Toward the end of each class, they participate in the learning activities with their human teachers, requiring them to generalize the acquired social skills to human interaction. Eventually learners discover how their initiations and responses influenced others’ behaviors.

Results: RABI’s effectiveness is empirically supported. Using an RCT approach, after 12 weeks of classes, RABI improves the narrative abilities of mild-to-moderate autistic preschoolers with normal IQ (number of clauses increased by 63.04%, proportion of complex clauses by 48%, percentages of stories with cognitive and emotional inferences by at least 30%, and number of gestures by 64.51%). These learning outcomes are maintained in the delayed post-tests and are not reported in the wait list control group. RABI improves not only spoken narrative abilities in experimental settings but also conversational skills in daily life. Indeed, RABI promotes parent–child interaction in mild-to-moderate school-age autistic children with a wide range of IQs. After 9 months of classes, RABI increases the number of conversational turns by 85.71% and the proportion of conversations initiated by the autistic children by 10%. Besides verbal skills, RABI enhances non-verbal communication such as joint attention and functional play behaviors. Even more promising, RABI has been shown to be more effective in promoting joint attention than human-based interventions.

Conclusions: The use of social robots provides autistic children with a supportive environment to learn social and communication skills. Given the empirical evidence, RABI can provide affordable and effective interventions for autistic individuals.

**Poster Session****436 - Adult Outcome: Medical, Cognitive, Behavioral II**

May 3rd, 2025, 12:30 PM - 1:30 PM - Hall 4A

436.001 Loneliness of Autistic Adults and Its Personal, Environmental, and Daily Social Correlates

W. Song¹, E. Brusilovskiy², J. Gifford¹, C. Carlton³, L. Shea¹ and M. Salzer², (1)A.J. Drexel Autism Institute, Drexel University, Philadelphia, PA, (2)Temple University, Philadelphia, PA, (3)AJ Drexel Autism Institute, Drexel University, Philadelphia, PA

Background: Loneliness, a growing public health concern, disproportionately affects autistic adults and results in more severe consequences compared to the general population. Loneliness is a subjective phenomenon in which one perceives their social connections as unsatisfying or inadequate. Loneliness is associated with several detrimental outcomes in mental and physical health. Research on loneliness among autistic adults has been limited, particularly regarding the contributions of personal, environmental, and daily social experiences among autistic adults. Identifying factors that impact loneliness is essential for facilitating the creation of effective, individualized support strategies.

Objectives: This study used ecological momentary assessment (EMA) to examine personal, environmental, and daily social correlates associated with loneliness.

Methods: Autistic adults aged 18 and over who were not in high school were recruited. Participants completed questionnaires measuring demographic variables, loneliness, personal psychological factors, and environmental factors. The 3-item UCLA Loneliness Scale was used to assess general levels of loneliness. EMA was used to assess momentary feelings of loneliness in daily life (“How do you feel right now?”- Lonely) from “not at all” to “extremely.” We calculated the EMA loneliness score by averaging these ratings across all EMA responses for each participant. EMA also captured daily social contexts – being alone, at home, and feeling invisible. The EMA period occurred over 14 days and involved 4 semi-random assessments per day between 9am and 9pm. A total of 32 participants (Table 1 for sample characteristics) completed the study by the abstract submission, providing 1,709 EMA data points, with an average of 53 surveys completed per participant (max of 56). Data presented is part of ongoing data collection, so a larger sample size will be included at the Meeting.

Results: UCLA and EMA loneliness had a moderate and significant correlation ($r_{\text{spearman}}=0.47$, $p=0.007$). Females had higher levels of UCLA loneliness compared to their male counterparts (Cohen’s $d=0.71$, $p=0.068$). Higher social responsiveness scale scores were associated with EMA loneliness ($r_{\text{spearman}}=0.37$, $p=0.039$). Proportions of EMA responses of being alone were positively correlated with EMA loneliness ($r_{\text{spearman}}=0.35$, $p=0.050$), while feeling invisible was correlated with both UCLA and EMA loneliness. Both loneliness measures were positively correlated with levels of stress, depression, generalized anxiety, and intolerance of uncertainty. Regarding environmental factors, better neighbor relations, higher satisfaction with services, and satisfaction with physical environments were negatively correlated with both loneliness measures. Additional multilevel analysis will be presented for INSAR.

Conclusions: Our findings emphasize the pivotal role of daily experiences, personal psychological characteristics, and environmental factors in understanding loneliness in autistic adults. It should be noted that self-reporting loneliness in-the-moment via EMA may be quite different than loneliness measured by questionnaires. Daily social experiences (being alone and feeling invisible) and personal psychological factors seem to have higher correlations with EMA loneliness than UCLA loneliness, except for self-efficacy. Correlations suggest that understanding the loneliness of autistic adults through different assessment methods is crucial for providing support for their mental well-being and quality of life.

436.002 Longitudinal Associations between Social Support and Quality of Life Among Middle-Aged and Older Autistic Adults: A Cross-Lagged Panel Analysis

W. Song¹, G. A. McQuaid², R. A. Charlton³ and G. L. Wallace⁴, (1)A.J. Drexel Autism Institute, Drexel University, Philadelphia, PA, (2)George Mason University, Fairfax, VA, (3)Psychology, Goldsmiths University of London, London, London, United Kingdom, (4)The George Washington University, Washington, DC

Background: Autistic adults often experience lower quality of life (QoL), particularly in social and psychological well-being, compared to neurotypical adults. Improving QoL has become a critical focus for both the autistic community and researchers/clinicians. As the population ages, there will be an increased demand for both formal and informal long-term supports that maximize QoL. Among the modifiable factors that may promote QoL, multiple studies have indicated that higher quality social support has been linked to better QoL among older autistic adults. However, all these studies have been cross-sectional; thus, little is known about the longitudinal, bidirectional relationship between social support and QoL for this population.

Objectives: This two-wave cross-lagged panel study aimed to examine the longitudinal association between perceived social support and subjective QoL among middle-aged and older autistic adults (40+ years) in the United States.

Methods: Participants were 201 autistic adults ($M_{\text{age}}=52.99$, $SD_{\text{age}}=9.25$) with a self-disclosed autism diagnosis, further validated by the Autism-Spectrum Quotient-28 (98.5% met the >65 threshold). All self-reported data were collected in December 2019/January 2020 (Time 1) and again in December 2021/January 2022 (Time 2). Subjective QoL was captured by the short form of the World Health Organization Quality of Life instrument (WHOQOL-BREF) and the Autism-specific Quality of Life measure (AQOL). An overall mean score for the WHOQOL-BREF was calculated by averaging the responses to all 24 items across its four domains. A total score was computed for the AQOL. Social support was measured using the 23-item Duke Social Support Index (DSSI), which includes three subdomains: Social Interaction, Subjective Support, and Instrumental Support. Cross-lagged panel models (CLPM) were run to examine longitudinal associations between the social support subdomains and QoL measures accounting for assigned sex, Time 2 age, and perceived pandemic stress (only at Time 2).

Results: At both Time 1 and Time 2, social support subdomains were positively correlated with the WHOQOL and AQOL (see Table 1). Repeated measures ANOVA showed that subjective support marginally but significantly increased (3.29 vs. 3.40), $p=0.019$, while there were no significant changes in social interaction and instrumental support. There was also a significant increase in both WHOQOL (75.44 vs. 79.56, $p<0.001$) and AQOL (23.73 vs. 25.23, $p<0.001$) scores. The CLPM analysis revealed a bidirectional relationship between subjective support and AQOL, where each predicted the other at the subsequent time point (Figure 1a). Time 1 AQOL also predicted instrumental support at Time 2. Time 1 WHOQOL significantly predicted subjective support at Time 2, but the reverse was not true (Figure 1b).

Conclusions: In this unique longitudinal study of middle-aged and older autistic adults, findings indicate that increasing subjective social support plays a crucial role in improving autism-specific QoL, and that both autism-specific and overall QoL predict later levels of subjective social support. Further investigations are needed to evaluate how modifying different types of social support influence QoL in older autistic adults as we seek to optimize aging outcomes.

436.003 Longitudinal Characterization of Changes in Autistic Features over Time in the AIMS LEAP Cohort

L. Colomar¹, J. Tillmann², J. K. Buitelaar³, T. Charman⁴, M. Parellada⁵, E. Jones⁶, E. Loth⁷, D. Murphy⁸ and B. Oakley¹, (1)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (2)Neuroscience and Rare Diseases (NRD), Pharma Research & Early Development, Roche Innovation Center Basel, F. Hoffmann-La Roche AG, Basel, Switzerland, (3)Department of Cognitive Neuroscience, Donders Institute for Brain, Cognition and Behaviour, Radboud University Nijmegen Medical Center, Nijmegen, NETHERLANDS, (4)Department of Psychology, Institute of Psychiatry, Psychology & Neuroscience, King's College London, London, United Kingdom, (5)Hospital General Universitario Gregorio Marañón, Madrid, Spain, (6)Centre for Brain and Cognitive Development, Birkbeck University of London, London, United Kingdom, (7)Department of Forensic and Neurodevelopmental Sciences, Flat 2, 116, South Hill Park, London, London, United Kingdom, (8)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, UNITED KINGDOM

Background: The design of effective personalized support strategies across age requires us to better understand the evolution of core autistic features over time. Previous longitudinal studies have mainly reported stability in autistic core features, with only a small subgroup of autistic people exhibiting significant changes in these features over time. However, variability in autistic features varies widely between studies (with reports ranging from 10% to 50% of participants experiencing significant changes). Further research with large, well-characterized cohorts is needed to identify individual developmental profiles from childhood to adulthood.

Objectives: To describe the changes in core autistic features in a sample of 452 autistic participants (27.21% female) across diverse developmental stages from the EU-AIMS/ AIMS-2-TRIALS Longitudinal European Autism Project (LEAP; Development in children and adults – LEAP (aims-2-trials.eu)), encompassing accelerated cohorts of children (6-11 years), adolescents (12-17 years), and adults (18-30 years).

Methods: We assessed stability/change in autistic features—including social-communication differences, restrictive and repetitive behaviours (RRB), and sensory processing—using the Autism Diagnostic Observation Schedule – 2nd Edition (ADOS-2), Social Responsiveness Scale – 2nd Edition (SRS-2), and Short Sensory Profile (SSP). We calculated the difference in scores on these measures between two timepoints, ~12-to-24 months apart, and set a significant change threshold at half the standard deviation of the baseline scores. Subsequently, participants were classified into three groups: stable, increasing, or decreasing traits intensity. We then analyzed how these change groups related to sex, age, and intellectual quotient (IQ), and examined both cross-sectional correlations among symptom domains and how longitudinal change in one domain correlated with change in others. To ensure the generalizability of our findings, we employed a hold-out method (70/30 test/hold-out sample). Currently, we are expanding our analysis to include data from a third timepoint up to 7-years after initial assessment (Figure 1).

Results: In the test sample, we observed a consistent pattern across autistic features measures, with most participants (>55%) following a stable trajectory, and smaller groups showing significant changes (Table 1). No significant associations were found between changes in autistic features and age, sex, or IQ. Cross-sectionally, we identified strong correlations between the SRS Social Communication and Interaction (SCI) and RRBs sub-scale scores ($r = 0.82$; $p < 0.01$), SRS SCI and SSP total scores ($r = -0.60$; $p < 0.01$), and SRS RRBs and SSP ($r = 0.61$; $p < 0.01$). Similarly, longitudinally we identified significant associations between change in SRS subscales ($r = 0.63$; $p < 0.01$), in SRS SCI and SSP total scores ($r = -0.62$; $p < 0.01$), and in SRS RRBs and SSP total scores ($r = -0.52$; $p < 0.01$). These results were replicated in the hold-out sample.

Conclusions: Our findings demonstrate stability in autistic features in most people over time. However, smaller subgroups of individuals exhibit significant change (with ~ 25 – 40 % showing either a significant decrease or increase in differing features). Changes in autistic features were not associated with age, sex, or IQ. Identifying distinct profiles within the autistic population may inform more personalized support strategies for specific groups.

**436.004** Luck and Judgement: Analysing the Lived Experiences of Autistic Student Teachers.

R. V. Davis¹, C. Jack² and C. Blaisdell¹, (1)Division of Psychology, Sociology & Education, Queen Margaret University, Edinburgh, United Kingdom, (2)Queen Margaret University, Edinburgh, Edinburgh, United Kingdom

Background: While research highlights the importance of autistic and neurodivergent teachers as key facilitators of inclusive educational environments, autistic educators are more likely to leave the teaching profession than neurotypical students. Furthermore, autistic students are more likely to leave or divert from their initial course of study and face disproportionate hurdles to qualification even than their otherwise neurodivergent peers.

Previous studies examined the experiences of neurodivergent students in other professional degree programmes, such as healthcare. Yet there is a dearth of research considering the specific lived experiences of student teachers navigating both university and education placement settings throughout their programmes of study. Here we addressed this knowledge gap by using qualitative methods to understand the lived experiences of autistic student teachers.

Objectives: The overall aim of this research was to identify key barriers and enablers for autistic students in programmes leading to careers in education.

Methods: Fifteen autistic adults currently enrolled on Undergraduate or Postgraduate Education programmes in the UK participated in this study (mean age = 22 years, 10 female, 4 male, 1 non-binary). Nine students disclosed having an ADHD diagnosis in addition to being autistic. Neurodivergent consultants with relevant lived experience shaped the interview questions and interview process. Participants completed an online semi-structured interview ($n=13$) or an open-ended survey ($n=2$) depending on communication preferences. Data was analysed using Reflexive Thematic Analysis following the six phases of analysis Braun and Clarke (2022). Crucially, this method incorporated lead researcher's own neurodivergent lived experience as a methodological lens.

Results: Three key themes were generated from this data: (1) The Role of Luck – particular aspects of placement, such as school inclusivity and ethos, receipt of accessible information and commute time, were identified as being key for success but were highly influenced by luck. (2) The Role of Judgement – reactions to disclosure, stigmatizing views of neurodivergence and not fitting the 'teacher type' mould were identified as influential aspects of placement experiences that were influenced by fear of negative judgement. (3) The Role of Equity – consistency of mentoring, capacity considerations and transition requirements were identified as areas crucial for course success, but where students lacked equity of access.

Conclusions: This study builds on recommendations from previous findings that qualitative research must better understand the experiences and needs of this under-served community. Here, we extend knowledge in this area by identifying key areas for change to improve placement and educational experiences for autistic student teachers. Results highlight the difficulties autistic students experience when trying to access support to complete their degrees and move into the teaching profession. We identify ways to reduce barriers and improve the capacity of this population. Implementing these much-needed changes in key areas will support sustained, successful programme attendance, subsequent professional qualifications, and retention pre- and post-graduation. Amplifying autistic voices and experiences is key to encouraging necessary change, and the changes identified here can increase positive representation of this community within the profession.

436.005 Divided Attention Advantage in the Broader Autism Phenotype

E. Gurcan¹ and **M. D. Rutherford²**; (1)McMaster University, Hamilton, ON, Canada, (2)Psychology, Neuroscience & Behaviour, McMaster University, Hamilton, ON, Canada

Background:

Adults with autism have an advantage in divided attention tasks compared to a control group (Rutherford et al., 2009). The Broader Autism Phenotype (BAP) refers to sub-clinical autistic traits that are more common in relatives of individuals with autism compared to the general population.

Objectives:

This study was designed to test for a UFOV advantage among adults with not autism diagnosis but with autism in the family (BAP), and a relationship between characteristics of autism (the AQ) and UFOV performance.

Methods:

We replicated Rutherford et al. (2007)'s UFOV paradigm, which involves perceiving central and/or peripheral targets under focused and divided attention. In the divided attention task, both targets were presented, whereas in the focused attention task, only one target was presented. Participants were 12 parents with autism in the family (Mean = 39.58 years, SD = 6.14; 3 male, 1 gender-fluid, 1 non-binary, 7 female) and 9 parents without autism in the family (Mean = 38.89 years, SD = 2.47; 5 male, 4 female).

Results:

Attention type (divided or focused) on the central task was significant, $F(1, 122) = 458.46, p < .001, \eta^2 = 0.78$, as was the AQ cutoff, $F(1, 122) = 4.24, p = 0.042, \eta^2 = 0.03$; however, their interaction was not. Parents who scored above 26 on the AQ performed more accurately (mean difference (MD) = 0.07, $p = 0.042$). There was no BAP effect on accuracy; only attention type was significant, $F(1, 122) = 433.94, p < .001, \eta^2 = 0.78$ in that model.

In the reaction time (RT) analysis, neither AQ nor attention type significantly predicted it. However, only BAP predicted RT, $F(1, 122) = 7.56, p = 0.007, \eta^2 = 0.06$ and the BAP group were faster detecting central targets (MD = -0.43, $p = 0.007$).

In the peripheral task, both attention type $F(1, 185) = 21.77, p < .001, \eta^2 = 0.11$, and AQ $F(1, 185) = 12.84, p < .001, \eta^2 = 0.06$ predicted accuracy, with those above the AQ cutoff performing better (MD = -0.054, $p < 0.001$). For BAP, only the attention type predicted accuracy, $F(1, 185) = 20.54, p < .001, \eta^2 = 0.10$, indicating no advantage of genetic-relatedness.

Attention type ($F(1, 185) = 4.00, p = 0.047, \eta^2 = 0.02$), and AQ, ($F(1, 185) = 4.85, p = 0.029, \eta^2 = 0.03$) both predicted RT. Parents were faster in focused (MD = -0.17, $p = 0.047$), and parents above the AQ cutoff performed faster (MD = -0.21, $p = 0.029$). There was a main effect of BAP on RT, $F(1, 185) = 3.92, p = 0.049, \eta^2 = 0.02$ and the BAP group was faster (MD = -0.17, $p = 0.049$).

Conclusions:

Our preliminary results support Rutherford et al.'s (2007) findings and demonstrate advantages in divided attention based on autism characteristics. Our findings suggest that autism characteristics are associated with better performance on target detection and faster peripheral target detection. However, familial history was related with the only shorter reaction times.

436.006 Medication Usage in Adults Presenting for Autism Diagnostic Assessment: A Retrospective Chart Review

A. Li¹, **A. Porthukaran¹**, **Y. Lunsky²**, **A. Tafler¹**, **K. Jackson¹** and **P. Desarkar³**; (1)Centre for Addiction and Mental Health, Toronto, ON, Canada, (2)Arieli Adult Neurodevelopmental Centre, Centre for Addiction and Mental Health, Toronto, ON, Canada, (3)Department of Psychiatry, University of Toronto, Toronto, ON, Canada

Background: Autistic individuals have high rates of psychotropic medication usage and polypharmacy (concurrent use of two or more psychotropic medications) (Jobski et al., 2017). Some research has found prescription trends to be associated not only with co-occurring psychiatric conditions, but also with gender (Huber et al., 2022). Autism is typically diagnosed in early childhood; however, some individuals (particularly women) are not identified and supported until adulthood. Late-diagnosed individuals have worse mental health outcomes, and remain an underserved population (Rim et al., 2023). Delayed diagnosis during elementary years has been associated with increased medication usage, however little is known about the impact of adult diagnosis on prescription patterns (Zuckerman et al., 2017).

Objectives: Identify patterns in psychotropic medication usage and polypharmacy in adults newly diagnosed with autism, at the time of assessment. The most prevalent psychotropic medication classes used, as well as rates of polypharmacy will be explored. We examine variables including sex and gender, as well as co-occurring mental health conditions.

Methods: We conducted a retrospective chart review of adult autism diagnostic assessments performed at Adult Neurodevelopmental Services in Centre for Addiction and Mental Health in Toronto, Ontario from Jan 2023 – Dec 2023. Of 203 assessments, 183 individuals were diagnosed with autism. Individuals with co-occurring intellectual disability were excluded. Demographic information and co-occurring psychiatric conditions, as well as prior and current psychiatric medications were collected. To our knowledge, this is the largest retrospective chart review examining adult autism diagnostic assessments in a single outpatient setting to date.

Results: Of 183 individuals who received a diagnosis of Autism, 63.9% were using a psychotropic medication at the time of diagnostic assessment. Of those using medications, 47% were using 1 medication, and 53% were experiencing polypharmacy. The most common class of medications prescribed were SSRIs (26% of participants), followed by stimulants (23%), other anti-depressants (17%) and atypical anti-psychotics (14%). Medication use did not differ by gender identity, however participants assigned female at birth were more likely to be using medications.

Medication use was associated with co-occurring ADHD, $X^2(1, N=183) = 6.854, p=.009$, anxiety disorder $X^2(1, N=183) = 9.437, p=.002$, bipolar disorder $X^2(1, N=183) = 10.572, p=.001$, and borderline personality disorder $X^2(1, N=183) = 7.273, p=.007$. Depression was not associated with medication use. Of those using medications, participants with bipolar disorder were more likely to be experiencing polypharmacy, $X^2(1, N=117) = 4.402, p=.036$. A logistic regression was performed to test whether sex, gender and co-occurring psychiatric conditions would predict medication usage. Sex assigned at birth ($B = 1.068, p=.032$), ADHD ($B = 1.104, p=.003$) and anxiety disorder ($B=.793, p=.044$) emerged as significant predictors.

Conclusions: The rates of medication usage and polypharmacy in late-diagnosed adults at time of assessment are comparable to that of the general autistic population. SSRIs were the most prescribed medication class in our late-diagnosed cohort, compared to anti-psychotics in the general autistic population. Sex assigned at birth, ADHD and anxiety disorder were identified as predictors of medication use.

436.007 Mental Health and Service Use Among Cisgender and Sexual and/or Gender Minority Autistic Young Adults

S. Brammell¹, S. Sivathanan², M. J. Crown³, E. Rutenber⁴, C. M. Conner¹, K. B. Beck¹, D. Rofey¹ and C. A. Mazefsky¹, (1)Department of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, PA, (2)Counseling, Developmental, and Educational Psychology, Boston College, Chestnut Hill, MA, (3)Department of Occupational Therapy, Boston University, Boston, MA, (4)Dietrich School of Arts and Sciences, University of Pittsburgh, Pittsburgh, PA

Background: Mental health challenges are highly prevalent among autistic adults, with recent estimates indicating that up to 50% of autistic adults experience at least one psychiatric disorder. Approximately around a third of autistic adults identify as a sexual and/or gender minority (SGM), with recent work suggesting that SGM autistic adults have worse mental health outcomes compared to cisgender heterosexual (CisHet) autistic adults. This is particularly concerning given the multitude of barriers that autistic adults encounter when seeking quality mental health care. Yet, few studies have explored the intersectional impact of being both autistic and having an SGM identity related to mental health services utilization.

Objectives: This study aimed to examine participant characteristics, mental health history, and patterns of mental health service utilization among SGM and CisHet autistic young adults.

Methods: Secondary data analyses were conducted with a subset of autistic young adults recruited to a larger, measurement development and online psychometric study of the Relationship, Employment, Autonomy, and Life Satisfaction measures. SGM ($n=91$) and CisHet ($n=119$) autistic participants (18-25 years) were identified from that dataset. Self-report measures of measures of sociodemographics, mental health history, and current anxiety and depression symptoms were compared across SGM and CisHet groups using chi-square, t-tests, and regression analyses.

Results: Of 210 autistic young adults, 91 participants comprised the SGM group ($M_{age}=22.9$ years) and 119 comprised the CisHet group ($M_{age}=22.3$ years). Analyses revealed a negligible, though statistically significant, group difference in age ($p=.035$), and no group differences in race/ethnicity (78% White Non-Hispanic/Latine). The SGM group was more likely to have higher education, be in a committed relationship, and prefer 'identity-first' language concerning autism, whereas the CisHet group had less education, were single/dating, and preferred 'person-first' language to refer to autism.

Overall, SGM autistic adults endorsed significantly higher rates of mental health diagnoses ($M=3.1$) than CisHet autistic adults ($M=2.3$), $p=.003$. While both groups reported high rates of bipolar disorder, OCD, and ADHD, the SGM group was more likely to report higher rates of depression (62% SGM; 44% CisHet; $p < .001$), anxiety (88% SGM; 59% CisHet; $p < .001$), and PTSD diagnosis (39% SGM; 20% CisHet; $p=.003$). The SGM group also had greater current anxiety ($p=.005$) and depression ($p<.001$) symptoms than the CisHet group, even after controlling for age. Both groups were equally likely to be utilizing some type of mental health services, however, service type and medication used differed by group. For example, the SGM group was more likely to utilize individual therapy ($p=.01$) and antidepressants ($p=.004$).

Conclusions: Nearly half (43%) of young autistic adults identified with an SGM identity. Both SGM and CisHet groups reported significant mental health challenges yet comparable mental health service utilization. Ultimately, extending beyond efforts to support the mental health needs of both autistic and LGBTQIA+ populations, it is critical that future research identifies specific barriers to care resulting from the intersectional impact of SGM identity among autistic adults.

436.008 Modified CBT and Quality of Life for Autistic Adults

K. Whaling¹, G. Veed^{1,2}, E. T. Crehan³ and R. L. Loftin⁴, (1)Prosper Health, New York, NY, (2)University of Wisconsin, Parkside, Kenosha, WI, (3)Eliot-Pearson Department of Child Study & Human Development, Tufts University, Medford, MA, (4)Prosper Health, Chicago, IL

Background: Autistic adults are at a high risk for anxiety, depression, and other mental health concerns for which cognitive behavioral therapy (CBT) is a go-to treatment (e.g., Maddox et al, 2021). Measurement of disorder-specific symptoms (such as PHQ-9 or GAD-7) may be useful in capturing change in symptoms associated with a diagnosis over time, but they do not give global information about the client's functioning. Quality of life (QoL) is an important metric in assessing therapy outcomes.

Objectives: The study sought to see whether CBT modified for autistic adults yielded positive changes in QoL ratings. The hypothesis was that mood, anxiety, and overall sense of well-being would show improvement, and only a small change was expected in social relationships. Participation in an education group, which provided opportunity for community with other autistic adults was expected to have a further modest impact on QoL scores, which they have in preliminary analyses.

Methods: At intake and sessions 4, 8, 16, and 24, therapy clients ($n = 900$) completed QoL ratings on a 5-point Likert scale. Ratings in the domains of social relationships, mood, anxiety/worry, and overall sense of well-being after different numbers of sessions will be compared to scores at intake. In addition, participants were able to self-select into education sessions led by autistic clinicians. In the education sessions, participants had the opportunity to interact with other recently diagnosed autistic adults. Multilevel modeling will be used to examine the within-subjects change from intake score over number of sessions nested within groups that participated in the education group and those who did not.

Results: Data are preliminary at the time of submission and will continue to amass until analyses are performed before the conference date. At present, 636 participants have completed baseline data and 108 participants have completed QoL ratings after the 8th session. Results will discuss: (a) descriptive statistics of the sample, (b) discussion of the data structure, (c) details on model specification and software (MILwiN), (d) justification of the multilevel analysis, (e) model estimations and assumptions. The comparison to baseline for each QoL measure will be reported, as well as information obtained about whether the change is linear over time.

Conclusions: The different trajectories of QoL change over number of CBT sessions will be discussed, as well as comparison of different aspects of QoL (e.g., mood vs social relationships). Comparison of observed QoL change with CBT in an autistic population to what is typically described in neurotypical populations will be discussed. The added benefit, if any, of education sessions will be discussed. Specific implications based on the findings and their usefulness to researchers, clinicians, the autistic community, and other stakeholders will be discussed, as will limitations and future research.

436.009 Navigating Autistic College Students' Identity Formation in Their Journey of Career Development

Y. Jiang¹, B. E. Cox¹, K. Ball¹ and B. R. Nachman², (1)Michigan State University, East Lansing, MI, (2)University of Pittsburgh, Pittsburgh, PA

Background:

Existing studies on autistic college students' experiences focus on general identity development and institutional support (Coleman, 2018; Cox et al., 2017), while limited research interrogates these students' preparedness for post-graduate employment. The current focus of career development is on individual motivation and interests (Meijers, 1998), while few studies have discussed the impact of socioeconomic environment on this population's career development.

Objectives:

Based on major critical arguments about the medical deficit-based model of interpreting autistic identity (Cox et al., 2017; Kapp et al., 2013), this study explores autistic college students' identity formation in the process of career development by examining the interplay between environmental factors and individual agencies. This research contributes to critiquing the deficit-based model of autism by highlighting structural barriers and social misconceptions for autistic students' career choices and discovering these students' agency and advocacy in seeking career support.

Methods:

Our study adopted a mixed-method design, achieving 509 valid survey responses, 43 interviews, and 35 photovoice entries (see Table 1 attached). We compared autistic students' perspectives of successful employment and students' actual achievements (0 as very unsuccessful to 7 as very successful) on topics such as "having a job as others respect" with a paired-sample t-test. We analyzed qualitative interviews to understand their explanation of career exploration and identity development at the college. The team developed codebooks and coded transcripts independently, followed by group meetings to refine codes and establish consensus to ensure consistency and transferability of the study.

Results:

Our study found that autistic students experienced social barriers when pursuing their career explorations. The t-test showed that participants rated their success in getting a respected job ($M = 4.31$, $SD = 1.54$) 1.31 points higher than the importance of this goal for college success ($M = 4.00$, $SD = 1.99$). In the follow-up interviews, participants like Orange shared that job expectations from other people contained misconceptions about the labor market and biases against the competencies of autistic students to take the role: "I stopped telling people I wanted to be an actor and I've started telling people I wanna be a psychologist, just because I get less, like 'are you sure about that' reactions?"

Correspondingly, autistic students developed advocacy identity in academic and career development when they planned to use knowledge and skills to benefit the research and practice of the autistic community. For instance, after receiving suggestions from their advisor, Jeremy decided to major in rehabilitation, since it was "more broad, flexible, and focused ... (where I can) learn more about real-life situations (about autistic youth and adults)".

Conclusions:

The paper extends the current critique of the deficit-based model of autism. Our paper explores how autistic students navigate their career development in the face of structural oppression that limits the agency needed for such development to occur. Practically, our findings encourage colleges and student services to rethink their policies and accommodations for supporting autistic students' academic and career development.

436.010 Navigating Intersectionality: Quality of Life Among Autistic Adults with Multiple Marginalized Identities

M. J. Barrett¹, A. B. Ratto² and A. Jack¹, (1)George Mason University, Fairfax, VA, (2)Center for Autism Spectrum Disorders, Children's National, Washington, DC

Background:

The autistic community has identified quality of life (QoL) as a top research priority, and previous studies have shown that autistic people often report lower QoL compared to their nonautistic peers (Beck et al. 2023). Research highlights that individuals with stigmatized identities (e.g., race or gender) encounter more stressors and barriers that can further diminish QoL (Reinka et al., 2020). Autism itself is often stigmatized, yet there remains a significant gap in understanding how having multiple marginalized identities might compound these challenges. Examining this could offer valuable insights into unique stressors faces by this population.

Objectives:

To examine the relationship between holding one or more marginalized identities and autistic adults' self-reported QoL.

Methods:

Participants included 200 autistic ($n=126$) and non-autistic ($n=74$) adults (18-35y) from Wave 2 of the longitudinal GENDAAR cohort (54% assigned female at birth [AFAB], 26% Black or Latine). They completed the World Health Organization Quality of Life brief version (WHOQoL-BREF), a subjective measure of QoL in four domains: Physical Health, Psychological Well-Being, Social Relationships, and Environment. We used a linear regression model in SPSS v.29.0.2.0 to analyze the main effects and two- and three-way interactions of sex assigned at birth (SAB), autism status, and ethnoracial identity for each domain; standard errors were HC3-corrected to address heteroscedasticity concerns in models predicting Psychological Well-Being and Environment.

Results:

Physical Health. Consistent with our hypothesis, we found a main effect for autism status, $F(1, 192)=21.83, p<.001$, showing autistic individuals reported lower subjective physical health. There was a two-way interaction between SAB and autism status, $F(1, 192)=3.83, p=.036$, with AFAB autistic people reporting lower scores. The three-way interaction among ethnoracial identity, SAB, and autism status was marginal, $F(1, 192)=3.83, p=.056$, with Black or Latine AFAB autistic people trending towards reporting poorer physical health.

Psychological Well-Being. Consistent with our hypothesis, there was a main effect of autism status, $t=-2.76(1), p=.006$, with autistic individuals reporting lower subjective psychological well-being. Contrary to our hypothesis, there were no significant interactions.

Social Relationships. Consistent with our hypothesis, there was a main effect for autism status, $F(1, 192)=12.69, p<.001$, such that autistic individuals reported lower or poorer subjective social relationships. Contrary to our hypothesis, we found no significant interaction effects.

Environment. There was a main effect of autism status, $t=-2.82(1), p=.005$, consistent with our hypothesis, such that autistic individuals reported poorer subjective environments. Contrary to our hypothesis we found no significant interaction effects.

Conclusions:

Our findings indicate, consistent with previous research, that autistic people report lower subjective quality of life across all well-being domains.

With regards to intersecting identities, the domain in which this appears to be most relevant is physical health. We found that AFAB autistic people report significantly poorer physical health, with a trend towards AFAB Black or Latine indicating worse physical health than other assessed groups. Our findings suggest that public health policy and future research should provide increased focus on the physical well-being of autistic people.

AFAB autistic individuals in particular may require additional support around physical health needs.

436.011 Navigating Uncertainty: Autistic Adults' Perspectives on Their Quality of Life during the COVID-19 Pandemic

X. Jiang and **S. R. Cohen**, *University of California - San Diego, La Jolla, CA*

Background: While it has been suggested that autistic individuals may be less affected by social restrictions due to lower motivation for social interactions, many reported increased feelings of isolation and negative mental health impacts during the COVID-19 pandemic (Pellicano et al., 2022). Some relied on family and friends for mental health support (Stewart et al., 2023). Few studies were conducted during the later stages of the pandemic, and fewer addressed multiple life domains such as social, educational, and employment contexts (Bal et al., 2021; Mosquera et al., 2021). This study provides a broad understanding of autistic adults' quality of life across these areas during COVID-19.

Objectives: The purpose of this qualitative study was to understand autistic adults' perspectives on their quality of life during the pandemic. We specifically examined autistic adults' mental health and sense of belonging in social, educational, and employment settings.

Methods: Participants were recruited from a large sample of autistic adults who had taken part in a summer computer game development internship at a local university in the western United States. Fourteen autistic adults, aged 19 to 32, participated in the study. Participants reported being either in high school or college when the pandemic began. Each participant completed a semi-structured interview lasting between 20 to 45 minutes during the summer of 2023. Interviews were audio-recorded and transcribed verbatim. A theme-based approach was used for data analysis and coding (Braun & Clarke, 2006). A codebook was developed, detailing all the themes, their definitions, and example excerpts. The interview transcripts were coded using the Dedoose software tool.

Results: Thematic analysis identified four key themes: (1) Emotional well-being and mental health support, (2) Social interactions and relationships, (3) Sense of belonging in educational settings, and (4) Inclusion and exclusion in employment. First, autistic adults reported diverse mental health experiences. While some faced challenges like worsening depression, others noted positive aspects, such as increased personal focus due to reduced social interactions. However, many struggled to find therapists who could adequately support their mental health needs. Second, although some participants had limited social lives before the pandemic, they experienced deeper feelings of loneliness and isolation during the pandemic. Most relied on social media or online platforms (e.g. Discord) to maintain relationships with friends. Third, while some participants were satisfied with online classes and felt supported by their teachers, they expressed a desire for deeper peer connections that could only be achieved through in-person interactions. Finally, remote work made it difficult for autistic adults to access support for job-related tasks. They suggested that workplaces organize more social events to help them connect with coworkers.

Conclusions: The varied emotional and mental health experiences of autistic adults during the pandemic highlight the need for accessible, neurodiversity-affirming mental health support such as individualized counseling. Both educational institutions and workplaces should adopt inclusive, flexible models that promote meaningful connections and community, ensuring autistic adults receive the support needed to thrive.

436.012 Negative Automatic Thoughts, Emotion Regulation, and Anxious and Depressive Symptoms in Autistic Adults

V. V. Izaac^a, B. Carik^a, E. Rho^a and A. Scarpa^a, (1)Department of Psychology, Virginia Polytechnic Institute and State University, Blacksburg, VA, (2)Virginia Tech Department of Psychology, Blacksburg, VA, (3)Virginia Tech, Blacksburg, VA, (4)Department of Psychology, Virginia Tech, Blacksburg, VA

Background:

Theoretical frameworks based in Cognitive Behavioral Therapy postulate negative cognitions arise in reaction to life stressors. These negative thinking patterns may lead to significant psychopathological symptoms, including anxiety and depression (Buschmann et al., 2017). Anxiety and depressive disorders are two of the more prominent co-occurring conditions experienced by autistic adults and have been linked to repetitive negative thinking (McKenney et al., 2023). Emotion regulation (ER) is a transdiagnostic feature found in anxiety/depression, and autistic adults are more likely than their neurotypical peers to use maladaptive emotion regulation strategies, including less cognitive reappraisal and more expressive suppression (Cai et al., 2018). However, the relationships among negative automatic thoughts (NAT), ER strategies, and anxiety/depression have not yet been tested in autistic adults.

Objectives:

1. To evaluate the relationships between NAT, ER, and anxious and depressive symptoms; and,
2. To test whether ER serves as a mediator between NAT and anxious or depressive symptoms.

Methods:

The current study included 144 autistic adults (62 females, 52 males, 30 other-reported gender; Mage= 38.06 years; SD age= 12.47; 54.5% White) who were recruited as part of a larger online study through Simons Powering Autism Research (SPARK) Research Match (<https://sparkforautism.org/portal/page/spark-research-match/>). To be eligible, individuals needed to self-report an autism diagnosis and score above the clinical cutoff on the Autism Spectrum Quotient – 10 items (AQ-10; Allison, Auyeung, & Baron Cohen, 2012). Eligible participants then completed the Automatic Thoughts Questionnaire-8 (ATQ-8; Netemeyer et al., 2002), the Emotion Regulation Questionnaire (ERQ, Gross & John, 2003), and the PROMIS measures of Anxiety and Depression (Cella et al., 2010). The ERQ consisted of cognitive reappraisal and expressive suppression subscales. Correlations were used to examine relationships among the variables, while Process Macro (Hayes, Allison & Alexander, 2014) was used to examine the direct and indirect effects of NAT on anxious and depressive symptoms as mediated by ER strategies.

Results:

Correlations indicated significant relationships between depression and anxious symptoms, as well as anxious and depressive symptoms with NAT (Table 1. The overall models for both anxious symptoms (Figure 2a) and depressive symptoms (Figure 2b) were significant, indicating that 25% of the variance for anxiety and 56% of the variance for depression were explained by the full model of NAT, cognitive reappraisal, and expressive suppression. While there were significant main effects showing positive relationships of NAT both with anxious symptoms, $\beta=.45$, $p>.001$, and with depressive symptoms, $\beta=.65$, $p>.001$, no direct or indirect effects for cognitive re-appraisal or expressive suppression emerged.

Conclusions:

The results indicate significant relationships between negative thinking and anxious/depressive symptoms in autistic adults, consistent with prior findings. However, cognitive reappraisal and expressive suppression do not appear to mediate these relationships. Future work might consider the moderating role of ER, and the possibility that autistic adults use alternative ER strategies. These findings have implications for intervention strategies for anxious and depressive symptoms in this population, as negative thinking patterns may need to be targeted more directly than ER strategies.

**436.014 Outcomes of People Who Received ABA Therapy: Life Satisfaction and Camouflage**

G. N. Michel and I. M. Eigsti, Psychological Sciences, University of Connecticut, Storrs, CT

Background: Some individuals diagnosed with autism spectrum disorder (ASD) early in life via gold-standard methods go on to lose the autism diagnosis (LAD) as adolescents (Fein et al., 2013). LAD individuals are more likely to have received applied behavior analysis (ABA) therapy than those who retain the diagnosis (Orinstein, et al., 2014). Interventions like ABA can enhance functional and adaptive skills, likely leading to greater life satisfaction (Schmidt et al., 2015). However, critics have argued that ABA leads to increased masking or camouflaging of autistic traits rather than skill-building (e.g., Anderson, 2022).

Objectives: The current study compares the types of interventions received by autistic and LAD participants, and tests associations between intervention history and later outcomes of life satisfaction and camouflaging.

Methods: The study sample included autistic ($n=31$, 9 females) and LAD ($n=30$, 3 females) participants ages 15-30 years; Table 1. Participants in both groups had received an expert diagnosis of autism prior to the age of five years. Participants in the LAD group could not meet criteria for autism, according to the Autism Diagnostic Observation Schedule-2 (ADOS-2) and expert clinical judgement at follow-up; all participants in the autism group did meet ASD criteria in this way. Participants completed self-report questionnaires including the Satisfaction with Life Scale (SWLS) and the Camouflaging Autistic Traits Questionnaire (CAT-Q).

Results: Participants in the autism group were more likely to have received special education services, $p=.02$. They were also significantly more likely to have received social skills services and to have had an Individualized Education Program (IEP), $p<.05$; in contrast, many LAD individuals did not receive these supports. Autistic and LAD participants who received ABA therapy reported significantly higher Life Satisfaction ($M=25.5$, $SD=5.2$) relative to those who did not ($M=19.3$, $SD=6.6$), $p=.01$; Figure 1. Contrary to predictions, participants who had received ABA therapy reported fewer camouflaging behaviors ($M=3.9$, $SD=.94$) than those who did not ($M=4.6$, $SD=1.0$), $p=.03$.

Conclusions: Results suggest that currently autistic participants were more likely than their peers who had lost the autism diagnosis to have received more intensive school-based services such as special education and to have had an IEP. For both groups, engagement in ABA services was associated with positive outcomes including overall life satisfaction and less camouflaging. These cross-sectional results are consistent with two possibilities, which are not mutually exclusive. Individuals with a history of ABA may have built skills that enabled greater community and social engagement, leading to enhanced satisfaction. The pattern of group differences could also indicate that the LAD group may have started with milder autism symptoms.

436.015 Participatory Autism Knowledge Matters: Perceptions of an Autistic Employee's Competency and Attitudes Towards Workplace Social Inclusion

K. A. Szechy¹ and **L. A. O'Donnell²**, (1)*Social Work, University of Windsor, Windsor, ON, Canada*, (2)*Social Work, Wayne State University, Detroit, MI*

Background: Autistic adults are unemployed at high rates. Differences in the way autistic adults socialize and empathize compared to non-autistic, are often associated with employment challenges. Previous findings have indicated that consistent with the Double Empathy Problem (DEP), the different ways that autistic people function and socialize at work are more likely to be misunderstood by non-autistic others compared to autistic. The consequences of autistic workplace behaviour being misunderstood by the non-autistic majority, are potentially negative perceptions towards an autistic employee's competency and suitability for their job and negative attitudes towards their social acceptability as a coworker. However, being autistic, being more knowledgeable about autism, or being familiar with autistic persons may predict more positive perceptions of and attitudes towards an autistic employee. It is not known if these associations independently contribute to positive perceptions and attitudes or do so through better understanding of autistic behaviour.

Objectives: This study examined neurotype (autistic/non-autistic), interpretation of autistic employee behaviour, autism knowledge and autism experience, as predictors of perceptions of an autistic employee's competence and attitudes towards their social acceptability in the workplace. Additionally, this study explored accurate autistic employee behaviour interpretation as a mediator of associations between the predictors and more positive perceptions and attitudes.

Methods: Data for this study were previously collected from a larger sample in an online anonymous survey that asked participants to read and answer questions about a hypothetical autistic employee (described in a vignette) having a difficult workday. Participants (77 autistic, 152 non-autistic) read the vignette and completed scales measuring perceptions of the autistic employee's competency and suitability for their job and attitudes towards their social acceptability as a coworker. Included in the analysis were previously measured behaviour interpretation scores, autism knowledge, and autism experience.

Results: Autism knowledge significantly predicted more positive competency/suitability scale scores ($b = .570, p < .001$) and social acceptability scale scores ($b = .417, p < .001$) towards the hypothetical autistic employee, regardless of neurotype, behaviour interpretation ability, and autism experience. However, autism knowledge was significantly more influential regarding more positive perceptions and attitudes scale scores when participants scored poorly on behaviour interpretation towards the autistic employee.

Conclusions: Negative impressions of an autistic adult's competency and suitability for work, and negative attitudes about socially including them in the workplace have the potential to impact their employment success and workplace quality of life. Autism knowledge was strongly associated with having more positive perceptions towards an autistic employee's competency and more positive attitudes towards their social acceptability as a coworker. Additionally, autism knowledge was more impactful regarding positive perceptions of and attitudes towards the autistic employee when the autistic employee's workplace behaviour was poorly understood. Findings have implications for educating employers and coworkers about autism and autistic experiences in employment as a promising workplace support for autistic adults.

436.016 "It's a Very Strange Metamorphosis" Unmasking the Impact: A Qualitative Study Exploring Experiences of Traumatic Brain Injury in Autistic Adults

R. Cole, *Social, Genetic & Developmental Psychiatry, Social, Genetic & Developmental Psychiatry, London, England, United Kingdom*

Background:

There are no existing publications specifically exploring the impact of traumatic brain injury (TBI) on autistic individuals, despite an elevated risk of TBI in this population due to co-occurring conditions (e.g., epilepsy, sleep disorders), self-injurious behaviours and risk from assault. The experience of TBI in autistic individuals may differ from non-autistic individuals due to neurobiological differences, sensory processing variations, and sociocultural challenges. These characteristics could significantly affect recovery trajectories, symptom burden, and healthcare needs. This study addresses the gap by investigating the experiences of autistic TBI survivors and how TBI affects their daily lives and self-identity.

Objectives:

- Conduct semi-structured interviews with 16 autistic TBI survivors
- Conduct a mixed inductive and deductive thematic analysis

Methods:

A phenomenological approach was used to capture first-person perspectives on post-TBI life among autistic individuals. Sixteen participants with a confirmed autism diagnosis and history of TBI, were recruited through autism and brain injury charities. Data collection involved semi-structured interviews focusing on the impact of TBI across various life domains. A Public and Patient Involvement (PPI) group reviewed the interview questions. Thematic analysis of transcripts was conducted using NVivo 14, guided by Braun and Clarke's six-phase approach.

Results:

Participants included 6 women (37.5%), 9 men (56.3%), and 1 non-binary person (6.3%), with an average age of 42.88 years. The mean age at the time of TBI was 27.31 years (range 14-45), and the mean age of autism diagnosis was 35.81 years (range 6-60). TBI severity was distributed as 37.5% moderate-severe, 31.3% mild, and 31.3% symptomatic (possible TBI). Injury mechanisms comprised falls (31.3%), motor vehicle accidents (25.0%), being struck by or against an object (25.0%), assaults (12.5%), and sports injuries (6.3%). Co-occurring neurodevelopmental conditions included ADHD (18.8%), dyslexia (12.5%), dyspraxia (6.3%), and intellectual disability (6.3%).

Preliminary thematic analysis revealed four key themes:

1. **Transformation of Self and Identity:** A sense of disconnection from their pre-injury identity was reported, sometimes viewing the injury as exacerbating feelings of being different. Some experienced a loss of social masking drive, perceived as an opportunity to embrace authenticity.
2. **Heightened Sensory Sensitivities:** Many reported increased sensitivity to noise, light, and touch, resulting in sensory overload and disrupted daily functioning. Altered pain perception was also noted.
3. **Social Isolation and Withdrawal:** Increased social avoidance was commonly linked to sensory overload and anxiety, with many participants adopting reclusive behaviours as a coping mechanism.
4. **Challenges in Healthcare Experiences:** Participants frequently encountered difficulties communicating their needs to healthcare providers, encountering impaired communication due to pain or environmental disturbance

Conclusions:

The findings suggest that TBI may interact with pre-existing neurobiological and sociocultural challenges associated with autism, leading to compounded and atypical difficulties. This dual impact often results in experiences of identity disruption, amplified sensory sensitivities, and increased social withdrawal. Research is needed on the prevalence of TBI in autistic populations and the influence of co-occurring conditions, such as ADHD, to better support this population. Future studies should guide the development of autism-specific interventions to address the unique recovery needs of autistic TBI survivors.

436.017 Persistence of Autism Spectrum Disorder: Insights from a Longitudinal Follow-up Study in China

M. Xu, Xinhua Hospital affiliated to Shanghai Jiaotong University School of Medicine, Shanghai, China

Background: Research on the stability of autism spectrum disorder (ASD) has become a growing area of interest, as it is related to the screening policies and special health-care services. Previous studies indicate that approximated 10-20 percentage of children with ASD no longer met the diagnostic criteria as they age. A recent study by Harstad et al. found that 37.1% of children with ASD no longer met the diagnostic criteria. The high rate of diagnosis withdrawal raises important questions about early diagnosis and treatment for autism spectrum disorder, particularly in China where the National Health Commission has implemented a screening and intervention service for children aged 0-6 as part of the Healthy China 2030 project this year.

Objectives: To better understand this issue, we reviewed data from the Shanghai Autism Early Development (SAED) Cohort, which follows ASD children for 3 to 7 years, to provide further insights and contribute to the ongoing discussion.

Methods: The participants in this study were part of the SAED Cohort, a longitudinal cohort established in 2015 aimed at promoting the diagnosis, treatment, and prevention of ASD. The study included 66 children (median age 44.00 months, 78.8% boys) who had previously been diagnosed with ASD according to the DSM-5 criteria. Follow-up assessments were conducted using the ADOS module scores and CARS total scores.

Results: Out of the 66 participants, 15 (22.7%) no longer met ASD diagnosis at follow-up. There were no significant differences in age, gender, age of independent walking, caregiver's education level or family economic situation between two groups. However, compared to the persistent ASD group, the non-persistent ASD group had significantly differences in baseline CARS scores, ADOS-CSS scores and cognitive levels (threshold: 70). In a multilevel logistic regression model, compared to children with persistent ASD, children with non-persistent ASD tend to have lower baseline CARS and ADOS-CSS scores.

Conclusions: The withdrawal rate for diagnosis in this study of SAED Cohort is 22.7% (42.3% of cognitive >70, 10% of cognitive <70), which is closer to the 19% withdrawal rate reported by Lord et al. in 2022, but significantly lower than that reported by Harstad et al (37.1%). This difference may stem from a combination of factors, such as medical referral system, cultural differences, socioeconomic factors. The current prevalence of autism in China is estimated to be 1%, suggesting a possible lack of sufficient screening. While there are variations and constraints, the patients identified in the persistent group in SAED cohort share similarities in characteristics, including age, gender distribution, and cognitive ability distribution, with those in the study by Harstad et al which has provided valuable insights into the literature. While the withdrawal rate for ASD diagnosis in school age still requires further research with a larger sample size, potentially involving the use of different ethical data. Data from various countries and cultural backgrounds should obtain a more comprehensive and diverse global perspective on the persistence of ASD diagnosis, providing evidence to fit health economics and to guide screening policies and special health-care services.

436.018 What about the Well-Being of Autistic Adults Living in an Autism Specific Group-Home ?

A. M. Nader¹, E. St-Jean², B. Forgeot d'Arc², I. Courcy³ and R. Godbout², (1)Psychology, Université de Montréal, Montréal, QC, Canada, (2)Psychiatry, Université de Montréal, Montréal, QC, Canada, (3)Department of Sociology, Université de Montréal, Montréal, QC, Canada

Background: Most autistic adults stay in residential facilities operating with limited resources and rarely are they specifically designed to meet their needs. Literature shows that quality of life (QoL) of autistic adults living in group-homes is often inferior compared to other living situations while living in an autism-specifically designed facility has not been assessed yet to our knowledge. Considering that the living environment is an important determinant of quality of life and social inclusion, this context provides a unique opportunity to understand the factors in the living environment that promote the well-being of autistic adults living in group-homes.

Objectives: This study aims to assess the well-being of autistic adults for 3 years after moving to an autism specifically designed residence (specific architectural and clinical approaches) on 1) QoL; 2) emotional well-being; 3) level of functioning.

Methods: 12 autistic adults (8 females; 4 males), aged 21-55 years, all living in the same autism-friendly residence each with their own bedroom were included. The majority of participants (92%) came from a family setting and all required mild to moderate levels of support (mean IQ 61.3 ± 16.1). Data was gathered from (a) clinical records (eg. IQ, associated diagnoses) and (b) questionnaires completed by parents and staff, measuring QoL (*San Martin Scale - Quality of life Assessment for People with significant disabilities*), emotional well-being (*Emotional Problem Scales*), and level of adaptive functioning (*Adaptive Behavior Assessment System, 2nd edition*). Data was collected at four different time points: three months before moving into the residence (T0), and at 9 months (T1), 21 months (T2), and 36 months (T3) after moving in. Repeated paired-samples t-test assessed the progression of each variable over time.

Results: Before moving in (T0), the participants showed average levels of QoL ($M 97.6 \pm 9.8$) and emotional well-being ($M 9.9 \pm 2.0$) according to their parent's assessment. Notably, no decline in quality of life, emotional well-being, or adaptive functioning was observed during the three years following the move. According to parents and educators, QoL increased at T2 (21 months) and this increase remained at T3 ($M T2$ parents 104.1 $SD 6.7$, $p=.03$; $M T2$ educators 106.0 ± 10.1 , $p=.01$), while emotional well-being and adaptive behaviour remained stable across the four measures (all $p>.05$).

Conclusions: Moving from a family setting to an autism-friendly residence did not impair QoL, emotional well-being nor level of functioning of autistic adults over a 3-year period. An improvement in QoL was observed 21 months after moving in and remained until the end of the study. Living in an autism-friendly residence facility, which provide autism-specific architectural and clinical approaches, seems to support the well-being of autistic adults. Further analyses will identify the contribution of specific architectural, clinical and lifestyle components to the current results.

436.019 Pilot Testing a Novel Self-Reported Measure of Loneliness for Autistic Adults

H. K. Schiltz¹, D. Gohari², D. J. Sw³, C. A. Mazefsky⁴ and C. Lord⁵, (1)University of Washington, Los Angeles, CA, (2)Semel Institute for Neuroscience and Human Behavior, Los Angeles, CA, (3)University of Pittsburgh Medical Center, Pittsburgh, PA, (4)Department of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, PA, (5)UCLA Semel Institute for Neuroscience and Human Behavior, Los Angeles, CA

Background: Advancing measurement of well-being and related constructs in autism is a priority echoed by researchers, autistic adults, and others in the autistic community. Loneliness - an unpleasant feeling due to a perceived incongruence between desired and actual social functioning - is common among autistic adults and linked with a range of poor adult outcomes. Existing measures of loneliness do not fully capture the experience of loneliness among autistic adults and have little to no psychometric support, which precludes further advancement of this line of research.

Objectives: Guided by the Patient-Reported Outcomes Measurement Information System (PROMIS) framework, this study aimed to 1) develop and refine an item pool based on a pre-specified conceptual model of loneliness and cognitive interviews, and 2) pilot test the novel self-reported measure of loneliness, the Loneliness in Interpersonal Networks Questionnaire for Autistic Adults (LINQ-AA).

Methods: The item pool was developed by mapping items from existing loneliness measures onto a conceptual model (119 items from 7 measures) created as part of previous phases of the larger research study and includes 3 relationship domains [1) closest relationships (CR), 2) causal friends and/or acquaintances (CFA), and 3) community connections (CC)]. Items were revised and excluded as needed and new items were written to ensure adequate construct coverage. Cognitive interviews (n = 6) were conducted with autistic adults following a combined think-aloud and respondent debriefing methodology previously used by Mazefsky and colleagues (2018) and resulted in minor revisions to the instructions, response options, and item pool. Pilot data were collected from autistic adults (n = 38) via Qualtrics on the LINQ-AA as well as another measures of loneliness (UCLA Loneliness Scale Version 3), mental health (Hospital Anxiety and Depression Scale), and quality of life (WHO Quality of Life 4-item composite). Sum scores were generated for all three LINQ-AA loneliness relationship domains, as well as an overall total. Scores were graphed, and descriptive statistics and preliminary psychometrics (i.e., internal consistency and construct validity) were calculated.

Results: LINQ-AA scores covered a wide range of loneliness (Table 1) and were normally distributed (skew = -.29 - .22; kurtosis = -.75 - .15). Regarding internal consistency, Cronbach's alpha was excellent for all domains (CR: $\alpha = .94$; CFA: $\alpha = .90$; CC: $\alpha = .90$). Correlation amongst the three LINQ domains were all positive and ranged in magnitude from weak to strong (Table 1). The LINQ-AA scores were generally more strongly correlated with another measure of loneliness, compared to measures of mental health and quality of life, and uncorrelated with age; all correlations were in the expected directions (Table 1).

Conclusions: The findings of this study provide preliminary psychometric support among autistic adults for the LINQ-AA - a novel self-reported loneliness questionnaire developed using the PROMIS framework that taps into areas often excluded from existing tools. Future studies should examine the latent factor structure and further evaluate the LINQ-AA's properties. This tool may be useful for research and clinical practice that have direct implications for the well-being and quality of life of autistic adults.

436.020 Predictors of Adaptive Functioning in Autistic Dependent Adults

M. Luby, P. Feliciano, C. Lehman and W. Chung, Department of Pediatrics, Boston Children's Hospital, Boston, MA

Background:

In adults with autism, difficulties with adaptive functioning (ability to manage everyday tasks) can create significant challenges, but we lack a deep understanding of the factors that impact these skills. Exploring how socioeconomic status (SES), race, and ethnicity impact these outcomes is also crucial, as these factors influence access to services and support. Identifying key predictors can guide the development of personalized interventions to improve the quality of life for dependent autistic adults.

Objectives:

To explore behavioral, genetic and demographic predictors of adaptive functioning as measured by the Vineland-3 in dependent autistic adults within the Simons Foundation Powering Autism Research Knowledge (SPARK) study (The SPARK Consortium, 2018).

Methods:

Stepwise multiple linear regressions were used to identify predictors of adaptive functioning in dependent autistic adults (n = 2,918). Dependent variables were standard scores from the Vineland Adaptive Behavior Scales, Third Edition (Vineland-3), including overall adaptive functioning (ABC) and its Communication, Daily Living Skills, and Socialization domain composites. Predictors included the presence of a genetic diagnosis, behavioral scores from the Repetitive Behavior Scale-Revised (RBS-R), such as stereotyped, self-injurious, compulsive, ritualistic, sameness, and restricted sub-scale behavior scores, age at autism diagnosis, socioeconomic status (Area Deprivation Index percentile), sex, and race/ethnicity. Model fit was evaluated using R-squared values. Results include unstandardized coefficients, showing the expected change in Vineland-3 scores for a one-unit increase in predictors.

Results:

The analysis identifies several negative predictors of adaptive functioning, including the presence of a genetic diagnosis (Estimate = -6.02, 95% CI [-7.77, -4.29], $p < .001$), higher scores in stereotyped behavior (Estimate = -1.62, $p < .001$), self-injurious behavior (Estimate = -0.80, $p < .001$), and sameness behavior (Estimate = -0.43, $p < .001$). These are significantly associated with poorer adaptive functioning across domains. In contrast, increased ritualistic behavior predicts better outcomes in adaptive functioning (Estimate = 1.01, $p < .001$).

Age at autism diagnosis (Estimate = 0.08, $p < .001$) and Area Deprivation Index (ADI) (Estimate = 0.04, $p < .01$) show a small, positive predictive association with adaptive functioning. Greater socioeconomic challenge is associated with higher Vineland scores across domains. Racial and ethnic influences vary, particularly in socialization, but the small sample sizes of non-White groups caution against over-interpretation.

Overall, the models explaining the variation in the four Vineland-3 composite scores performed similarly, with the ABC composite and communication models both explaining around 23.8% of the variation ($R^2 = 0.238$ vs. $R^2 = 0.239$, Adjusted $R^2 = 0.2347$ vs. 0.2367). The low percentages suggest that other, unmeasured factors contribute to adaptive functioning, indicating the need for further analysis.

Conclusions:

Behavioral and demographic factors are associated with adaptive functioning in dependent autistic adults. A strong negative relationship exists for those with an autism-related genetic diagnosis. A small but consistently positive relationship exists between lower socioeconomic status and adaptive functioning. Interestingly, ritualistic behavior also shows a positive association with adaptive functioning. The nuanced effects of race and ethnicity highlight the need for further research to identify additional predictors that can improve our understanding of adaptive functioning.

436.021 Predictors of Transition Readiness Among Diverse Autistic Adolescents

N. Menon¹, E. Barnard², M. Much-Hichos³, E. Hickey⁴, J. S. Wilson⁵, M. Adebogun⁶, A. Gonzalez Laca⁶, M. Sarith Valdivia Acosta⁷ and J. L. Kuhn⁶, (1)Department of Psychology, Emory University, Atlanta, GA, (2)Psychiatry, Boston Medical Center, Boston, MA, (3)Waisman Center University of Wisconsin - Madison, Madison, WI, (4)Department of Psychological and Brain Sciences, Boston University, Boston, MA, (5)Clinical Psychology, Boston University, Boston, MA, (6)Pediatrics, Emory University School of Medicine, Atlanta, GA, (7)Emory University School of Medicine, Marcus Autism Center, Atlanta, GA

Background:

The transition from high school to adulthood presents unique challenges for autistic adolescents and their families. Autistic adolescents experience low rates of employment and reduced access to structured support prior to leaving the formal school system.^{1,3} Latinx autistic adolescents and their parents may experience additional barriers to a successful transition, such as a higher likelihood of experiencing poverty, limited Spanish resources, and reduced autism knowledge.^{4,6} Emerging literature highlights how unique cultural values, such as emphasis on familial and community relations, can increase transition readiness.⁵ Support from community, family, and peers, as well as mental health and transition support services, can positively influence an individual's transition to adulthood.^{3,7-9}

Objectives:

We sought to understand whether the quality of family and peer relationships relate to transition readiness among Latinx and non-Latinx autistic adolescents, with consideration of primary language and level of independence.

Methods:

English and Spanish-speaking parents and their autistic adolescents (n=36, aged 14-21) participated in a larger clinical trial testing a transition to adulthood support program. At baseline, parents completed the Transition Readiness Scale (measures feelings, thoughts, and behaviors related to the transition), PROMIS Parent Proxy Peer Relationships (measures quality of youth's friendships), PROMIS Parent Proxy Family Relationships (measures youth's subjective experience of being in their family), Waisman Activities of Daily Living (W-ADL) (assesses youth's activities of daily living such as chores and preparing food), and a sociodemographic survey. We performed multiple linear regressions to investigate the association between peer and family relationships with transition readiness (Table 2).

Results:

Thirty-six parents completed the baseline questionnaires (Table 1). Linear regression analyses showed that Family Relationships were significantly positively associated with Transition Readiness, but this association did not remain significant when controlling for language and level of independence on the W-ADL. Language, however, was a significant positive predictor of Transition Readiness, with Spanish-speaking families ($M=52.55$, $SD=15.57$) reporting significantly higher levels of transition readiness than English-speaking families ($M=39.64$, $SD=10.69$), $t(34) = -2.71$, $p=.01$. In a separate linear regression model, Peer Relationships were significantly positively associated with Transition Readiness, and remained a significant positive predictor of Transition Readiness after controlling for language and level of independence. When analyzed in a single regression model, peer relationships were a significant predictor of transition readiness, controlling for family relationships, language, and level of independence. This full model accounted for the greatest variance of all models tested.

Conclusions:

Peer relationships are a strong predictor of transition readiness. Interventions aiming to help parents and their autistic adolescent with the transition to adulthood should consider including content that fosters peer relationships, communication, and other skills related to peer relationship building. In contrast, family relationships do not significantly predict transition readiness after controlling for language. Because Spanish-speaking families reported higher levels of transition readiness, this indicates that cultural background may be a moderator, playing a greater role in shaping the association between family relationships and transition readiness. Future studies should examine the influence of language, culture, and resilience on transition readiness, empowerment, and social support, especially among Latinx families.

**436.023 Presence and Age of Onset of Parkinsonism Features Among Middle Age and Older Adults with Autism, Parkinson's Disease, or Neurotypical Development**

R. Spransy¹, G. A. McQuaid², R. A. Charlton³ and G. L. Wallace⁴, (1)George Washington University, District of Columbia, DC, (2)George Mason University, Fairfax, VA, (3)Psychology, Goldsmiths University of London, London, London, United Kingdom, (4)The George Washington University, Washington, DC

Background:

The motoric features associated with Parkinson's Disease (PD), such as tremors, slowness in movement, and limb stiffness are increasingly linked with autism during middle and older adulthood. However, no study to date has directly compared these parkinsonism features between autistic adults and adults with PD to identify similarities and differences in motoric symptoms and their age of onset. This information is a critical first step towards pinpointing shared and unique developmental and etiological origins of these motoric features for autistic adults as compared to adults with PD.

Objectives:

Compare and contrast parkinsonism motoric features and their age of onset between autistic adults, adults with PD, and neurotypical adults.

Methods:

210 autistic adults (58% female assigned-sex; Age: $M=55$, range=42-80 years) were recruited via the Simons Powering Autism Research (SPARK) Research Match service. 103 adults with PD (47% female assigned-sex; Age: $M=65$, range=40-91 years) were recruited via The Michael J. Fox Foundation participant registry and NIH Research Match. And finally, 106 neurotypical (NT) adults without autism or PD (54% female assigned-sex; Age: $M=60$, range=40-78 years) were recruited via NIH Research Match. Participants from all three groups completed the Parkinsonism Screening Questionnaire (PSQ) to compare PSQ screening score $[(2 \times \text{stiffness}) + (5 \times \text{tremors}) + (5 \times \text{arm swing}) + (5 \times \text{stuck on floor})]$ and screening-status. Additionally, age (9 categories ranging from 'Before-age-10' to '80-89') when endorsed parkinsonism symptoms were first noticed was compared between the autism and PD groups.

Results:

While groups did not differ in assigned-sex ratio ($\chi^2=3.38$, $p=.19$), they differed in age (PD group > NT group > autism group; $F=34.64$, $p<.001$). After controlling for age, parkinsonism screening score differed by group, with the PD group ($M=10.16$, $SD=4.43$) having a higher score than the other two groups and the autism group ($M=2.63$, $SD=3.52$) having a higher score than the NT group ($M=1.12$, $SD=1.51$; $F=137.62$, $p<.001$). Similarly, parkinsonism screen positivity rates were highest for the PD group (84%) followed by the autism group (20%), and the NT group (3%; $\chi^2=187.15$, $p<.001$). There were also marked differences in age of onset of parkinsonism symptoms between the PD and autism groups. Specifically, the autistic adults reported earlier ages of onset for all 6 parkinsonism symptoms evaluated compared to the adults with PD ($Zs>4.54$, $ps<.001$; see simplified [adult vs. child onset of symptoms] data depiction in Figure 1).

Conclusions:

In the first study to directly compare parkinsonism features among autistic adults, adults with PD, and NT adults, the current study extends prior findings of elevated parkinsonism in autism. While middle and older age autistic adults were more likely to screen positive on a self-rated parkinsonism scale than similarly aged NT adults, screen positivity rates were considerably lower in the autism group than the PD group. Perhaps most strikingly, parkinsonism symptom onset differed markedly between autistic adults (younger onset) and adults with PD. Findings implicate a different developmental course to several parkinsonism features among many autistic people compared to those with PD, though the results reveal large individual differences in the autism group. This study represents a first step to better understanding the developmental origins of parkinsonism among autistic people.

436.024 Prevalence and Context of Injurious Falls Among Young, Middle, and Older Autistic Adults

H. L. Miller¹, I. Munoz Orozco¹, J. Ashton-Miller² and N. Alexander², (1)School of Kinesiology, University of Michigan, Ann Arbor, MI, (2)University of Michigan, Ann Arbor, MI

Background: Mobility limitations and fall risk increase as non-autistic adults age and are associated with high morbidity and mortality in older adulthood (Hirvensalo et al., 2000; Davis et al., 2015; Freiburger et al., 2020). One in four non-autistic older adults (65+ years) falls, and one in five of these falls is injurious (Kakara et al., 2023; CDC, 2023). However, little is known about the prevalence of injurious falls in autistic adults, the context of these falls (i.e., when and why it occurred, how severe it was), and whether autistic fall risk changes over the lifespan in a way that mirrors that of non-autistic adults. Given that autistic people experience motor differences including postural instability, they may be at risk for earlier and/or more injurious falls compared to non-autistic peers.

Objectives: To determine the prevalence of falls experienced by autistic adults across young, middle, and older adulthood compared to non-autistic adults, and to characterize the context of autistic adults' falls.

Methods: We accessed retrospective data from the electronic medical records of patients who were seen by Michigan Medicine providers (University of Michigan healthcare system) between January 1, 2000 and December 22, 2023. Data were obtained using the university's data warehousing service, DataDirect. Autistic vs. non-autistic patients and fallers vs. non-fallers were classified based on their problem list and list of diagnoses using ICD-9, ICD-10, and Michigan Medicine billing and diagnostic codes.

Results: 7,807 autistic adults (18-89 years) and 4,459,006 non-autistic adults (18-90 years) were seen within the Michigan Medicine system during this period. These two groups were equivalent in age distribution, but the autistic group had a higher proportion of males, consistent with population sex ratios (Table 1). Of these, 16.28% ($n=1,271$) of autistic adults were seen for injurious falls compared to 3.68% ($n=164,003$) of non-autistic adults. Young, middle, and older autistic adults all experienced more falls than non-autistic adults (Fig. 1). Differences were especially pronounced in older adulthood, where 30.23% of autistic adults experienced injurious falls relative to 4.98% of non-autistic adults. Autistic fallers and non-fallers were similar in age, sex, and racial and ethnic distribution (Table 1). For autistic fallers, "abnormality of gait" (50.14%), "history of falls" (21.50%), and "fall (general/unspecified)" (21.07%) were the most frequent encounter codes across 3,921 fall-related encounters.

Conclusions: Autistic adults experienced injurious falls more often than non-autistic adults across young, middle, and especially older adulthood. These findings underscore the need for prospective studies of fall risk and protective factors to determine the appropriate assessment and intervention protocol for autistic people as they age. Planned future analyses will examine patient-centered risk factors including co-occurring conditions and polypharmacy. Although a wide range of specific ICD codes for fall context exists, encounter codes assigned by clinicians were nonspecific, yielding little information that could be used to support intervention. As the autistic population ages into middle and older adulthood, it is crucial to determine whether they experience the same type and timing of risks as non-autistic adults, and whether existing fall prevention strategies are effective for this community.

436.025 A Dimensional Approach to Measuring “Outcome”: Measurement of Changes in Mental Health and Community Engagement in a Sample of Middle-Aged Autistic Adults Enriched for High Support Needs

C. B. Klein¹, V. Gadikota², E. M. Lamarche², A. T. Meyer³, P. Powell⁴ and L. G. Klinger², (1)TEACCH Autism Program; Psychology & Neuroscience, TEACCH Autism Program, UNC Chapel Hill, Chapel Hill, NC, (2)TEACCH Autism Program; Psychiatry, UNC TEACCH Autism Program, Chapel Hill, NC, (3)JFK Partners, University of Colorado School of Medicine, Aurora, CO, (4)TEACCH Autism Program; Psychology & Neuroscience, UNC TEACCH Autism Program, Chapel Hill, NC

Background: The few longitudinal studies in autism have found that 3-50% of autistic adults experience what researchers have classified as a “positive” outcome (Mason et al., 2020). However, researchers typically use a single “fixed” outcome rating (e.g., Overall Outcome Rating Scales [OOR], Howlin et al., 2004) that does not capture changes across adult development. The goal of the current study was to contrast a commonly used outcome measure with a dimensional measure of outcome as it changes across adulthood in mental health and community engagement.

Objectives: We aimed to 1) Assign outcome group ratings, 2) Identify patterns of changes in mental health and community engagement over 8.5 years, and 3) Contrast patterns of change with outcome rating groups.

Methods: Participants were part of a longitudinal cohort diagnosed in childhood at the UNC TEACCH Autism Program between 1969-2000 ($M_{age}=7.29$, $SD=4.04$, $range=2.72-16.56$) enriched for high support needs ($M_{IQ}=61.71$, $SD=24.74$). Caregivers completed a survey about adult outcomes between 2014-2016 (Wave 2) and 2023-2024 (Wave 3). The OOR (a “fixed” rating) defined outcome based on employment, independent living, and social participation. Dimensional ratings were calculated for Mental Health (e.g., anxiety, depression, maladaptive behavior) using the Anxiety, Depression, and Mood Scale (ADAMS) and Reiss Scale of Maladaptive Behavior (RSMB). Ratings for Community Engagement included belonging (QOL-Q; Schalock & Keith, 1993), community participation, and employment ratings. Dimensional change in Mental Health and Community Engagement was calculated using residuals from Wave 2 predicting Wave 3, with negative scores indicating improvement. K-Means Clustering identified patterns of change. Cluster membership and change scores in Mental Health and Community Engagement were compared between outcome groups.

Results: Wave 3 included 47 participants ($M_{age}=48$, $range=40-61$). Adults were categorized using OOR as Very Good/Good ($n=7$), Fair ($n=16$), and Poor/Very Poor ($n=24$). Wave 3 Mental Health ($p=.23-.87$) and Community Engagement ($p=.20-.16$) did not differ across outcome groups, although better outcome was associated with greater employment. Examining patterns of dimensional change from Wave 2 to Wave 3, two clusters were identified in Mental Health ($n=24$ “Worsening”, $n=23$ “Improving”) and three in Community Engagement ($n=15$ “Improving Employment”, $n=11$ “Improving Community Participation and Belonging”, $n=21$ “Worsening”). Change cluster membership in Mental Health was not associated with fixed outcome group rating, $X^2(2)=1.68$, $p=.49$, and change scores did not differ between the groups ($p=.11-.71$; Figure 1). Change cluster membership in Community Engagement was significantly associated with outcome group, $X^2(4)=20.01$, $p<.001$. Outcome groups differed in employment change, $H(2)=16.50$, $p<.001$, but not in community participation ($p=.30$) or belonging ($p=.46$; Figure 2).

Conclusions: In a sample of middle-aged autistic adults enriched for high support needs, outcome groups showed no differences in mental health and community engagement at Wave 3, except employment. Positive changes were observed across outcome groups, especially in mental health, community participation, and belonging. However, the pattern of changes in community engagement was most positive in the Very Good/Good group, who showed the greatest improvement in employment. Results documenting change during adulthood serve as a reminder to consider outcomes across adulthood as amenable to change to support aging well.

**436.026** Pubertal Trajectories in Autism: Predicting Adult Social and Adaptive Outcomes

N. Schisterman and C. Lord, UCLA Semel Institute for Neuroscience and Human Behavior, Los Angeles, CA

Background: Puberty is a critical developmental period that interacts with pre-existing developmental differences in ASD in complex ways. While previous research has shown substantial variability in pubertal timing and tempo among autistic individuals (Corbett et al., 2020), the long-term implications of these differences are not well understood.

Objectives: This study investigates how distinct pubertal trajectories predict long-term adult outcomes in individuals with autism, providing insight into how adolescent developmental processes may shape the adult lives of autistic individuals.

Methods: Data were collected from 170 participants with autism or non-ASD developmental delays (ASD=80.3%, female=15.2%, White=78.8%) from an ongoing longitudinal study. Thirty-one participants never received an ASD diagnosis, and participants are now in their early thirties. Pubertal development was assessed annually using the Pubertal Development Scale (PDS; Peterson et al., 1988) from ages 9-20. Adult outcomes included social factors (e.g. living situation, relationships, friendships), behavioral measures (e.g. irritability, hyperactivity), and adaptive skills (e.g. Vineland daily living skills). Group-based trajectory modeling was used to identify distinct pathways of pubertal development, followed by one-way ANOVAs and correlation analyses. Multi-level models (MLMs) assessed how trajectory groups predicted adult outcomes, controlling for pre-pubertal cognitive and adaptive functioning.

Results: Three distinct pubertal trajectory groups were identified: early onset with moderate development (35.2%), moderate onset with rapid development (57.1%), and late onset (7.7%). One-way ANOVAs revealed significant differences in post-pubertal outcomes, including education ($F(2,123)=3.57$, $p=.050$), Vineland socialization ($F(2, 127) = 4.88$, $p = .009$), and ABC irritability ($F(2, 133) = 4.95$, $p = .008$). Participants in the rapid development group had significantly higher socialization scores and lower irritability scores than those in the early and late development groups ($p=.045$; $p=.046$). There were no significant differences in post-pubertal ADOS CSS scores between groups ($p>.05$). However, more advanced pubertal development by age 16 was correlated with lower CSS restricted/repetitive behavior (RRB) scores ($p=.003$). MLMs further indicated that trajectory groups significantly predicted employment outcomes ($X^2 = 5.27$, $p = .027$), with participants in the early onset group more likely to be employed than those in either the rapid or late development groups. Correlation analyses showed that advanced pubertal development at ages 12, 15, and 18 was associated with higher educational attainment, employment, living independently, and happiness in adulthood.

Conclusions: This study highlights the importance of pubertal development in predicting long-term adult outcomes in individuals with ASD. Early and rapid pubertal development was associated with more positive adult outcomes in socialization, education, and employment. In contrast, delayed pubertal development was linked to greater behavioral challenges, and was associated with higher CSS RRB scores. Understanding these developmental trajectories can help inform targeted support during adolescence, improving long-term outcomes for autistic individuals as they transition to adulthood.

436.027 Recommendations for Improving Gastrointestinal Health Among Autistic Adults – Results from the GI Wanna Talk about Autism Study

C. B. Holingue^{1,2}, M. Johnson³, K. Almendinger⁴, K. Daley⁵, F. DiJulia⁵, Z. Williams⁶, L. G. Kalb⁷, S. N. Brasher³ and E. Pellicano⁸, (1)*Mental Health, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD*, (2)*Center for Autism Services, Science, and Innovation, Kennedy Krieger Institute, Baltimore, MD*, (3)*Nell Hodgson Woodruff School of Nursing, Emory University, Atlanta, GA*, (4)*Johns Hopkins Bloomberg School of Public Health, Baltimore, MD*, (5)*Kennedy Krieger Institute, Baltimore, MD*, (6)*Vanderbilt University, Nashville, TN*, (7)*Department of Mental Health, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD*, (8)*Clinical, Health and Educational Psychology, University College London, London, London, United Kingdom*

Background:

Gastrointestinal (GI) symptoms are common and disabling among autistic people. The "GI Wanna Talk About Autism" study used a participatory approach, involving a Community Board of autistic and non-autistic adults (n=26), to explore the lived experiences of autistic adults with GI symptoms and develop recommendations to improve their GI health. In Phase 1, we interviewed autistic adults and parents (n=27), who provided insight into GI-related experiences and recommendations for future research.

Objectives:

Phase 2 determined which of the Phase 1 recommendations were preferred by a larger sample of autistic adults and parents.

Methods:

A total of 509 participants were recruited via SPARK Research Match: independent autistic adults (n=259, 51%), dependent autistic adults (n=35, 7%), and caregivers of dependent autistic adults (n=215, 42%). Autistic adults in this sample were mostly men (n=283; 56%), non-Hispanic/Latino (n=428; 84%), with White (n=303; 60%), African-American/Black (n=132; 26%), and Asian (n=99; 19%) as the largest racial groups. Each group provided demographic and GI symptom data, and ranked the nine identified recommendations, which included: healthcare provider training, autistic adult healthcare advocacy training, interoception intervention, GI anxiety intervention, an electronic GI toolkit, GI symptom questionnaires, behavioral diet interventions, a healthcare professional database, and an interdisciplinary care coordination model.

Results:

Of the 259 independent autistic adults, most (n=197; 76%) experienced weekly GI symptoms over the past 3 months, of which 57% (n=112) reported symptoms lasting over 5 years. Two-fifths (n=109; 42%) had a GI diagnosis. The same number reported often/very often impairing symptoms. Over half rated the identified recommendations as very/extremely important (n=155; 60%) and very/extremely impactful (n=174; 67%). The top three recommendations were the healthcare provider training, autistic adult healthcare advocacy training, and the interdisciplinary care coordination model.

Among the self-reporting dependent autistic adults (n=35; 7%), most (n=22; 63%) reported experiencing weekly GI symptoms over the past 3 months, among which most (n=27; 77%) reported symptoms lasting over 5 years. A third (n=11; 31%) reported having a GI diagnosis, but a minority of the population (n=5; 13%) found the symptoms frequently impairing. Additionally, about half (n=18; 51%) rated the recommendations as very/extremely important and very/extremely impactful. Top three recommendations were healthcare provider training, advocacy training, and GI anxiety intervention.

Of the caregivers of dependent adults (n=215; 42%), most (n=138; 64%) reported their child experienced weekly GI symptoms in the past 3 months, of which the majority (n=97; 70%) reported symptoms for over 5 years. Two-fifths (n=88; 41%) reported their child had a GI diagnosis, and the same number symptoms often impairing. Most caregivers rated the recommendations as very/extremely important (n=135; 63%) and very/extremely impactful (n=157; 73%). Top recommendations included healthcare provider training, interdisciplinary care coordination model, and GI anxiety intervention.

Conclusions:

Most participants rated the recommendations as very/extremely important and impactful, with remarkable agreement across the three groups for the top priorities for future services-related research: healthcare provider training, advocacy training, interdisciplinary care coordination, and anxiety interventions. Future research should focus on pursuing these recommendations to enhance the lives of autistic people living with GI issues.

**436.028** Relationship between Imaging Evidence of Dopamine Transporter Binding Deficits and Functional Connectivity of the Striatum in Autism Spectrum Disorder

N. Nuraini^{1,2}, C. Appling³, A. Schupp⁴, B. J. Ferguson^{2,5}, A. Singh⁶, A. M. Gunn², B. B. Braden⁷ and D. Q. Beversdorf⁸, (1)*Interdisciplinary Neuroscience Program, University of Missouri - Columbia, Columbia, MO*, (2)*University of Missouri Thompson Center for Autism & Neurodevelopment, Columbia, MO*, (3)*Interdisciplinary Neuroscience Program, University of Missouri, Columbia, MO*, (4)*Department of Psychological Sciences, University of Missouri, Columbia, MO*, (5)*Department of Neurology, University of Missouri, Columbia, MO*, (6)*Department of Radiology, University of Missouri, Columbia, MO*, (7)*College of Health Solutions, Arizona State University, Tempe, AZ*, (8)*Department of Radiology, Neurology, and Psychological Sciences, University of Missouri, Columbia, MO*

Background:

In the nascent aging and autism literature, one of the most replicated findings across independent cohorts is increased risk for parkinsonism/Parkinson's disease (PD), as high as a 6-fold elevation of risk. As PD is characterized by the progressive loss of dopaminergic neurons, it is noteworthy that atypical dopamine activity has been observed in autistic adults and children, and animal models of autism spectrum disorder (ASD). The only FDA approved medications for ASD are the atypical antipsychotic medications risperidone and aripiprazole, which inhibit postsynaptic dopaminergic and serotonergic transmission to treat irritability. Studies using resting state functional magnetic resonance imaging (fMRI) show disruption in striatal circuits in ASD. However, no studies have examined the striatal PD biomarker, the dopamine transporter (DaT) scan™, or how abnormal dopamine function in the striatum may affect its functional connectivity (FC) with other brain areas in adults with ASD.

Objectives: In this pilot study, we aimed to evaluate the PD biomarker, DaTscan, in autistic individuals and functional connectivity between the striatum and other brain areas in autistic individuals with varying dopaminergic integrity on imaging.

Methods: DaT single photon emission computed tomography (SPECT) and resting state fMRI was collected in twelve participants (age range = 16-24) with ASD, and whole-brain seed-to-voxel striatal FC was calculated

Results: Five of the twelve participants were found to have focal deficits in striatal DaT uptake (Figure); therefore, participants were separated into abnormal (n=5) and normal (n=7) DaT groups for striatal FC analyses. The abnormal DaT group showed greater FC between right caudate and lateral occipital cortex, precuneus; between the bilateral putamen and right frontal pole, brain stem, precuneus; and between the bilateral accumbens and right precentral gyrus, juxtapositional lobule cortex, and right cerebellum.

Conclusions: These findings suggest that the PD biomarker, DaTscan, may be sensitive to high rates of clinical abnormalities in autistic individuals and that there is a relationship between focal striatal deficits in DaT uptake and greater striatal functional connectivity to areas involved with the motor control as well as sensory integration in ASD. These findings have the potential to inform future clinical trials in ASD but should be interpreted with caution until their relation to core symptoms is better understood in a larger sample. Additionally, examining how these findings changes with age will be critical to understand how the DaTscan and striatal FC may inform increased PD risk in autistic individuals.

436.029 Exploring Discrepancies in Self-and-Caregiver Reports across Autistic and Non-Autistic Adults

G. Sotomayor¹, Y. Bolourian² and E. A. Laugeson², (1)Semel Institute for Neuroscience and Human Behavior, University of California Los Angeles, Los Angeles, CA, (2)UCLA Semel Institute for Neuroscience and Human Behavior, UCLA PEERS® Clinic, Los Angeles, CA

Background: Previous research suggests autistic adults tend to agree more with their parents than non-autistic adults on traits like empathy and social functioning, though the direction of these effects remains unexplored (Sharp et al., 2023). Despite these patterns of agreement, discrepancies between self- and parent-reports are still common, as observed in broader research (De Los Reyes et al., 2015). These discrepancies may arise from autism-specific factors, such as social communication differences, which are central to the autistic experience. Furthermore, co-occurring mental health conditions, commonly seen in autistic individuals, can add additional complexity to symptom reporting (Curnow, et al., 2023; Sandercock et al., 2020; Trammell et al., 2013). Understanding these dynamic factors that contribute to discrepancies is crucial for accurate assessments and effective interventions.

Objectives: This study examines diagnostic differences (autism with/without co-occurring conditions versus non-autistic conditions) and autism-related social communication differences to determine their unique contributions to discrepancies in self- and parent-reports of social anxiety, empathy, and autism traits.

Methods: Participants included 211 adults ($Mage = 22.42$, $SD = 4.12$) who attended PEERS® for Young Adults, an evidence-based social skills program where parents serve as social coaches. Adults and their parents completed several measures before the program, including the Social Anxiety Scale (SAS; La Greca et al., 1988), assessing social anxiety; the Empathy Quotient (EQ; Baron-Cohen, 2004), measuring empathy levels; the Autism Quotient (AQ; Baron-Cohen & Wheelwright, 2004), evaluating autistic traits, and the Social Responsiveness Scale, Second Edition (SRS-2; Constantino & Gruber, 2012), assessing autism-related social communication differences. Discrepancy scores were calculated as differences between self- and parent-reports, with positive scores indicating higher participant-reported scores. Two multivariate analyses of covariance (MANCOVA) examined the effect of autism diagnosis on discrepancies and the effect of parent- and self-reported SRS scores, a continuous measure of autism-related social communication differences, on discrepancies.

Results: The model including autism diagnosis as a predictor revealed no significant effect of diagnosis on discrepancies in SAS ($p = .316$), EQ ($p = .558$), or AQ ($p = .298$). In contrast, both parent and self-reports of autism-related social communication differences significantly predicted discrepancies in social anxiety, empathy, and autism traits (all p 's $< .05$). As parents reported higher SRS scores, participants reported higher SAS ($B=0.188$) and AQ scores ($B=0.116$) but lower EQ scores ($B=-0.110$) than their parents. Conversely, when adults reported higher SRS scores, they reported lower SAS ($B=-0.116$) and AQ scores ($B=-0.125$) but higher EQ scores ($B=.0219$) than their parents.

Conclusions: Findings suggest that an autism diagnosis may not always result in self- and parent-report discrepancies, indicating that diagnosis alone does not explain these differences. Instead, autism-related social communication differences emerged as a key transdiagnostic predictor, highlighting notable variations in reported empathy and social functioning. This treatment-seeking sample may not reflect the general population, as participants and their parents mutually committed to attending social skills programming together, potentially indicating a level of pre-existing agreement and understanding. Future studies could explore how such discrepancies manifest among individuals who are not engaged in a program accompanied by a parent.

436.031 Sensorimotor and Executive Differences in Autistic Individuals with Borderline IQ

C. J. Stevens¹, K. E. Unruh², R. L. Shafer³ and M. W. Mosconi⁴, (1)University of Kansas, Lawrence, KS, (2)Kansas Center for Autism Research and Training (K-CART), University of Kansas Life Span Institute, Lawrence, KS, (3)Life Span Institute, University of Kansas Life Span Institute, Lawrence, KS, (4)Clinical Child Psychology Program, Schiefelbusch Institute for Life Span Studies, University of Kansas, Lawrence, KS

Background: Our group and others have repeatedly demonstrated reduced saccade accuracy, increased variability of saccade accuracy, and increased rates of inhibitory control errors in autistic individuals (e.g., Schmitt et al., 2014). These studies implicate basic sensorimotor and executive processes, respectively, though few studies have directly examined sensorimotor and executive processes in autistic individuals with lower IQs. Determining the extent to which sensorimotor and executive processes vary as a function of IQ in autism is important for defining neurodevelopmental mechanisms and guiding more individualized support strategies.

Objectives: To explore relationships between IQ, sensorimotor behavior, and inhibitory control in a preliminary sample of individuals with borderline IQ relative to autistic individuals with average or above average IQ.

Methods: A preliminary sample of 18 autistic participants completed eye movement tests of sensorimotor and executive control. Six autistic individuals with borderline IQ (71-84) were compared to six age-matched autistic individuals with average IQ (85-115) and six with above average IQ (116-130). To examine sensorimotor control, participants completed a visually guided saccade task in which they looked reactively to visual targets presented at 12 or 24 degrees of visual angle. Saccade latency, accuracy (error), and velocity were examined. To test executive control, participants completed an antisaccade task during which visual targets were presented at 12 or 24 deg of visual angle and participants were instructed to make an "antisaccade" to the opposite hemifield. Latency of correct antisaccades and proportion of trials in which participants looked toward rather than away from targets were examined.

Results: Autistic individuals with borderline IQ showed greater error of their reactive saccades ($M=1.58$, $SD=.43$) than autistic individuals with average or above average IQ ($M=1.13$, $SD=.23$, $t(10)=2.24$, $p=.05$, Cohen's $D=1.29$). IQ groups did not show differences in saccade latency or velocity. Similarly, the borderline IQ group was more variable in their degree of error ($M=1.31$, $SD=0.26$) than the above average IQ group ($M=.944$, $SD=.26$), $t(10)=2.43$, $p=.04$, Cohen's $D=1.4$. During the test of executive control, autistic individuals with borderline IQ showed similar antisaccade latencies and error rates as autistic individuals with average or above average IQ.

Conclusions: Autistic individuals with borderline IQ show reduced saccade accuracy and increased saccade accuracy variability than autistic individuals with average IQ suggesting impairments in the ability to execute rapid sensorimotor behaviors and modulate precision over time based on sensory feedback information. Autistic individuals with borderline IQ did not demonstrate differences in antisaccade error rates suggesting that sensorimotor systems, but not executive systems, may be selectively impacted in autistic individuals with lower IQs. Results indicate that cerebellar-brainstem circuits involved in supporting sensorimotor behaviors may be more severely disrupted in autistic individuals with borderline IQ.

436.032 Sexual Functioning of Autistic People in Menopause and the Relationship with the Reproductive Hormones, Sensory Sensitivities, Camouflaging and Other Autistic Traits

A. Rynkiewicz^{1,2}, E. Ferensztajn-Rochowiak³, M. Galczyńska-Rusin⁴, P. Gutaj⁵, R. L. Moseley⁶, A. Lacroix^{7,8}, K. Sohl⁹, A. Brewer Curran¹⁰ and D. Darmochwał-Kolarz¹¹. (1)Department of Psychiatry, University of Rzeszow, Rzeszow, Poland, (2)Center for Diagnosis, Therapy and Education SPECTRUM ASC-MED, Gdansk, Poland, (3)Department of Adult Psychiatry, Poznan University of Medical Sciences, Poznan, Greater Poland Voivodeship, Poland, (4)Department of Orthodontics and Temporomandibular Disorders, University of Medical Sciences, Poznan, Greater Poland Voivodeship, Poland, (5)Department of Reproduction and Perinatal Medicine, Poznan University of Medical Sciences, Poznan, Greater Poland Voivodeship, Poland, (6)Department of Psychology, Bournemouth University, Poole, United Kingdom, (7)Campbell Family Mental Health Research Institute, Toronto, ON, Canada, (8)University of Grenoble Alpes, University Savoie Mont Blanc, CNRS, LPNC, Grenoble, France, (9)ECHO Autism Communities, University of Missouri School of Medicine, Columbia, MO, (10)Department of Pediatrics, University of Missouri, Columbia, MO, (11)Department of Obstetrics and Gynecology, Institute of Medical Sciences, College of Medical Sciences, University of Rzeszow, Rzeszow, Poland

Background: Sensory processing disorders (SPD) are associated with poorer quality of life, contributing to fluctuation in well-being, daily functioning, and health (Cost-Lopez et al. 2021). SPD could be associated with susceptibility to develop a wide range of psychiatric symptoms and disorders, including depressive and anxiety disorders (Engel-Yeger et al. 2015), alexithymia, internalizing disorders and emotional dysregulation (McMahon et al. 2019). Emerging literature on menopause in autism suggests that the interplay with sensory processing and modulation worsen menopausal symptoms and make every day functioning more difficult for autistic and other neurodivergent populations. The menopausal complaints are associated with higher levels of depression and autistic traits (Groenman et al. 2022; Rynkiewicz et al. 2023). Quantitative data suggest that autistic people experience more severe menopausal symptoms (Groenman et al. 2022; Rynkiewicz et al. 2023), and qualitative reports describe a breakdown in established coping skills which can develop additional psychiatric disorders and symptoms including self-harm and suicidal behavior (Moseley et al. 2021; Rynkiewicz et al. 2024).

Objectives: To investigate if the severity of menopausal symptoms experienced by autistic people were linked to the sensory issues, autistic traits and the levels of reproductive hormones.

Methods: The participants were five white menopausal women, with no intellectual disability (ID), diagnosed with ASD, and including one case from ECHO Autism training on best-practice recommendations. ADI-R, the Autism Clinical Interview for Adults (ACIA), ADOS-2 (Module 4), and self-reported questionnaires: Highly Sensitive Person Scale (HSP Scale), Adolescent/Adult Sensory Profile (AASP), GQ-ASC/Q-ASC (Girls' Questionnaire for ASC) for adult women, Menopause-Specific Quality of Life (MENQOL) Questionnaire were used. The HSP Scale was translated to Polish and validated by the researchers from the Department of Adult Psychiatry, Poznan University of Medical Sciences (PUMS). The researchers from UR and PUMS were formally trained on ACIA. In addition, the full gynecologic examinations, including cytology and hormonal lab testing were performed. The study was approved by the University of Rzeszow (UR) Bioethical Commission (№ 2024/02/007), and patients gave their informed consents.

Results: MENQOL total score, psychosocial and sexual score correlated positively with GQ-ASC total score. MENQOL sexual score correlated positively with AASP Sensory Sensitivity and GQ-ASC camouflaging, but negatively with GQ-ASC Interests. Estradiol levels correlated negatively with MENQOL vasomotor and psychosocial score and FSH, LH and cortisol level correlated positively with MENQOL sexual score. No relation was found between MENQOL and HSPS. Gynecological assessment showed no abnormalities.

Conclusions: Severity of menopausal symptoms was related to intensity of autistic traits. Psychosocial functioning in menopause worsens as the severity of autism symptoms increases. Higher sensory sensitivity deteriorates sexual menopausal symptoms. A strategy for dealing with sexual symptoms of menopause might be intensification of camouflaging. Low estradiol levels worsens vasomotor symptoms of menopause. Although the results are preliminary, they are promising and emphasize the importance of menopause research in autism.

436.033 What Influences the Participation in Physical Activity for Autistic Adults?

K. Halls, K. Walker, A. Lawrence, E. McGlone and C. Thompson, Curtin School of Allied Health, Curtin University, Perth, Western Australia, Australia

Background: Autism spectrum disorder (ASD) is a lifelong neurodevelopmental condition characterised by differences in social communication, and restricted or repetitive behaviours and interests. Autistic adults experience higher rates of chronic health conditions and premature mortality, often attributed to suspected insufficient physical activity. Despite this, limited research has investigated the factors influencing physical activity engagement in autistic adults.

Objectives: This study aimed to explore the factors influencing the types, patterns and volumes of physical activity in autistic adults.

Methods: A total of eight autistic adults (female $n=4$; male $n=3$; non-binary $n=1$). The participants were aged between 23 and 48 ($M=33.5$; $SD=7.9$). Participated in face-to-face semi-structured. In the seven days prior to interview the participants wore an ActivPAL accelerometer and they completed an online daily diary. The interview was guided by a physical activity report from the ActivPAL accelerometer and their daily diary. Interview were audio recorded and transcribed verbatim. The data were analysed using Interpretative Phenomenological Analysis.

Results: The analysis identified seven themes that impacted engagement in physical activity. The first theme, *management of a personal energy quota*, outlined how participants needed to balance the demands of their everyday life to consider engaging in physical activity. The energy quota was influenced by work, poor sleep and masking. The , *adapting physical activity to meet personal needs*, described the relationship between an individual's sensory thresholds, the environment, and the type of physical activity. Autistic adults also noted how their co-occurring challenges influenced their participation in physical activity. Theme three, the *influence of social pressures and connections*, outlined the impact of social connections on participation in physical activity. Strong positive social connections supported participation, but previous experience of bullying was a negative influence. Theme four, *sense of fulfilment through activity*, outlined having a personal goal helped autistic adults participate in physical activity. In outlining theme five, *mandatory and incidental physical activity*, participants noted that they had previously been coerced into participating in physical activity. The autistic adults also noted that they also participated in physical activity to complete a preferred activity. The sixth theme, *the role of sedentary behaviour*, outlined how autistic adults' participation in physical activity was influenced by their preference for desk-based tasks.

Conclusions: The findings of this study provide insights into what influences autistic adults' participation in physical activity. It appears that autistic adults must be aware of balancing their personal energy quota, which is affected by other aspects of life, in order to engage in physical activity. The findings of this study highlight the need to consider how the broader environmental, social, and sensory contexts interact with and influence the engagement of autistic adults in physical activity. These findings provide valuable insights into the barriers and facilitators influencing physical activity participation among autistic adults, which may inform further research and support the development of tailored interventions to promote physical activity and overall well-being in this population.

436.034 Social Anxiety in Autistic Adults: Acceptability and Tolerability of Cognitive-Behavioural Methods and the Role of Camouflaging.

B. Berger Roisenberg¹, K. A. Boulton², E. E. Thomas³, E. A. Demetriou⁴, M. Munro⁵, N. Perry⁶ and A. J. Guastella⁷, (1)The University of Sydney, Sydney, Brazil, (2)Brain and Mind Centre, Children's Hospital Westmead Clinical School, Faculty of Medicine and Health, University of Sydney, Sydney, NSW, Australia, (3)Brain and Mind Centre, University of Sydney, Camperdown, NSW, Australia, (4)Eleni Demetriou, Camperdown, NSW, Australia, (5)University of Sydney, Camperdown, NSW, Australia, (6)The University of Sydney, Sydney, NSW, Australia, (7)Faculty of Medicine and Health, University of Sydney, Sydney, NSW, Australia

Background: A notable concern within the autistic community is the high incidence of social anxiety disorder (SAD), which can negatively impact social well-being and quality of life. This paper aims to evaluate the applicability of cognitive-behavioural models of therapy in addressing social anxiety in autistic individuals. Additionally, there has been some debate that such therapies may enhance camouflaging, but there is very limited data on this issue.

Objectives: This paper aims to evaluate the applicability of a modified cognitive-behavioural model of therapy to address social anxiety in autistic adults.

Methods: The author provides a brief overview of the published evidence linking cognitive-behavioural mechanisms of social anxiety to autistic adults. They then present a qualitative and quantitative study exploring the experiences of autistic adults when they receive a social anxiety cognitive-behaviour group therapy program. This analysis breaks down different aspects of the therapy process to receive feedback. Finally, the author presents a study that examines how camouflaging changes following therapy.

Results: The review found very few studies that test relevant cognitive-behavioural mechanisms of therapy for autistic adults. Both qualitative and quantitative data from the authors own study largely support the implementation of cognitive behavioural practices for autistic adults, with some adaptations and modifications needed. There was no evidence that camouflaging was increased by cognitive-behavioural therapy for social anxiety with a skills component included. In addition, positive feedback was consistently received for the skills aspect of the program.

Conclusions: The findings suggest that cognitive-behavioural models of social anxiety have potential to provide a safe and effective approach for reducing social anxiety in autistic adults. There is a limitation of data, further studies will be needed, and accommodations and adaptations are necessary. The combination of quantitative and qualitative data show the multifaceted generally positive impact of the intervention in treating social anxiety in autistic adults, particularly with the modifications discussed.

436.035 Social Behaviors Among Preschoolers with Vision Impairment (VI), with Autism Spectrum Disorder (ASD) and with Typical Development (TD): Implications for Diagnosis and Intervention

Z. Nir¹ and C. Shulman², (1)*The school of social work, The Hebrew University, Jerusalem, Isreal, Israel,* (2)*The School of Social Work, Profile Resources Group, Jerusalem*

Background:

Vision impairment (VI) is a sensory disability that affects many areas of development, including social development (Vann et al., 2015; Hobson, 2005). Although research reveals an overlap between the profiles of social behaviors in children with vision impairment and those characteristic of children with Autism Spectrum Disorder (ASD), the nature of this phenomenon has not been sufficiently examined (Do et al, 2017).

Objectives:

The main aim of this study is to compare profiles of social behavior of preschool children with VI, those with ASD and typically developing children (TD). This unique comparison among these three groups of children is necessary because social behaviors are quite variable in preschool children.

Methods:

The participants in this study were 120 preschool children, divided equally into three research groups: 40 children with congenital VI, 40 children with ASD, and 40 children with TD, all matched on gender and chronological age. The two clinical groups (VI and ASD) were also matched on mental age. Social behavior was measured using the Social Responsiveness Scale-2nd edition (SRS-2: Constantino, 2012) and child behaviors were evaluated by the Child Behavior Checklist (CBCL: Achenbach & Rescorla, 2000), while adaptive behavior was characterized through parent interviews (Vineland Adaptive Behavior Scales-3, VABS-3: Sparrow et al., 2005).

Results:

Findings suggest that children with VI face similar challenges to children with ASD in receptive and expressive language as well as in adaptive personal skills, anxiety/depression and attention problems. However, play skills and aggressive behavior of children with VI were similar to those with TD. Findings from this study provide support for the claim that children with VI have a separate profile of social skills than that of those with ASD and those with TD, even in early childhood. VI social profile displays less intense, less frequent and less persistent social deficits compared to the social profile of the ASD group, and more than the profile of children with TD. These results are essential for both diagnostic clarity and development of appropriate interventions strategies.

Conclusions:

Preschool children with VI present various challenges in language, adaptive, emotional, and social behavior. Although there are similarities in those challenges among the VI and ASD groups, the social profile of children with VI is unique and is influenced by visual experience which change with maturation. The findings from this study suggest that there is a distinct social profile of children with VI, which reflects a necessary adjustment to the environment due to their visual deficits. Therefore, diagnosticians should be made aware of this unique social behavior profile when an ASD diagnosis is being considered for a child with VI. In addition, parents and professionals who work with preschool children with VI must be familiar with their social profile in order to optimally meet their social needs.

436.037 Socioeconomic Disparities Among Autistic Individuals in Mid- to Late-Adulthood in a Matched Sample with Comparable Educational Attainment in the UK

Y. Pu¹, Z. Wu², T. Ren³ and F. Li⁴, (1)*Xinhua Hospital Affiliated to Shanghai Jiao Tong University School of Medicine, Shanghai, Shanghai, China,* (2)*Shanghai Jiaotong University, Shanghai, Shanghai, China,* (3)*Developmental and Behavioral Pediatric Department & Child Primary Care Department, Brain and Behavioral Research Unit of Shanghai Institute for Pediatric Research and MOE Shanghai Key Laboratory for Children's Environmental Health, Xinhua Hospital, Shanghai, Shanghai, China,* (4)*Department of Developmental and Behavioral Pediatric and Child Primary Care & Ministry of Education-Shanghai Key Laboratory for Children's Environmental Health,, Xinhua Hospital, Shanghai Jiao Tong University School of Medicine, Shanghai, 200092, China., Shanghai, Shanghai, China*

Background:

Individuals with autism spectrum disorder (ASD) are associated with multifaceted disadvantaged socioeconomic status, partially attributable to worse education. Evidence is scarce on the disparity in their adulthood unexplained by educational attainment.

Objectives:

This study aims to investigate socioeconomic disadvantages experienced by autistic individuals in the United Kingdom, given comparable educational attainment.

Methods:

Participants were identified from the UK Biobank study. We first identified individuals with ASD diagnosis, each of whom were randomly matched to up to 10 participants without ASD diagnosis by birth year, age, sex, race and education level. Multivariate linear regression analysis was applied to explore the relationship between TDI, employment status, income, and years of education among individuals with ASD compared to those without ASD.

Results:

The study included 672 ASD cases (66.8% male; mean age 51.5 [SD, 7.9]) and 6,720 matched non-autistic individuals. The average years of education for individuals was 15.2 (SD, 3.8) years, which corresponds to the completion of A levels/AS levels or an equivalent level. Of the 38.5% who took the cognitive tests, autistic individuals exhibited even higher fluid intelligence compared to the non-ASD. In the UK Biobank cohort, ASD individuals, despite similar educational levels, showed significantly lower TDI scores, employment rates, and income compared to non-ASD individuals. This disparity was evident across health, education, crime, and residential outcomes in a subsample of England residents with available data.

Conclusions:

Individuals diagnosed with ASD exhibit significant socioeconomic disadvantages compared to their non-ASD counterparts, particularly in mid-to-later adulthood. Access to suitable educational opportunities is instrumental in reducing the disadvantage.

436.038 Studying Recruitment and Retention in Randomized Controlled Trials Involving Autistic Adults: Lessons on Trial Design and Conduct

A. X. Realpe¹, N. Mills², J. E. Norris³, V. Nimmo-Smith⁴, A. Wilkinson⁵ and D. Rai², (1)University of Bristol, Bristol, United Kingdom, (2)Population Health Sciences, Bristol Medical School, University of Bristol, Bristol, United Kingdom, (3)Centre for Applied Autism Research, University of Bath, Bath, United Kingdom, (4)University of Bristol, Bristol, United Kingdom of Great Britain and Northern Ireland, (5)University of Bristol, Bristol, United Kingdom

Background:

Numerous studies have documented significant physical and mental health inequities in autistic adults compared to the non-autistic population. Addressing these inequities requires a robust evidence base, such as that provided by randomized controlled trials (RCTs) of treatment interventions. High-quality, well-powered studies of effective health interventions for autistic adults remain scarce, and prior RCTs involving autistic adults are often limited by small sample sizes. Poor recruitment and retention rates are major contributors to the failure of many RCTs to achieve sufficient power within the allocated time and budget. Psychosocial factors contributing to hesitancy to enrol to RCTs, as well as failure to complete participation are context- and population-specific, justifying further examination in trials involving autistic people. Understanding such factors is crucial to the recruitment success of future RCTs with the autistic population.

Objectives:

1) To systematically review barriers and facilitators to recruitment and retention in RCTs involving autistic adults; 2) To design and implement strategies to overcome such barriers to recruitment in a large trial involving autistic adults.

Methods:

We conducted a field-wide systematic review to assess whether previously conducted large RCTs in adult autism research effectively recruited and retained participants, and to identify reported barriers and facilitators to recruitment and retention. Additionally, we describe strategies from the QuinteT recruitment intervention (QRI) which uses a mixed-method approach to understand and optimize recruitment to RCTs in real time, and their application for the first time in a large complex medication trial for autistic adults (STRATA).

Results:

Most registered and published trials with autistic adults were small feasibility/pilot studies and did not report on planned sample sizes. Our systematic search identified 33 larger RCTs that collectively recruited 2,664 autistic adults, and retained 86% of their sample on average. Most successful large trials employed international recruitment efforts, leveraging established networks, press releases, community groups, and social media for advertising. Achieved samples report an underrepresentation of females and ethnic minorities. The QRI in the STRATA RCT identified key factors that contributed to recruitment success: 1) enthusiasm from both research teams and the autistic community for obtaining high-quality evidence about mental health treatments, and 2) commitment to co-production of the protocol, and making adaptations (e.g. remote consent/participation). Inconsistencies in communication from trial sites was identified as a key challenge. Specific strategies to address these challenges were developed and implemented in real time which translated to successful recruitment.

Conclusions: Most RCTs with autistic adults are small and not accompanied by pre-registered protocols or sample size calculations. However, our systematic review suggests that it is possible to successfully recruit to and retain autistic participants in large RCTs. These results, combined with our experience implementing the QRI in the STRATA RCT show that challenges to recruitment and retention in RCTs involving autistic adults can be identified and addressed with true co-production with autistic people, clinicians, and researchers.

436.039 "You're Not Going to Get Hired If You Just Act Autistic": Perspectives of Autistic Adults in Canada on Masking in Job Interviews

M. Waite¹, T. Q. Boucher¹, L. Ludwig², K. Armstrong³ and G. Iarocci¹, (1)Psychology, Simon Fraser University, Burnaby, BC, Canada, (2)Community Partner, Burnaby, BC, Canada, (3)Spectrum Works Consulting Group, Vancouver, BC, Canada

Background: Autistic adults in Canada face substantially higher rates of unemployment compared to the general population (Statistics Canada, 2017). Various barriers to autistic adults attaining employment exist (Maras et al., 2021; Sarrett, 2017). In particular, traditional job interviews can be challenging for autistic adults to navigate, often placing considerable emphasis on social conventions and interpersonal dynamics (Huffcutt, 2011; Vincent & Fabri, 2020). To improve their interview performance and conform to these expectations, autistic adults have reported concealing their autistic traits, or masking (Finn et al., 2023; Hull et al., 2017). However, previous research has established that masking is taxing and can negatively impact wellbeing (Bradley et al., 2021).

Objectives: The aim of this study was to explore the experiences and perspectives of autistic adults in Canada about masking in job interviews.

Methods: Twenty-three autistic adults (11 male, 6 female, 6 non-binary/gender-fluid/transgender) ages 19 to 59 years old ($M=31.65$, $SD=11.84$) participated in this study. Participants completed the Autism Spectrum Quotient (AQ) and a demographics questionnaire (see Table 1). They were asked to discuss their experiences with masking in job interviews either over a Teams call ($n=11$) or using a written survey ($n=12$). The authors, consisting of an autistic community member, a non-autistic psychologist with experience supporting autistic adults in their vocational development, and non-autistic researchers, collaboratively wrote the study interview questions. Following an interpretive phenomenological analysis approach, participant responses were analyzed using thematic analysis (Braun & Clarke, 2006). Codes generated independently by two authors were compared, and themes were developed from these codes.

Results: Six themes were generated: (1) Masking is expected and necessary, (2) Masking to appear “normal”, (3) Masking uses a lot of my resources, (4) Masking in the interview is just a temporary solution, (5) Masking is automatic, and (6) “I’m generally against masking”. A complete list of themes, subthemes, and a description of themes is provided in Table 2.

Conclusions: The findings highlight the pressure participants feel to mask their autistic identity during interviews and the associated costs of this masking. All female and gender-diverse participants, along with roughly half of male participants, reported masking their autism in job interviews. Many described masking as necessary for securing employment and detailed the considerable effort they exert to mask, including scripting their responses, practicing their mask with others, and consciously monitoring their behaviours and communication style. Participants indicated that masking is exhausting, feels inauthentic, is inconsistent with their internal experience, and is unsustainable to maintain in the workplace following the interview. To improve the accessibility of job interviews and alleviate the pressure to mask, participants offered a number of suggestions for employers, including providing remote interview options, incorporating skills-based assessments in the hiring process, identifying themselves as welcoming of neurodivergent employees, and initiating discussions about accommodation. Incorporating these suggestions into common practice is important for improving the quality of life for autistic adults (Mason et al., 2018).

436.040 “I Feel like I Don’t Fit in the World”: Self-Identified Autism, Diagnosis and Mental Health Challenges in Adults in Spain

D. Valdez^{1,2}, M. Casanovas² and C. Montiel-Nava³, (1)FLACSO Facultad Latinoamericana de Ciencias Sociales, Buenos Aires, CABA, Argentina, (2)Fundacion Quinta, Madrid, Madrid, Spain, (3)Department of Psychological Science, University of Texas Rio Grande Valley, Edinburg, TX

Background:

Autistic individuals are more likely to experience anxiety and depression than non-autistic individuals (Sedgewick et al., 2020), with autistic women and non-binary individuals reporting higher rates of mental health issues compared to autistic men (Sedgewick et al., 2020). Autistic adults also exhibit a higher prevalence of psychiatric conditions compared to those with other developmental disabilities (Tint et al., 2023). Gender differences influence the presentation of autism, with autistic women showing more sensory symptoms and self-reported autistic traits but fewer socio-communication difficulties than men (Lai et al., 2011). In contrast, autistic men display more repetitive behaviors (Wilson et al., 2016). These findings underscore the importance of gender-specific diagnostic tools and interventions for autistic adults.

Objectives:

This study aimed to compare the prevalence of psychiatric co-occurrences in autistic and non-autistic adults undergoing diagnostic evaluations in Madrid, Spain, with a focus on gender differences.

Methods:

A cross-sectional study was conducted with 101 adults (autistic: $n=79$, 78.2%; non-autistic: $n=22$, 21.8%) attending a nonprofit organization’s diagnostic services. Participants completed the ADOS-2, Beck Anxiety Inventory, and Toronto Alexithymia Scale. Data on previous assessments, use of mental health services, and psychiatric diagnoses were collected.

Results:

Among those who self-identify as autistic people, 78% ($n=79$) received an autism diagnosis. This group was predominantly female (61%, $n=49$), with an average age of 30.7 ($SD=11.8$) and a significant portion having college degrees (48%, $n=38$). Non-binary individuals were more represented in the autistic group (15.2%, $n=12$), though these differences were not statistically significant. Autistic individuals had significantly higher autism symptoms ($t=10.57$, $p<.001$), alexithymia ($t=4.29$, $p=.001$), and sensory issues ($\chi^2=4.28$, $p=.039$) compared to non-autistic individuals. Autistic women reported significantly more anxiety ($F=10.89$, $p=.002$) and autism symptoms ($F=18.44$, $p<.001$) than autistic men and non-binary individuals.

Conclusions:

This study highlights the prevalence of psychiatric co-occurrences among autistic adults in Madrid, with many receiving a first-time autism diagnosis in middle adulthood. It is a major challenge to provide access to diagnosis in adults, as there is a growing demand (Happé et al., 2016) and waiting a long time to get a diagnosis often means not being able to count on the support and treatments that could improve the emotional wellbeing of autistic adults. Our results show that more than 50% of autistic adults do not have treatment in the area of mental health at the time of receiving the diagnosis.

The lack of diagnosis leads to a worsening of the clinical conditions that co-occur with ASD, increasing difficulties in everyday life situations, the perception of loneliness and sometimes suicidal ideation or attempts. (Cassidy et al., 2020; Black et al., 2023). Gender differences play a crucial role in the clinical presentation and mental health outcomes of autistic individuals. Public health policies should prioritize improving diagnostic access and developing tailored diagnostic tools for adults, particularly women, to reduce the long-term impact of undiagnosed autism, including mental health challenges like anxiety and depression. Access to a diagnosis is a fundamental right that enhances self-understanding and improves quality of life through appropriate community support and services.

436.041 Task Collaboration between Dyads with and without an Autistic Partner: A Multi-Level Model

M. Fok¹, M. Wang², D. C. Martino¹, J. Kim³, C. B. Hornburg⁴, M. Jeon⁵, S. Kim⁵ and A. Scarpa¹, (1)Department of Psychology, Virginia Tech, Blacksburg, VA, (2)Virginia Tech Transportation Institute, Blacksburg, VA, (3)Department of Human Development and Family Science, Purdue University, West Lafayette, IN, (4)Department of Human Development and Family Science, Virginia Tech, Blacksburg, VA, (5)Department of Industrial and Systems Engineering, Virginia Tech, Blacksburg, VA

Background:

As autistic people transition to adulthood, fostering neurodiversity in the workforce becomes crucial. Competitive workplaces often demand proficiency in communication and teamwork skills, which can manifest differently in individuals with autism. Autistic adults who face challenges in collaborative problem-solving in the workplace may encounter poor employment outcomes. However, from a strengths-based perspective, autistic adults offer valuable attributes—such as being detail oriented—that benefit the workforce. This highlights the need for research to develop strategies that support autistic adults in collaborative work environments.

Objectives:

This study explored the behavioral interchanges of neurodiverse (non-autistic adults [NA]-autistic adults [AA]) and neurotypical (NA-NA) dyads during collaborative assembly tasks. Multi-level modeling (MLM) determined how collaboration changed over time, across varying difficulty levels, and between dyad types.

Methods:

The study included 46 participants (10 AA, 36 NA) with a mean age of 23.8 years ($SD=5.6$; range=18–44), forming 23 gender and age-matched dyads (10 NA-AA, 13 NA-NA). These dyads collaboratively assembled four Lego sets (i.e., four tasks) at two difficulty (or constraint) levels: medium (Tasks 1 and 2) and high (Tasks 3 and 4). For Task 1, participants were assigned the roles of builder (responsible for assembly) and assistant (provided support without assembling). Roles were reversed for Task 2. For Task 3, roles were engineer (provided verbal instruction without handling pieces) and builder (assembled without viewing written instructions). Roles were reversed for Task 4. Collaboration was assessed by evaluating dyadic behaviors in one-minute epochs across five dimensions (Meier et al., 2007): Collaboration Flow, Sustaining Mutual Understanding, Knowledge Exchange, Argumentation, and Cooperative Orientation. Each dimension was coded as +2=very good, +1=good, -1=bad, or -2=very bad for each epoch and averaged across the five dimensions (mean task length=11.67 min, mean collaboration=1.71 [$SD=0.44$]). Two graduate students independently coded each dyad, and any discrepancies were resolved through consensus discussion with a third coder.

Results:

Repeated measures of collaboration nested within dyad types were examined via MLM. There were significant increases in collaboration within the task across the whole observation ($F=4.39$, $p=.036$), driven by a Time x Dyad Type interaction showing significant increases in NA-AA dyads ($F=18.67$, $p<.001$; Figure 1). There were two significant main effects: Constraint Level ($F=50.78$, $p<.001$), indicating greater collaboration during the high vs. medium constraint tasks, and Dyad Type ($F=12.74$, $p=.001$) with NA-AA dyads exhibiting lower overall collaboration than NA-NA dyads. Post-hoc tests for a significant Constraint Level x Dyad Type interaction ($F=32.93$, $p<.001$) indicated that collaboration was lower during medium constraint tasks for both NA-AA ($p<.001$) and NA-NA ($p=.007$) dyads, whereas NA-AA dyads started lower and demonstrated steeper increase from medium to high constraint (Figure 2).

Conclusions:

These results suggest that for both dyad types, collaboration on shared tasks improves as the roles become more defined. Additionally, neurodiverse dyads especially benefit from an increase in role structure. This study provides preliminary evidence on how neurodiverse collaboration can be supported. Future research should examine individual-level factors (i.e., perceived task difficulty) and include AA-AA dyads to further understand collaboration dynamics.

**436.042 The Association between Autistic Traits and Trajectories of Anxiety in Middle-Aged and Older Adults: A Growth Mixture Model Analysis**

A. Eshetu¹, J. Stott², A. John³ and G. R. Stewart⁴, (1)University College London, London, London, United Kingdom, (2)University College London, London, London, (3)UCL, London, England, United Kingdom, (4)Social, Genetic and Developmental Psychiatry Centre, King's College London, London, United Kingdom

Background: Anxiety is commonly experienced by autistic people (Vasa et al. 2020). However, existing research into anxiety beyond midlife is scarce relying mostly on cross-sectional approaches and leaving much about the longitudinal course of anxiety in this population unknown (Mason et al., 2022).

Objectives: This study explored the relationship between autistic traits and longitudinal trajectories of anxiety using a large sample of middle-aged and older adults. The analyses within this abstract (which uses data from 2014 to 2020) will be updated to include additional data from 2014 to 2024 ahead of the INSAR 2025 Annual Meeting.

Methods: This study uses annually collected longitudinal data from the PROTECT cohort, an ongoing online study examining ageing and health. In our provisional analyses, a large sample of 13,927 middle-aged and older adults (aged 50–100 years; median age = 62) completed measures related to autistic traits (PROTECT Autistic Spectrum Traits questionnaire, Stewart et al., 2021) and current anxiety symptoms (Generalised Anxiety Disorder questionnaire, GAD-7; Spitzer et al., 2006). Among the provisional sample, 210 (~1.5% of the total sample; 73.3% female) endorsed high autistic traits (Autism Spectrum Trait: AST group) and 13,057 (~93.8% of the total sample; 75.8% female) reported no autistic traits (Control Older Adults: COA group). Growth mixture modelling (GMM) was employed to identify latent classes of anxiety symptom trajectories. The association between AST and anxiety class membership was examined using multinomial logistic regression.

Results: Provisionally, GMM analysis determined a three-class solution provided the best fit for the anxiety trajectories in this sample based on several fit indices (AIC = 292981, BIC = 203154, LMR and ALRT $p < .001$). The majority of participants exhibited persistently low anxiety symptoms that fell into the ‘minimal to mild’ range of the GAD-7 measure: ‘minimal’ (scores ≈ 1 ; 78.6%, $n = 10,674$) and ‘mild’ (scores ≈ 3 ; 18.4%, $n = 2,230$). A small proportion of the sample experienced sustained ‘moderate’ anxiety symptoms (scores ≈ 7 ; 3.0%, $n = 363$). AST participants were found in all three trajectories but were more likely to be in the highest anxiety class (OR adjusted = 1.61, $SE = 0.24$, $p < .001$).

Conclusions: These provisional results suggest that middle-aged and older adults who endorse elevated autistic traits are at higher risk of experiencing greater levels of anxiety over time. These findings highlight the need for comprehensive mental health support for ageing autistic populations. Future studies using more diverse samples, including those with diagnosed autism, are required to better understand longitudinal anxiety trajectories among this heterogeneous population.

436.043 The Big Move: Incidence, Timing, and Predictors of Residential Status Among Adults with Autism and Developmental Disabilities

H. Singer^a, E. B. Clarke^a and C. Lord^b, (1)UCLA CART (Center for Autism Research and Treatment), Los Angeles, CA, (2)Graduate School of Applied and Professional Psychology, Rutgers University - New Brunswick, Piscataway, NJ, (3)UCLA Semel Institute for Neuroscience and Human Behavior, Los Angeles, CA

Background:

Many adults with autism and other developmental disabilities (DDs) continue living in the family home well into adulthood (Dudley et al., 2018). Moving out of the family home can promote autonomy and well-being, but the transition is often surrounded by anxiety and unmet service needs. Further, residential outcomes for this population vary by co-occurring intellectual disability (ID): those with ID may require supported housing (e.g., group home, supported living arrangement), while those without ID are more likely to transition to independent living. Though housing is a key aspect of adult life, little existing research examines residential outcomes for adults with autism and DDs.

Objectives:

Leverage a well-characterized longitudinal cohort of adults with autism and other DDs ($n = 139$, $M_{age} = 31.46$ years, $SD = 2.78$; $n = 111$ autistic; $n = 28$ non-autism DD) to examine:

- 1) The percentage who live in their family home, in supported housing or independently (i.e. alone or with partners/roommates).
- 2) Associations between individual and sociodemographic characteristics with the timing and odds of transitioning out of the family home for participants with and without ID.

Methods: Participants were consecutive referrals to autism/neurodevelopmental clinics identified between ages 2-3 and followed for three decades. Given distinct residential transitions, analyses separately investigated participants with ID ($IQ < 70$) and without ID ($IQ \geq 70$; Table 1). Cox proportional hazards models assessed factors influencing the likelihood of leaving the family home, including employment, demographics, and autism symptomatology.

Results: By age 32, 51% of participants lived in their family home (Table 1). Among those who moved away ($n = 68$), roughly 30% of individuals without ID left home at age 18. Adults with ID moved away at varied ages (Figure 1). For individuals without ID, cox models revealed that having a college degree or higher ($B = 1.858$, $p < 0.001$) most significantly increased odds of transitioning, followed by having a mother with a college degree ($B = 0.920$, $p = 0.033$). For participants with ID, being from a rural area significantly decreased odds of transitioning ($B = -1.181$, $p = 0.029$). In contrast, having a mother with a college degree significantly increased odds ($B = 1.757$, $p = 0.005$). Interestingly, higher IQ decreased the odds of leaving home for individuals with ID ($B = -0.041$, $p = 0.011$). Race, autism symptomatology, and employment did not predict residential transitions for either group.

Conclusions: For adults with autism and other DDs without ID, having a college education was the single largest predictor of living independently. For adults with ID, maternal education was the largest predictor of transition. Notably, IQ was significantly negatively associated with residential transitions for adults with ID, but not for those without. There may be greater urgency from family and service systems to expedite residential transitions for individuals with more pronounced needs. Results may also underscore a call for greater transition support especially for families with less educational resources and from rural areas. As this population ages, there is a pressing need to better understand residential transitions and factors associated with positive outcomes.

436.044 The Experiences of Direct Support Professionals Working with Autistic Adults: An Exploratory Study

S. M. Colón, Health Sciences, Towson University, Towson, MD

Background: Direct support professionals (DSPs) are hired to provide adequate and meaningful habilitative services to autistic adults. DSPs work with many autistic adults who have varying levels of support needs. It is suspected that DSPs may feel they are not being set up for overall success when working with autistic adults due to their organization's inadequate onboarding and lack of trainings.

Objectives: To explore the perceived quality of support DSPs receive in the field while working with autistic adults and how they navigate challenges.

Methods: This study uses a qualitative study approach featuring semi-structured interviews of 5 direct support professionals who were recruited through a snowball sampling approach. Interviews were transcribed by a HIPAA compliant transcription service. One independent coder, plus peer debrief, implemented the constant comparative method associated with a grounded theory approach. Codes and themes will be developed accordingly.

Results: Six major themes emerged: **(1) Challenges.** DSPs shared their experiences with how challenging their role is since "you don't know what you're going to be faced with on a day-to-day basis." Challenges ranged from barriers "being prepared to de-escalate a community that doesn't fully understand someone with potentially autism" up to situations that don't "go over too well in the community setting and we got the cops called on us." **(2) DSP Role.** DSPs are not always trained to but are expected to provide supports that vary "from individual to individual [for] folks on the spectrum, it's very individualized." **(3) Lack of Professional Support.** Service provision expectations of DSPs can be negatively impacted by a lack of professional supports which includes instances where "the training is -- it might not be extensive enough." **(4) Lack of Understanding.** DSPs are then left with a lack of understanding when it comes to supporting autistic adults. This can create situations where DSPs feel like "how can I learn or be taught from a book that's an understanding for you and not for me if I haven't worked with this person hands-on?" **(5) Successes.** While challenges are critical to examine, successes are also worthy of noting. DSPs who are empathetic and show passion in their role can lead to successful outcomes for autistic adults. "I think being willing to listen, being willing to check in with yourself, make sure that your bias is not affecting their ability to succeed, and knowing that success looks different to everybody." **(6) Supportive Agencies.** The success of DSPs is fostered through supportive agencies. "The organization support is very crucial as well. So, the family support, the organization support, and the -- yeah, the support that you receive from all stakeholder, the -- it matters. So, yes, to let, to make you be a successful DSP."

Conclusions: Well-equipped direct support professionals are crucial for adequate service provision for autistic adults receiving supports through Medicaid home and community-based supports. Future research should focus on the complexities of service provision and the DSP role. Researchers should explore ways to create more comprehensive and person-centered approaches to service implementation.

436.045 The Interaction between Autistic Traits and ADHD Symptoms in Taiwanese Adults: A Network Analysis

P. Y. Pan¹ and C. B. Yeh², (1)Department of Psychiatry, Tri-Service General Hospital, Taipei, Taipei, Taiwan, (2)Department of Psychiatry, Tri-Service General Hospital, National Defense Medical Center, Taipei, Taipei, Taiwan

Background:

Autism and ADHD symptoms tend to co-occur among children and adolescents. The shared genetic architecture and neurocognitive deficits may contribute to the similar manifestations of some symptoms between these two diagnostic entities. Network analysis is a useful tool to unpack the overlap and to reveal interactions between individual autistic traits and ADHD symptoms. The results of previous network analyses indicated that autism and ADHD symptoms among children could be divided into two separate constructs. However, the cross-condition associations of autism and ADHD in adults has been understudied in Asian countries.

Objectives:

This study aimed to examine the interaction between autistic traits and ADHD symptoms using network analysis in a sample of Taiwanese adults.

Methods:

A total of 659 adult participants (age range 20-83 years, mean age 34.49 ± 11.08 years, 46.1% male) were recruited from the psychiatric outpatient and the physical examination department of two teaching hospitals, as well as a university in Taiwan. Of them, 167 participants reported to have psychiatric disorders, and 13 reported to have autism. The Chinese version of Social Responsiveness Scale-2 (SRS-2) adult (self-report) form was used to measure the participants' autistic traits, and the Adult ADHD Self-Report Scale (ASRS) was used to measure their ADHD symptoms. The eLasso procedures was adopted to estimate undirected networks of autistic traits and ADHD symptoms.

Results: The 65 items of SRS-2 were grouped into two factors: Social Communication and Interaction (SCI, 49 items, Cronbach's alpha 0.95–0.96) and Restricted Interests and Repetitive Behavior (RRB, 16 items, Cronbach's alpha 0.86–0.89). There were 53 nonzero edges (34.64% of all 153 possible edges) between two ADHD symptoms, 198 nonzero edges (4.71% of all 2,080 possible edges) between two autism traits, and 18 nonzero edges (1.54% of all 1170 possible edges) between one ADHD and one autistic trait. Nonparametric Kruskal–Wallis test indicated significant differences in edge weight between ADHD–ADHD, autism–autism, and ADHD–autism connections ($\chi^2 = 13.04$, $p = 0.001$); pairwise Wilcoxon test accounting for multiple comparisons indicated ADHD–autism connections were significantly weaker than ADHD–ADHD ($p = 0.003$) and autism–autism ($p < 0.001$) connections. There was no difference on the strengths between ADHD–ADHD and autism–autism connections ($p = 0.901$). Of the 18 nonzero ADHD–autism connections, inattention symptoms and hyperactivity symptoms did not differ in number of edges (8 vs. 10) and group edge weight ($W = 27$, $p = 0.267$). As for the two factors of autistic traits, SCI contributed to most of the edges with ADHD symptoms compared to RRB (17 vs. 1).

Conclusions:

Our findings indicate that autistic traits and ADHD symptoms remain segregated in adult individuals. The strengths of ADHD–ADHD symptom connection weakened along with the partial remission in developmental trajectory. Autistic traits in social communication domain explained most of the associations between autistic traits and ADHD symptoms in adults.

436.046 The Phenomenology and Network Connectivity Alterations of Low Dose Psilocybin in Autistic and Non-Autistic Adults
T. Whelan¹, M. Dimitrov², C. L. Ellis³, F. Moruzzi⁴, M. J. Kangas², N. Khalil⁵, G. Ivin⁶, E. Daly², N. A. Puts⁷, D. Murphy⁸ and G. McAlonan⁹,
 (1)COMPASS Pathways PLC, London, United Kingdom, (2)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (3)Institute of Psychiatry, Psychology and Neuroscience, Institute of Psychiatry, KCL, London, United Kingdom, (4)King's College London, London, United Kingdom, (5)South London and Maudsley NHS Foundation Trust and Institute of Psychiatry, Psychology and Neurosciences, King's College London, London, United Kingdom, (6)South London and Maudsley NHS Foundation Trust Pharmacy, UK, London, United Kingdom, (7)Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology & Neuroscience, King's College London, London, United Kingdom, (8)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, UNITED KINGDOM, (9)NIHR-Biomedical Research Centre for Mental Health at the Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, UNITED KINGDOM

Background: Accumulating evidence has implicated the serotonin system in the underlying neurobiology of autism. Differences in the serotonin system are reported across organisational levels of autistic brain function, including alterations in the cortical expression of 5HT_{2A} receptors and the connectivity of resting-state networks. Both of which are well-established targets of the classic psychedelic and partial 5HT_{2A} receptor agonist psilocybin. For example, cortical 5HT_{2A} receptor activation is primarily responsible for the subjective (or 'psychedelic') effects of psilocybin, which have been associated with the patterns of functional connectivity alterations that it produces.

Objectives: Psilocybin was used as a pharmacological probe of the serotonin system to directly establish whether the serotonergic targets of psilocybin function differently in autism. Specifically, the subjective effects and shifts in within- and between-network functional connectivity in response to psilocybin were investigated.

Methods: In our 'PSILAUT' experimental medicine study, non-autistic (n = 30) and autistic (n = 37) adult participants received either (inactive) placebo, 2 mg or 5 mg psilocybin on three separate visits in repeated-measures, double-blind, randomised order. A resting-state functional MRI scan was acquired at peak drug effects (~ 70 mins post-administration) and the 5-dimensional altered states of consciousness (5D-ASC) questionnaire was used to quantify self-reported subjective effects at the end of each visit (~ 4 hours post-administration).

Results: The results of these ongoing analyses will be reported here for the first time.

Conclusions: This work will have important clinical ramifications. Recent psilocybin clinical trials have reported efficacy across a range of psychiatric conditions, including depression – which is more common in autism. Hence, cohorts in psilocybin clinical trials will likely include autistic individuals. Our previous work has suggested that, for example, the functional connectivity of resting-state networks respond differently to drug challenge in autistic compared to non-autistic participants. Should this be replicated here, any potential differences in responsivity to psilocybin in autistic individuals specifically may influence clinical efficacy in this sub-population. Findings from this study may also inform sub-grouping of autistic participants based on individual responsivity to psilocybin.

436.047 The Role of Memory in Reading Intervention Success for Autistic Children

M. E. Beckerson, S. O'Kelley and R. K. Kana, Department of Psychology, The University of Alabama at Birmingham, Birmingham, AL

Background: A subset of autistic children excel at word reading (i.e., decoding) but struggle with reading comprehension, resulting in a *discrepant poor comprehender* reading profile (Nation et al., 2006; Davidson, 2021). Reading comprehension requires visual and verbal memory processes to create a cohesive representation of the text (Wooley, 2010; Cain, 2006). Weaknesses in short-term memory processes have been reported in many autistic individuals (Williams et al., 2006). Verbal and visual short-term memory have also been associated with the development of other cognitive abilities in autistic populations, including expressive vocabulary and syntactic production (i.e., sentence recall; Talli, 2020). As such, short-term memory processes likely contribute significantly to reading comprehension. However, the role of memory in general and working memory specifically, on reading comprehension, and the same in the context of response to intervention, have not been examined in autistic children with the *discrepant poor comprehender* profile.

Objectives: The current study examines relationships between working memory, short-term memory, and reading comprehension in autistic children with a discrepant reading profile. We also examine whether these memory variables predict autistic children's reading comprehension after they complete a reading intervention.

Methods: 26 autistic children (females=7) have participated in this ongoing study (M age=11.29, SD =1.69). Participants completed testing sessions before (T1) and after (T2) participating in a 10-week reading intervention based on visual imagery (Visualizing and Verbalizing (V/V) intervention; Bell, 1991). A full-scale IQ (FSIQ) and verbal IQ (VIQ) of 70 or above, as measured by the Weschler Abbreviated Intelligence Scale (WASI-II), was required to participate (FSIQ M =90.77, SD =12.31; VIQ M =86.92, SD =10.36). Participants also completed The Gray Oral Reading Test (GORT-5) and The Wide Range Assessment of Memory and Learning (WRAML-2). Visual and verbal memory indices of the WRAML-2 were combined into the *memory screening index*, which represents general short term memory functioning. The Behavior Rating Inventory of Executive Function (BRIEF-2) was used to obtain parent-reported estimates of participants' working memory.

After running Pearson correlations, BRIEF-2 working memory (T-scores) and WRAML-2 memory screening index (standard scores) were submitted to a multiple linear regression with T2 GORT-5 comprehension (scaled scores) as the dependent variable. T1 GORT-5 scores were also entered as a predictor in this model to control for baseline comprehension. It was hypothesized that better general short-term memory and working memory would predict higher T2 comprehension scores.

Results: WRAML-2 screening memory was significantly correlated with T2 GORT-5 scores ($r(19)=0.607$, $p=.004$), while working memory was not ($r(20)=-.202$, $p=.367$). After controlling for baseline reading comprehension, WRAML-2 screening memory significantly predicted T2 GORT-5 scores ($\beta=.049$, $t(20)=2.33$, $p=.032$), while working memory did not.

Conclusions: These preliminary results suggest that short-term memory plays a significant role in autistic children's ability to improve their reading comprehension after intervention. Children with poorer short-term memory may have greater difficulty creating gestalt mental images of large text to facilitate reading comprehension, which is the general mechanism of this intervention. These children may benefit from additional supports or strategies.

436.048 The Vocational and Educational Index: A Comprehensive Update to the Vocational Index

G. A. Herbert¹, J. L. Taylor¹, S. R. Carlson², L. E. Smith DaWalt³, M. M. Burke⁴ and M. R. Mailick³, (1)Department of General Pediatrics, Vanderbilt University Medical Center, Nashville, TN, (2)Special Education, The University of New Mexico, Albuquerque, NM, (3)University of Wisconsin-Madison Waisman Center, Madison, WI, (4)Special Education, Vanderbilt University, Nashville, TN

Background: The Vocational Index (VI) was developed in 2012 as a reliable method of categorizing vocational and educational activities of autistic adults (Taylor & Seltzer, 2012). Prior autism research often grouped activities into broad indicators of working or not working. The VI allowed for more nuanced coding that captured a range of vocational and educational experiences of autistic individuals. The VI has been well-used, but changes in postsecondary education (PSE) options and shifts in the employment landscape have created a need for an updated version (Sahin et al., 2020).

Objectives: This study outlines the process and outcomes of updating the VI into the Vocational and Educational Index (VEI), expanding the original framework to reflect the growing range of vocational and educational opportunities for autistic adults.

Methods: Updating the VI was an iterative process starting with reviewing over 200 interviews from a longitudinal study of autistic adults administered between 2020-2022. The research team identified activities not represented in the VI, and drafted code revisions to incorporate these activities. Through independent coding, two researchers applied new codes to the dataset, making minor adjustments to clarify and confirm accurate categorization.

Revised codes were applied to a sample of 384 autistic adults ages 18-35, drawn from four studies. Data was extracted from interviews/surveys then two researchers independently coded vocational and PSE activities using original and updated codes. Through consensus resolution, data review, and group discussions, the team ensured reliability and compared the two coding schemes for consistency and change.

Results: The most substantial change involved separating educational and vocational codes into parallel dimensions with activities benchmarked by community integration, supports, and number of hours. This allowed for more precise classification of PSE programs available to autistic adults. Other revisions clarified types of support and separated unpaid internships from volunteering.

The VEI introduced a summary code derived by taking the higher of the educational and vocational code. Compared to the original codes, the VEI dimensional codes provided insight into how vocational versus PSE activities contribute to overall summary codes. While just over 20% of adults had no vocational nor educational activities, the “no activity” codes were more frequent within each dimension with one-third of adults not participating in vocational activities, and about 70% of adults not in PSE programs.

Distributions of VI and summary VEI codes were similar (See Table). Nearly 50% of adults classified as a “9” in competitive employment or degree-seeking PSE programs, and around 25% in low-activity categories of “2” or “1”, indicating volunteering, non-degree/non-certificate seeking PSE programs, or no participation. A notable difference was the reduction in code “2” from 5.7% to 3.6%, due to reclassifications of unpaid internships and certificate programs into categories with higher scores.

Conclusions: The VEI offers a flexible framework for studying contemporary vocational and educational experiences of autistic adults, ensuring research can keep pace with evolving opportunities available to this population. Reliable coding categories will aid in tracking change in vocational/educational activities over time, examining outcomes of intervention, and comparing activities across cohorts and nationalities.

**436.049** Identifying Links between Parkinsonism Symptoms, Restricted and Repetitive Behaviors and Interests, and Caudate Volume in Autistic Adults across the Lifespan

M. Velez Galindo¹, E. Ofori¹, A. Rodi², M. Valdez², K. Grabeel³, A. Sabri², J. Smith-Plata², D. Peterson¹, D. Q. Beversdorf⁴, G. L. Wallace⁵ and B. B. Braden¹, (1)College of Health Solutions, Arizona State University, Tempe, AZ, (2)Arizona State University, Tempe, AZ, (3)Arizona State University, Phoenix, AZ, (4)Department of Radiology, Neurology, and Psychological Sciences, University of Missouri, Columbia, MO, (5)The George Washington University, Washington, DC

Background:

Autism spectrum disorder (ASD) is a complex neurodevelopmental condition primarily studied in children and young adults, leaving a significant gap in understanding its impact on aging autistic adults. Motor challenges are often overlooked in autism, and potentially contribute to elevated risk of parkinsonism, which has been demonstrated through healthcare records, the Unified Parkinson's Disease Rating Scale, and case reports. Our research group has shown elevated self-reported parkinsonism features in two independent cohorts, with one cohort showing cross-sectional evidence of accelerated volume loss in the caudate, a critical motor control brain region. Interestingly, caudate size has also been linked to restricted and repetitive behaviors and interests (RRBIs), a core feature of autism, but whether or not RRBIs are linked with parkinsonism in autistic adults has not been investigated. Elucidating behavioral risk factors that can help clinicians identify autistic adults that are more vulnerable to parkinsonism will be critical to providing the earliest and best care.

Objectives:

We aimed to investigate the relationship between self-report parkinsonism and RRBIs in two independent cohort, one from Arizona and a nation-wide sample recruited from Simons Powering Autism Research (SPARK). Relationships with caudate volume were also investigated in the Arizona cohort.

Methods:

The Parkinsonism Screening Questionnaire (PSQ) and the Adult Repetitive Behaviors Questionnaire-2 (RBQ-2A) were administered in both cohorts (Arizona $n=207$; SPARK $n=210$; see Figure 1 for full demographics). For the Arizona cohort, bilateral caudate volumes were calculated using FreeSurfer from T1-weighted MRI.

Results:

See figure 1 for graphical depictions and full statistical results. Correlations revealed that the RBQ-2A factor 1 – motor/sensory, factor 2 – rigidity/routines/restricted interests, and total score significantly correlated with the PSQ total score in both samples, showing moderate to small effect sizes (e.g. $r(38)=0.44$, $p=0.004$; $r(208)=0.34$, $p<0.001$ for RBQ-2A total in Arizona and SPARK, respectively). No significant correlations were found between left and right caudate volumes and RBQ-2A factor 1, factor 2, or total score, however, due to the explicit role of caudate in motor function, correlations were explored with a specific motor subscale of the RBQ-2A, which was significant bilaterally (e.g. Left: $r(83)=0.28$; $p=0.01$). No significant correlations between bilateral caudate volume and PSQ total scores.

Conclusions:

Our findings provide evidence that self-reported parkinsonism features are associated with RRBIs in autistic adults across two independent cohorts. Both factors and total scores from the RBQ-2A correlated with parkinsonism features, suggesting that RRBIs broadly contribute to parkinsonism risk in the autistic population, as opposed to repetitive motor behaviors alone. Importantly, there is no overlap in items assessed on the RBQ-2A and PSQ, suggest that this relationship is not a phenocopy or symptomatic overshadowing, but further investigation is needed to fully understand the association. In the Arizona cohort, repetitive motor behaviors correlated with caudate volume, but not parkinsonism features. This suggests that the potential risk that RRBIs may present for developing parkinsonism features in autistic adults is not mediated through the caudate. Future research is warranted to identify converging and diverging neural mechanisms of these two symptom domains in aging autistic adults.

436.050 Towards a Better Understanding of Adverse Life Experiences in Autism and Attention-Deficit Hyperactivity Disorder

O. Layinka¹, P. Shah² and L. A. Livingston³, (1)University of Bath, Bath, Somerset, United Kingdom, (2)Department of Psychology, University of Bath, Bath, United Kingdom, (3)Department of Psychology, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom

Background:

Adverse life experiences (e.g., poverty and abuse) are associated with negative life outcomes, such as depression and heart disease. This association follows a dose-response effect whereby the more adversities a person has experienced, the higher the likelihood of these negative outcomes. Research suggests that autistic/ADHD individuals are over twice as likely to experience adversity compared to neurotypical people, however, little is known about the intricacies of this relationship. Additionally, while research primarily focuses on negative outcomes, the hidden talents model theorises that adaptive strengths may also arise from adversity. This study aims to fill these gaps within research into adversity in autism and ADHD by investigating: (1) whether there are adversities specific to autism/ADHD, (2) why autistic/ADHD individuals may be more susceptible to adversities, and (3) whether these adverse experiences contribute towards adaptive strengths, following the hidden talents model.

Objectives:

Leveraging a large sample, diverse in sociodemographic characteristics, we conducted a qualitative investigation into adverse experiences and life outcomes in adults with ADHD and/or autism, to gain novel insights into adversity and adaptive strengths in neurodevelopmental conditions.

Methods:

One hundred and twenty-three individuals aged 18 years and over, living in the UK or USA, who were diagnosed or self-identified as autistic or with ADHD, were sampled via online platforms. Participants completed an online survey with three open-ended questions, reporting their adverse experiences, the role of their neurodevelopmental condition on these experiences, and any resulting strengths. Data were analysed in NVivo, using inductive thematic analysis.

Results:

The findings, shown in Figure 1, suggest that cognitive (e.g., disorganisation), social (e.g., difficulties maintaining social relationships), emotional (e.g., emotional dysregulation), and environmental (e.g., lack of accessible support) factors play a role in participants experiencing marginalisation (i.e., job insecurity, financial instability, and neglect) and mistreatment (i.e., bullying, abuse, and isolation). In total, 63% of participants reported experiencing mental and physical health decline as a result of these adverse experiences. Notably, 75% participants also reported adaptive strengths derived from these adverse experiences, with approximately 25% identifying that they were more empathetic and 23% identifying that they were more resilient. However, 22% of participants highlighted that they did not develop any strengths as a result of their adversities.

Conclusions:

The direct accounts obtained from autistic and ADHD adults highlight several cognitive, social, emotional, and environmental factors that may increase the risk of adverse experiences in neurodivergent populations. Our findings have the potential to inform support given to these individuals across a range of settings (e.g., school, home, workplace). Crucially, this is the first study to apply the hidden talents model to autism and ADHD, showing that adversity may lead to some adaptive strengths such as empathy and resilience. However, further empirical research is required to elucidate the extent of these adaptive strengths.

436.051 Training Community Clinicians in Tennessee to Provide Quality Care for Autistic Adults

J. R. Smith^{1,2}, **G. Stobbe**³ and **B. A. Malow**⁴, (1)Psychiatry and Behavioral Sciences, Vanderbilt University Medical Center, Nashville, TN, (2)Vanderbilt Kennedy Center, Nashville, TN, (3)Seattle Children's Autism Center, Seattle, WA, (4)Sleep Disorders Division, Department of Neurology, Vanderbilt University Medical Center, Nashville, TN

Background:

Autistic adults experience significant unmet healthcare needs, with opportunities for improvement in both the systems and the practitioners who serve this population. Novel models to provide training and support to practitioners are sorely needed.

Objectives:

This project developed and is currently testing an Extension for Community Healthcare Outcomes (ECHO) care model adapted from our previous work. It was specifically focused on training practitioners in Tennessee who care for autistic adults, and those with other neurodiverse conditions, in best-practice medical and behavioral care. A key aspect of the program was the inclusion of an autistic adult and also family advocates.

Methods:

Community healthcare practitioners (physicians, nurse practitioners, licensed clinical social workers) who accept Tennessee Medicaid insurance are part of the ECHO program, which meets virtually on the Zoom platform. One six-month cohort (meeting twice a month for an hour) ended in March 2024 and a second cohort is running from June – November 2024. An expert team guides these practitioners, and includes an autistic adult, two neurologists, a psychiatrist, an internal medicine physician, a psychologist, and several family advocates. The community practitioners present deidentified cases for discussion by the entire team. The expert team presents brief didactic sessions that include topics such as managing medical and psychiatric conditions, supporting the autistic adult, self-determination and life skill development, government, housing and community supports, enabling technology including assisted communication devices, and cultural competency.

Results:

Participants completed demographics surveys at baseline (pre-training) along with goals that they wanted to improve on based on the ECHO training. After the ECHO session, they rated their progress. The majority reported good to excellent progress in attaining their goals, which included “becoming more competent in treating individuals with IDD and to recognize common issues they face when obtaining healthcare,” and “to identify resources for patients and families to optimize their treatment outcomes.” Additional feedback included: “(before the ECHO) I felt like I was by myself trying to figure it all out. My nurse practitioner school did not provide IDD education,” and “I feel more confident in being able to provide the resources necessary for patients and their families to live the fullest life possible.” Throughout the ECHO, individuals with life experiences related to autism contributed their stories and perspectives.

Evaluation of self-efficacy measures and claims data one-year before and after ECHO sessions (number of ED visits, hospital bed days, PCP visits per member, collection of lipids and hemoglobin A1C) are ongoing.

Conclusions:

Interactive models focused on training community healthcare practitioners, with the involvement of an autistic adult and family advocates, are effective in empowering practitioners to work with autistic adults.

436.052 Traumatic Life Experiences and PTSD Symptoms in Middle-Aged and Older Autistic Adults

A. Quinton¹, E. McAdams¹, R. A. Charlton², F. Happe³ and G. R. Stewart⁴, (1)Social, Genetic and Developmental Psychiatry Centre, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (2)Psychology, Goldsmiths University of London, London, London, United Kingdom, (3)Social, Genetic and Developmental Psychiatry Centre, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, UNITED KINGDOM, (4)Social, Genetic and Developmental Psychiatry Centre, King's College London, London, United Kingdom

Background: High rates of traumatic life experiences and symptoms of poor mental health (including PTSD symptoms) are often reported by autistic people (Quinton et al., 2024), including by middle-aged and older people with high autistic traits (Stewart et al., 2021). However, these experiences and problems have yet to be studied in diagnosed autistic populations in midlife and older age.

Objectives: This pre-registered study (<https://osf.io/tnye7>) explored the differences in the frequency and types of traumatic experience and symptoms of post-traumatic stress among autistic and non-autistic adults in midlife and older age.

Methods: This study used data from the second wave of the AgeWellAutism project (collected in 2023), a sample of 469 autistic and 183 non-autistic adults aged 40 to 90 years old (mean = ~60 years; ~55% female). Participants completed widely used and standardised measures of trauma/adversity in childhood and adulthood (Grabe et al., 2012; Khalifeh et al., 2015), and of mental health, including PTSD symptoms (Lang et al., 2012), depression (Kroenke et al., 2001), and anxiety (Spitzer et al., 2006).

Results: The autistic group, particularly autistic women, reported significantly higher rates of self-reported traumatic events in both childhood and adulthood, including emotional and physical abuse/neglect and sexual abuse [ORs=2–6]. The autistic group reported more symptoms of PTSD than the non-autistic comparison group [$F(1,625)=144.10, p<.001$]. Severity of PTSD symptoms was positively correlated with the experience of trauma in childhood [$r=.346$ vs. $r=.199$] and adulthood [$r=.426$ vs. $r=.192$] in both autistic and non-autistic groups, respectively. These associations were significantly stronger in the autistic group than the non-autistic group (trauma in childhood $z=1.81, p=.035$; adulthood $z=2.97, p<.001$). This pattern of group differences and associations persisted when accounting for symptoms of depression and anxiety.

Conclusions: The findings from the current study align with similar findings from middle-aged and older populations with high autistic traits. Middle-aged and older autistic people, particularly autistic women, were found to be at a higher likelihood of reporting trauma from childhood and in adulthood, and experiencing high rates of current symptoms of PTSD when compared to non-autistic comparisons. A stronger association between trauma exposure and PTSD symptoms was found in the autistic participants compared to the non-autistic group. Taken together, these findings suggest that autistic people may be particularly susceptible to trauma and PTSD symptoms in midlife and older age. These findings highlight the importance of understanding autistic people's past experiences and ensuring they have access to trauma-informed help and support.

436.053 Autism Services and Support Implemented in a Sensible Timeframe (ASSIST) Michigan Families Study

H. R. Tursak¹, A. B. Tuladhar², M. W. Dawoud², H. O. Riley¹ and A. L. Miller¹, (1)Health Behavior and Health Equity, University of Michigan School of Public Health, Ann Arbor, MI, (2)University of Michigan, Ann Arbor, MI

Background:

Diagnosing and receiving treatment for Autism Spectrum Disorder (ASD) can be lengthy and costly for families. The Autism Services and Support Implemented in a Sensible Timeframe (ASSIST) Michigan Families study aims to understand families' experiences with ASD diagnosis, evaluation, and receipt of treatment services in the State of Michigan.

Objectives:

In partnership with the Michigan Chapter of the American Academy of Pediatrics (MIAAP) and the Autism Alliance of Michigan (AAOM), our team hopes to learn more about barriers to children receiving care for ASD and any inequities related to the timely receipt of services.

Methods:

Caregivers, ASD evaluators, and pediatric providers were invited to participate in surveys and follow-up interviews. Eligibility criteria for surveys and interviews were as follows: the participant lives in Michigan, and either has a child aged 0-6 years old receiving ASD services (caregivers) or provides autism-related services (autism evaluators and pediatric providers). Participants were recruited through AAOM (caregivers) and MIAAP (pediatric providers) membership email lists. ASD evaluators were recruited directly from evaluation centers in Michigan.

Surveys were developed in partnership with MIAAP and AAOM and included questions about diagnosis experiences and receipt of services, focusing on the time elapsed from initial diagnosis to treatment. After completing the survey, participants indicated whether they were interested in a follow-up interview. Interviews were conducted via Zoom and averaged about 30 minutes. The semi-structured interview script covered topics similar to the survey, allowing interviewees to tell their stories in detail. After completing the interview, participants received a \$25 gift card.

Results:

To date, 87 families have completed the survey, and 27 have completed an interview (data collection will be completed by November 2024). Initial analyses of survey data indicate that the average wait time for families to receive a formal ASD assessment after initial screening is about one to three months. Caregivers' interview responses described longer wait times, with many families waiting up to a year for a formal ASD assessment. Families indicated that insurance was a significant barrier to assessment and treatment. To date, 12 ASD evaluators have completed the survey, and 7 have completed interviews. Evaluators also indicated that insurance could be a significant barrier for families, especially if families are out of network and must pay for the evaluation out of pocket (estimated to cost \$1,500-\$3,000) (Cross River Therapy). To date, 44 pediatric providers have completed the survey, and 4 have completed interviews. Providers indicated that finding an evaluation center and treatment services promptly are significant barriers to their pediatric patients receiving treatment for ASD.

Conclusions:

Insurance status and wait times posed barriers to families needing ASD diagnosis and treatment. More research is needed on how insurance plans cover ASD, what steps families must take to receive a formal evaluation, and how to educate families on ASD management. Results from this study will be shared with partners and family-facing educational materials will be created in an effort to support families seeking ASD services in Michigan.

436.054 Understanding Provider Experiences and Needs with Treating Sleep Disorders in Autistic Adults Study

X. Li^{1,2}, G. Parolek^{2,3}, H. Grim^{2,4}, N. Dowd⁵, C. Cotton^{2,6} and T. A. M. McDonald^{2,5}, (1)Department of Psychology and Human Development, Vanderbilt University, Nashville, TN, (2)Spectrum for Life, Nashville, TN, (3)Neurodiversity Lab, the Institute for Human Neuroscience, Boys Town, NE, (4)Vanderbilt University, Nashville, TN, (5)FRIST Center for Autism and Innovation, Vanderbilt University, Nashville, TN, (6)Medical College of Georgia, Augusta, GA

Background:

Insomnia is a significant issue among autistic adults. Insomnia is associated with increased risks of cardiovascular disease, diabetes, psychiatric conditions, and mortality — autistic adults have higher risks for all these conditions. Despite the prevalence of sleep problems in this population, there is a lack of research focused on cognitive behavioral therapy for insomnia (CBT-i), an effective evidence-based treatment. Many providers in other fields report a lack of training and experience to treat this group effectively. This study explores the experiences and perceptions of sleep providers treating insomnia in autistic adults.

Objectives:

The study is to

- Examine whether sleep providers trained in CBT-i receive referrals to treat autistic adults with insomnia.
- Assess providers' perceived motivation and competence, including their training, experience, and confidence in treating this population.
- Identify barriers and facilitators impacting providers' ability to treat this population effectively.

Methods:

We recruited sleep providers certified in CBT-i or practicing behavioral sleep medicine to participate in a national online survey. Providers were recruited through professional listservs, including the Behavioral Sleep Medicine Group and CBT-i Networks. The research applied the Capacity, Opportunity, and Motivation for Behavior (COM-B) model, assessing sleep providers' self-reported experiences regarding referrals for autistic patients, previous treatment experiences, perceived competence, and motivation. Demographic information (age, gender, race/ethnicity, professional background) was also collected. Correlation analyses were performed to investigate relationships between sleep providers' intention to treat autistic adults and factors such as training, confidence, and experience.

Results:

Eighty-four verified sleep providers were included in the analysis. The average age of respondents was 43.64 years, with 21 men and 62 women. 71.4% of sleep providers have no experience treating autistic adults. Sleep providers reported inadequate training (66.7%), skills (61.9%), and resources (64.3%) to treat this population effectively. Sleep providers who treated autistic adults reported many concerns including therapy compliance, motivation, and provider-patient communication. Most providers (77.4%) reported that they received no referrals for autistic adults with insomnia. Among those who had treated autistic patients, only 0.9% of their caseload consisted of autistic adults. Nonetheless, 63.1% of sleep providers expressed a willingness to treat autistic adults in the future, and 76.2% of providers expressed at least moderate confidence that CBT-i could treat insomnia in autistic adults. Correlation analyses showed strong links between sleep providers' intention to treat autistic adults and their training ($r=.47, p<.001$), skills ($r=.52, p<.001$), resources ($r=.41, p<.001$), confidence ($r=.42, p<.01$), referrals ($r=.38, p<.001$), and experience in treating this population with insomnia ($r=.36, p<.001$) or in general ($r=.53, p<.001$).

Conclusions:

This study highlights substantial barriers to treating insomnia in autistic adults, particularly regarding referrals and sleep providers' preparedness. While many providers show willingness to treat this population, providers report that gaps in training and resources hinder their ability to provide effective care. These findings underscore the need for improved training and support for trained CBT-i sleep providers to enhance care access and quality for autistic adults with sleep disorders. Future research should focus on developing tailored interventions and resources to better equip sleep providers in treating this underserved population.

436.055 Understanding the Autism Phenotype Among Individuals with Hnrnp-Related Neurodevelopmental Disorders

M. A. Gillentine¹, L. Margolis¹, A. Hansen², S. Aigner³, K. Ward⁴, K. Murias⁵, L. Phillips⁶, S. Plecas Maricic⁷, B. Corneo⁸, C. Ricupero⁹, M. Balasubramanian¹⁰, A. D. Kline¹¹, G. Yeo¹², P. Y. B. Au¹³ and J. M. Bain¹⁴, (1)HNRNP Family Foundation, Seattle, WA, (2)Geneial, Houston, TX, (3)UCSD, la jolla, CA, (4)Department of Clinical Neurosciences, University of Calgary, Calgary, AB, Canada, (5)University of Calgary, Calgary, AB, Canada, (6)Columbia University, New York, NY, (7)University of Sheffield, Sheffield, -, United Kingdom, (8)Greater Baltimore Medical Center, Baltimore, MD, (9)UCSD, La Jolla, CA, (10)University of Calgary, Calgary, AB, Canada, (11)Department of Neurology, Division of Child Neurology, Columbia University Irving Medical Center, New York, NY

Background: The HNRNP-Related Neurodevelopmental Disorders (HNRNP-RNDDs) are a group of NDDs caused by damaging variants in the heterogeneous nuclear ribonucleoprotein (hnRNP) family. To date, several HNRNP-RNDDs have been described and multiple candidate HNRNP-RNDDs are being investigated. It has been observed that the HNRNP-RNDDs have an overlapping clinical spectrum, which includes autism spectrum disorder (ASD). Overall, about half in individuals with HNRNP-RNDDs have a diagnosis of ASD or autistic features.

Objectives: To better understand the autistic features among individuals with HNRNP-RNDDs.

Methods: Here, we utilize ongoing RNA-seq data in induced neurons from fibroblasts from individuals with HNRNP-RNDD, publicly available RNA-seq data, and the literature to better understand the contribution of variants in *HNRNP* genes to autism spectrum disorder and other behavioral differences. We also evaluate candidate genes to understand the molecular overlap they may share with ASD-associated *HNRNP* genes. Finally, we have queried available phenotypic data from studies such as SPARK and Simon's Searchlight focused on ASD to better understand the behavioral features of each HNRNP-RNDD.

Results: The prevalence of ASD varies by disorder, with the least frequently diagnosed being those with HNRNPC-RNDD (18%) and the most frequently diagnosed being those with HNRNPUL2-RNDD (83%). We are assessing the RNA-seq data to better understand the molecular mechanism(s) of HNRNP-RNDDs.

Conclusions: The HNRNP-RNDDs are an example of a family of molecularly related disorders. By gaining an understanding of the clinical and molecular features of each disorder, we can work towards development of shared therapeutics.

436.056 Understanding the Goals of Adults with Autism: Implications for Service Design and Support

F. Zollars¹, D. X. Hu², M. R. Pepper³ and G. Stobbe⁴, (1)The University of Washington, Seattle, WA, (2)Department of Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (3)Alyss Burnett Center, Seattle Children's Hospital, Seattle, WA, (4)Seattle Children's Autism Center, Seattle, WA

Background:
