Approximately 1 in 45 adults in the United States are diagnosed with autism spectrum disorder (ASD) (Dietz et al., 2020), with an estimated 50,000 adolescents transitioning to adulthood annually (White et al., 2021). These individuals often experience poorer quality of life outcomes compared to their peers (Mansell & Beadle-Brown, 2012). Goal setting is a critical factor in improving outcomes across various domains for individuals with ASD (White et al., 2018). Understanding the goals they prioritize in adolescence and adulthood is crucial for designing services that support autonomy, skill development, and quality of life. This research poster leverages data from a center for adults 18+ with autism spectrum disorder (ASD) and other neurodevelopmental disabilities. The center offers a wide array of classes and outings tailored to the diverse interests and support needs of its participants.

Objectives:

This research analyzed qualitative data from participants who self-identified as having ASD collected during intake at an adult life center over the past decade. It aims to understand the goals these individuals prioritize as they engage in lifelong learning and community activities. This research provides insights into the specific service needs and goals of adults with ASD.

Methods:

This poster presents the stated goals of 284 adults at the time they enrolled in an adult life center between 2014 and September 2024. During the intake process, participants, their caregivers, or support staff completed a form providing demographic information and responding to an open-ended question about their current goals. These responses were qualitatively coded to identify recurring themes.

Results:

284 adults with self-identified ASD participated at the Center between 2014 and 2024. 66% of the sample were male, 31% were female, 2% identified as nonbinary, and 1% chose not to disclose their gender. The ages of individuals in the sample are between 17 and 52 years old, with a mean age of 23 years at the time of intake. The interquartile range (IQR) was between 19 and 25, with about half of the sample falling between those ages. The sample was 64% White, 13.4% Asian, 3.2% Black or African American, 2.1% Hispanic or Latino Origin, 0.4% Native Hawaiian or Other Pacific Islander, 2.1% Other, 7.4% were two or more races, and 7.4% declined to provide their race.

Ten goal themes were identified for the sample: social connection, skill acquisition, hobbies and activities, independence, vocation, education and learning, physical health, wellbeing, routine and structure, as well as those who stated they did not currently have any goals they were working towards.

Conclusions:

Understanding the desires and goals of adults with ASD have for themselves in both the short and long term can inform the types of services and supports that should be provided for adults with autism spectrum disorder. These goals highlight what kinds of engagement adults want out of their communities to foster their growth.

436.057 Unraveling the Path from Autism Acceptance to Quality of Life in Autistic Transition-Age Youths: A Parallel Mediation Model

K. Zhou¹ and **J. Kim²**, (1)University of North Texas, Denton, TX, (2)Michigan State University, East Lansing, MI

Background: Autistic young adults experienced unique psychosocial challenges in transitioning to postsecondary settings. These challenges may result from both the nature of autism and the developmental tasks associated with this unique developmental stage. Given the challenges and barriers faced by this population, understanding the relationship among factors impacting QOL in this transition period and developing relevant interventions is crucial. According to Beatrice Wright's "coping vs. succumbing" framework, individuals who accept their disability as non-devaluing and are oriented to what they can do are often described as coping, which is associated with improved QOL. The critical role of acceptance and coping in enhancing QOL during the psychosocial adaptation process has been well-recognized in studies on various types of disabilities. However, the intricate interplay between these factors and their collective influence on QOL remains unclear.

Objectives: The purpose of the study was to investigate the role of autism acceptance, which represents autistic individuals' internal perceptions and understanding of the external environment and self, in the psychosocial adaptation process. Also, the study aimed to elucidate the relationship between autism acceptance, coping, and QOL based on Wright's "coping vs. succumbing" framework. It was hypothesized that (a) both autism acceptance (i.e., perceived and self-acceptance) and coping (i.e., engagement and disengagement coping) significantly predict levels of QOL and (b) coping serve as a partial mediator in the relationship between autism acceptance and QOL. This investigation intended to provide practical implications that can inform the development of effective transition interventions.

Methods: 204 autistic young adults aged 18 to 26 recruited from Prolific and Amazon Mechanical Turk (MTurk) completed an online survey consisting of instruments measuring target variables. Two parallel mediation models were examined to explore the relationships between autism acceptance, coping, and QOL.

Results: Both parallel mediation models showed good fit. In the first model, perceived acceptance had a significant direct effect on QOL ($\beta = .512$, $p < .01$) and a significant indirect effect through engagement coping ($\beta = .059$, $p < .01$). In the second model, the effects of self-acceptance on QOL were fully mediated by both engagement ($\beta = .073$, $p < .01$) and disengagement coping ($\beta = .089$, $p < .01$).

Conclusions: Autism acceptance is a crucial psychosocial factor in impacting successful transition to postsecondary settings. Acceptance-based transition services should be developed for autistic young adults to help them gain a comprehensive understanding of their relationship with self, others, and their autism. Findings in this study emphasized the necessity to incorporate the concept of acceptance into transition services that can prepare autistic youths with necessary strategies to cope with adverse societal attitudes and develop positive self-images when entering postsecondary settings. Both perceived and self-acceptance should be integral components of the techniques and activities used in these services. Provision of relevant trainings and interventions is essential to assist practitioners in ameliorating any derogatory understanding of autism. Practitioners should learn to echo the neurodiversity movement and advocate with this population for their deserved rights.

436.058 Unseen Disability: Autism and Severe Menstrual Pain

A. Sturm¹, **A. Matar²**, **A. Nariman²**, **M. D. Failla³** and **A. Jacobs⁴**, (1)Loyola Marymount University, Los Angeles, CA, (2)Psychological Science, Loyola Marymount University, Los Angeles, CA, (3)College of Nursing, The Ohio State University, Columbus, OH, (4)Unaffiliated, San Francisco, CA

Background: Autistic women are underserved in research and clinical practice. There is increasing evidence of women's health concerns at all stages of life among autistic women, and debilitating impairment related to reproductive health-related pain. However, there are few reports of menstruation-related pain among autistic women.

Objectives: The present report of original research aims to describe experiences of menstrual pain reported by autistic natal females (assigned a sex of female at birth), and the impact of menstrual pain on work and wellbeing.

Methods: The study sample was drawn from a larger study of reproductive health among autistic natal females who were recruited through SPARK Research Match in 2023. Participants in the present study (N=335) ranged in age from 19 to 74 (M=36.45, SD=11.06), who were still or no longer menstruating. 28.60% had a bachelor's degree or higher and 86% were Caucasian. The present study reports on responses to the following open-ended survey (Qualtrics) questions: "describe the location and intensity of the pain that you experienced with your period," "have you ever had to take time off of work due to menstruation or menstruation-related experiences?", "was the impact of menstruation on your well-being so significant that you needed medical intervention?". Numeric responses were tabulated (presence and frequency of menstrual pain), open-ended responses were reviewed, topics (initial codes) were identified, and themes bridging two or more topics were created by the PI and two undergraduate research assistants.

Results: Of the N=335 participants, N=223 (66.56%) were currently menstruating. Of those currently menstruating, 35.52% (N=119) always and 24.48% (N=82) sometimes experienced pain with menstruation. The locations and intensities of menstrual pain are reported in Table 1. Pain was reported throughout the body and ranged in severity from severe ("My cramping feels like someone is trying to sever my body in half") to mild ("Tenderness"). 43.58% (N=146) of participants reported needing to take time off work (at least once a month to the occasional day; see Table 2) due to menstrual pain. Among participants who did not take off work, some wished to take time off, but feared losing their jobs and would instead "power through" the pain. N=81 (36.3%) of menstruating and N=65 (58%) of not menstruating participants reported requiring medical intervention due to intense menstrual pain. Severity of medical intervention ranged from over-the-counter medications to invasive surgery (e.g. N=20 hysterectomies) to reduce the pain. Participants described being sent home from medical appointments with no answers about their menstrual pain, causing major strain on mental health and relationships. Menstrual pain caused a struggle to understand "what's wrong with them."

Conclusions:

Participants in the present study described intense menstrual pain that significantly impacted their ability to work, often requiring medical intervention. Barriers to health care were noted, including dismissal from health professionals who did not understand or doubted the degree of pain. Greater understanding of menstrual pain and its impact on body systems (e.g. cognition) and daily life (e.g. work, relationships) is necessary. Additionally, investigation of effective and targeted treatments for menstrual pain are needed.

436.059 Using Epigenetic Clocks to Examine Biological Aging in Autistic Adults

A. H. Dickinson¹, C. Lord² and J. Carroll³, (1)University of California, Los Angeles, Los Angeles, CA, (2)UCLA Semel Institute for Neuroscience and Human Behavior, Los Angeles, CA, (3)UCLA, Los Angeles, CA

Background: Autism is a lifelong condition, and in line with general aging trends, the number of older autistic individuals will increase in the coming years. This demographic shift highlights the urgent need to enhance our understanding of aging processes in the context of autism, including identifying risk and resilience factors to promote optimal aging outcomes. Epigenetic clocks offer a valuable tool for gaining insights into biological aging processes well before observable behavioral signs of aging emerge. These clocks estimate an individual's biological age by measuring age-related changes in DNA methylation at specific CpG sites. By comparing an individual's biological age to their chronological age, we can determine whether they are aging faster or slower than expected. This knowledge provides an opportunity to explore the factors that may influence the pace of aging, potentially guiding interventions to optimize aging trajectories.

Objectives: This study examines epigenetic aging in autistic adults followed since diagnosis at age two, providing a valuable chance to explore biological aging in a well-characterized sample. We sought to 1) compare epigenetic aging measures between autistic and neurotypical adults, and 2) identify factors predicting variations in epigenetic aging among autistic adults.

Methods: Oragene kits were used to collect saliva samples from 43 autistic adults (Mean Age: 29.77, 28-33 years; Mean NVIQ =71; 5-133) as part of an ongoing longitudinal study. DNA was extracted according to the manufacturer's protocol and underwent methylation analysis using the Illumina Infinium MethylationEPIC BeadChip. Matched control data were sourced from the Gene Expression Omnibus database, focusing on age-matched neurotypical individuals with saliva-derived methylation data (Mean age: 30.63, Range: 28-33). Methylation data from all participants were uploaded to the Epigenetic Clock Calculator (<https://dnamage.genetics.ucla.edu>) to estimate biological age using first- (Horvath, Hannum) and second-generation (PhenoAge, GrimAge) clocks. Epigenetic age acceleration (EAA) was quantified by regressing age estimates against chronological age, with residuals indicating acceleration (positive) or deceleration (negative).

Results: Independent samples t-tests indicated no significant group-level differences in EAA estimates using any of the four clocks (Figure 1). Although group-level differences were absent, substantial variability exists in EAA estimates among autistic adults (Figure 2). This underscores the necessity of recognizing individual variations within this population, beyond merely considering group-level distinctions. We will present findings from ongoing analyses examining how specific sociodemographic, lifestyle, and clinical factors, such as education, health conditions, and social engagement, predict EAA variations.

Conclusions: Our analysis revealed no significant group-level EAA differences between autistic and neurotypical adults. However, this underscores the need to focus on individual aging processes within the autistic population, rather than assuming uniform patterns of accelerated or slowed aging. Importantly, our findings show that epigenetic clocks can be successfully applied to study aging in a diverse sample of autistic adults, encompassing a wide range of cognitive, language, and functional abilities. This approach offers a powerful tool for understanding who may be at greater risk of accelerated aging and who demonstrates more resilient aging processes. By identifying these key risk and resilience factors, we can develop strategies to better support aging autistic adults.

436.060 Using Wearable Devices and Machine Learning Model to Predict Depressive Symptoms in Autistic People

Y. L. Chien¹, S. Y. Ni² and F. Lai³, (1)National Taiwan University Hospital, Taipei, Taiwan, (2)National Taiwan University Hospital, Taipei, Taiwan, (3)National Taiwan University, Taipei, Taipei, Taiwan

Background: Autism spectrum disorder (ASD) is frequently co-occurred with mood disorders, that may impact quality of life of the individuals in the adulthood. Proper assessment of mood symptoms will be important in terms of clinical care in autistic adults. However, identifying and monitoring depressive symptoms in autistic individuals present a significant challenge, primarily due to communication deficits and difficulties in emotional regulation inherent to this population.

Objectives: This study aims to develop predictive models for mood symptom monitoring in ASD individuals using digital biomarkers from wearable devices and machine learning algorithms.

Methods: Seventeen autistic adults were recruited from the Department of Psychiatry at National Taiwan University Hospital, Taipei, Taiwan. Utilizing Garmin Vivosmart 4 devices and weekly mental health questionnaires for depressive symptoms and sleep problems, as well as physical biomarkers including sleep, activity levels, and heart rate features were collected. Machine learning models, including the Logistic Regression, the Decision Tree, the KNN, the Random Forest, the AdaBoost, and the XGBoost were employed. We used the method of 5-fold cross-validation was employed for assessing the performance and generalizability of machine learning models.

Results: The preliminary analysis revealed that the XGBoost model demonstrated superior predictive efficacy, accurately identifying mild depressive states with an 84% accuracy and an AUROC of 0.91. Using SHAP for explainable AI, among all features of sleep, activity, and heart rate, lower activity levels, decreased sleep duration, and a reduced average heart rate emerged as potential predictors for mild depressive states.

Conclusions: Despite limitations such as sample size and data collection methods, this study highlights the importance of early detection for depression in autistic adults. Wearable technology and machine learning approaches show promise for mood monitoring in ASD. Our findings warrant further exploration of additional physiological variables and validation of clinical significance.

436.061 Utility of the W-ADL to Assess Daily Living Skills in Minimally Verbal Autistic Adults

Y. Y. Yu¹, E. B. Clarke¹, E. Wilkinson² and V. H. Bal¹; (1)Graduate School of Applied and Professional Psychology, Rutgers University - New Brunswick, Piscataway, NJ, (2)Department of Psychology, Rutgers University, Piscataway, NJ

Background: Approximately 30% of autistic individuals are minimally verbal (MV), but this subgroup is understudied and often excluded from research (Rose et al., 2016). Evaluating daily living skills (DLS), and adaptive functioning more broadly, is an essential part of characterizing autism research samples. Comprehensive measures of DLS, such as the Vineland Adaptive Behavior Scales (VABS-3; Sparrow et al., 2016), are cost- and time-intensive. The Waisman Activities of Daily Living (W-ADL; Maenner et al., 2013) is a 17-item caregiver-reported DLS questionnaire. Given its brevity and open-access availability, the W-ADL may present a more feasible alternative to assess DLS, particularly in research contexts where the time and cost of evaluating critical constructs such as DLS may limit or impede the collection of other information.

Objectives: In a sample of MV autistic adults, this study evaluated the psychometric properties of the W-ADL. Specifically, this study examined:

1. criterion validity by comparing W-ADL and VABS-3 scores across parent-reported expressive language levels
2. convergent validity by examining correlations between W-ADL and VABS-3 scores.

Methods: Participants included 156 caregivers of MV autistic adults who completed the W-ADL as part of a larger SPARK Research Match study (Table 1). One-way ANOVA was used to compare W-ADL total and VABS-3 DLS domain standard scores (SS) across parent-reported expressive language levels (*No words/does not speak*, *Use single words meaningfully*, *Combines 3 words together into short sentences*). Pearson correlations were conducted to compare W-ADL total scores and the VABS-3 Adaptive Behavior Composite (ABC), DLS domain SS, and DLS subdomain (personal, domestic, and community) raw scores.

Results: W-ADL total and VABS-3 DLS standard scores differed significantly as a function of expressive language level (Figure 1). Correlations with W-ADL total scores were all statistically significant ($p < 0.05$) and ranged from moderate to very strong ($r_{ABC} = 0.612$; $r_{DLS} = 0.731$; $r_{Personal} = 0.842$; $r_{Domestic} = 0.759$, $r_{Community} = 0.591$).

Conclusions: The present study supports the W-ADL's validity for capturing DLS variability within MV autistic adults. Correlations indicate strong associations between the W-ADL and VABS-3 DLS estimates. Furthermore, W-ADL and VABS-3 showed similar patterns of variability across expressive language subgroups, with individuals with single words or phrases demonstrating more DLS than those who were non-speaking. Comparison of effect sizes suggests the VABS may be more sensitive to detecting differences than W-ADL, particularly in relation to the phrase-speech group. Item-mapping across instruments is underway to better understand comparability of estimates.

Given the limited time for collecting information from families in research, lengthy measures like the VABS-3 can be time-intensive and burdensome for families to reiterate daily challenges. Hence, the W-ADL may offer a viable alternative for characterizing DLS, particularly when research teams wish to dedicate more time to understanding other needs and strengths of autistic individuals. Future research evaluating the validity of the W-ADL across the full range of verbal and cognitive abilities is needed to further understand its utility across diverse settings.

436.062 Validating a Non-Wearable Device (Withings Sleep Analyzer) in Measuring Sleep Behaviours in an Autistic Adult Population.

P. Wan¹, M. Turner¹, A. Ward¹, M. Morgan¹, H. Toneman¹, C. Thompson¹, V. N. Duong² and J. McVeigh¹; (1)Curtin School of Allied Health, Curtin University, Perth, Western Australia, Australia, (2)Curtin School of Population Health, Curtin University, Perth, Western Australia, Australia

Background: Autistic adults experience a higher incidence of sleep disturbances that influence well-being and quality of life compared to non-autistic peers. Addressing and improving sleep behaviours requires accurate monitoring and measurement for targeted intervention. However, existing device-derived measurements of sleep are typically obtrusive and incompatible with the sensory or routine preferences of autistic individuals. Thus, the exploration of alternative device-based measurements for sleep is warranted. The Withings Sleep Analyzer (WSA) is a non-wearable, nearable and commercially-available device that measures the sleep behaviours of people in their own environments. The WSA has not yet been validated in an autistic adult population.

Objectives: This study examined the concurrent validity of the WSA compared to the ActiGraph GT9X in measuring sleep behaviours among autistic adults.

Methods: A total of 28 autistic adults (18-64 years) were included in the study. Individuals used the WSA and wrist-worn ActiGraph GT9X within their typical, everyday environments for 10-consecutive days. Participants self-installed the WSA device under their home mattress and wore the ActiGraph GT9X on their non-dominant wrist during their primary sleep period. Total sleep time (TST), wake after sleep onset (WASO), sleep onset latency (SOL), sleep efficiency, and wake and sleep times were compared to determine the level of association between the devices. Bland-Altman plots were used to analyse the level of agreement between devices and intraclass correlation were used to assess internal reliability.

Results: The WSA consistently overestimated outputs for TST, WASO and SOL, compared to the Actigraph GT9X. There were moderate associations between devices in measuring WASO, sleep efficiency and wake times. There were poor associations between devices for TST and sleep time. There was a strong association between devices for predicting SOL. Overall, there was good compliance in the use and wear-time of both devices.

Conclusions: This study demonstrated that the WSA is a useful, objective method of attaining device-derived sleep data. The associations between the WSA and ActiGraph GT9X were not statistically significant and encompassed systematic bias for TST, SOL and WASO. Future research and interventions incorporating the WSA should be used with caution due to consistent overestimation of sleep behaviours compared to the ActiGraph GT9X. However, as an affordable, non-wearable and commercially-available device the WSA provides autistic adults a sensory-affirming option to measure and monitor sleep behaviours within their home environments

436.063 Sleep Quality and Mental Health in Middle-Aged and Older Autistic and Non-Autistic Adults.

G. R. Stewart¹, A. Barbint², A. Quinton³, R. A. Charlton⁴ and F. Happe⁵, (1)Social, Genetic and Developmental Psychiatry Centre, King's College London, London, United Kingdom, (2)King's College London, London, England, United Kingdom, (3)Social, Genetic and Developmental Psychiatry Centre, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (4)Psychology, Goldsmiths University of London, London, London, United Kingdom, (5)Social, Genetic and Developmental Psychiatry Centre, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, UNITED KINGDOM

Background: Sleep is an important biological function, and impaired sleep can lead to a range of problems, including poor health and wellbeing. Many autistic children and adults have been found to have poor quality sleep and higher rates of sleep disorders and problems (Schreck & Richdale, 2020), as have middle-aged and older people with high autistic traits (Stewart et al., 2020). However, these experiences and problems have yet to be studied in diagnosed autistic populations in midlife and older age.

Objectives: This pre-registered study (osf.io/973z8) explored differences in sleep quality and mental health problems among middle-aged and older autistic adults compared with an age- and sex-matched non-autistic comparison group.

Methods: This study used data from the first wave of the AgeWellAutism project (collected in 2019), from a sample of 265 autistic and 167 non-autistic adults aged 40 to 93 years (mean = ~60 years; ~50% female). Participants completed widely used and standardised measures of sleep quality/problems (PSQI; Buysse et al., 1989) and of mental health, including depression (PHQ-9; Kroenke et al., 2001), anxiety (GAD-7; Spitzer et al., 2006), and PTSD symptoms (PCL-6; Lang et al., 2012).

Results: The autistic group reported significantly more difficulties with various aspects of sleep, including lower perceived sleep quality, longer sleep onset latency (i.e., how fast you fall asleep), shorter sleep duration, worse sleep efficiency, more sleep disturbances, higher rates of requiring medication to sleep, and having more daytime tiredness and dysfunction. Overall, the autistic group reported significantly worse sleep quality index scores than the non-autistic comparisons, including when controlling for age and symptoms of mental health. Additionally, sleep quality index scores were significantly associated with older age and poor mental health in both groups, with the association between sleep and anxiety being stronger in the autistic group.

Conclusions: The findings from the current study align with similar findings from middle-aged and older populations with high autistic traits. Middle-aged and older autistic people were found to be at a higher likelihood of experiencing a broad range of sleep problems and worse overall sleep quality index scores when compared to non-autistic comparisons. Sleep index scores were associated with older age and mental health problems, particularly anxiety. These findings, albeit cross-sectional and correlational, suggest causal connections should be explored through intervention. Treating and managing symptoms of poor mental health, particularly anxiety, may help with improving sleep quality in autistic populations, particularly as autistic people get older.

436.064 Personality Disorder Diagnoses in UK Autistic People: Evidence from a Matched Cohort Study

J. Stott¹, E. O'Nions², C. El Baou³, G. R. Stewart⁴, W. Mandy⁵, C. Cooper⁶, F. Happe⁷, J. Brown⁸, J. Buckman⁹, S. Hoare¹⁰, M. Richards¹¹, D. Lewer¹², D. McKechnie¹³, R. Saunders¹⁴, C. Long¹⁵ and R. A. Charlton¹⁶, (1)University College London, London, London, (2)University College London, London, London, United Kingdom, (3)Social, Genetic and Developmental Psychiatry Centre, King's College London, London, United Kingdom, (4)Research Department of Clinical, Educational & Health Psychology, University College London, London, United Kingdom, (5)Social, Genetic and Developmental Psychiatry Centre, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, UNITED KINGDOM, (6)University College London, London, United Kingdom, (7)Research Department of Clinical, Educational & Health Psychology, University College London, London, London, United Kingdom, (8)Psychology, Goldsmiths University of London, London, London, United Kingdom

Background: Clinical accounts and cohort studies suggest that autistic people are disproportionately likely to be diagnosed with a personality disorder, which potentially increases their chances of exclusion from services.

Objectives: We measured the incidence of personality disorder diagnoses in UK autistic people between 2000 and 2019 and report the prevalence of diagnosed personality disorder among autistic people relative to the general population.

Methods: We conducted a cohort study of adults drawn from the IQVIA Medical Research Database with a diagnosis of autism, with follow-up from Jan 1, 2000 to Jan 16, 2019. We included a comparison group without diagnosed autism, matched (1:10) by age, sex, and primary care practice. We compared incidence of personality disorder, stratifying results according to diagnosis of intellectual disability (ID).

Results: We included 22,112 autistic adults. 6,437 (29.1%) had a diagnosis of intellectual disability, the median age was 20.36 (IQR 18- 28.47), and 16,881 (76.3%) were men. Compared to the general population, the rate of personality disorder diagnosis in autistic people without ID was 4.8 (3.5 to 6.7) times higher for men and 4.6 (3.1 to 6.8) times higher for women. For autistic participants with ID, the rate was 2.0 (1.0 to 3.7) times higher for men and 8.3 (4.0 to 17.2) times higher for women. Estimated incidence of personality disorder diagnosis for autistic people aged 20 increased from 14.67 (95% CI 10.36-20.77) per 10,000 person-years in 2009 to 22.43 (95% CI 13.86-36.30) in 2019. Incidence of personality disorder diagnosis increased in women (including autistic and comparison women) but remained largely stable in men.

Conclusions: Personality disorder diagnoses were more common in autistic people, and more so in women. We argue that this perhaps suggests attribution of autism/associated mental health support needs to personality disorder. Other hypotheses are also considered.

436.065 Systematic Review and Meta-Analysis of Recorded PTSD Prevalence Rates in Diagnosed Autistic Populations

J. Stott¹, G. R. Stewart², H. Mansour³, A. Gillions⁴, S. Kurana⁴, E. O'Nions^{3,5}, A. Eshetu¹ and C. El Baoui¹, (1)University College London, London, United Kingdom, (2)Social, Genetic and Developmental Psychiatry Centre, King's College London, London, United Kingdom, (3)University College London, London, London, United Kingdom, (4)University College London, London, Lo, United Kingdom, (5)Bradford Institute for Health Research, Bradford, Bradford, United Kingdom

Background: Autistic individuals are more likely to experience traumatic life events and increased mental health difficulties. Surprisingly, there have been no comprehensive reviews to examine the prevalence rates of post-traumatic stress disorder (PTSD) among diagnosed autistic individuals. It is hard to understand how this feeds into prevalence using current diagnostic criteria. For example, several reviews have indicated increased PTSD symptoms within autistic populations, particularly when using self-report measures.

Objectives: The aim of this review is to conduct a meta-analysis to understand the recorded prevalence rates of PTSD in diagnosed autistic child-adolescent, and adult populations, as well as the factors that may influence these rates.

Methods: A systematic literature search was conducted to identify relevant studies reporting current and lifetime PTSD prevalence rates in diagnosed autistic populations. After screening, a total of 15 child-adolescent (n = 53,329) and 10 adult (n = 5,902) studies were included in the meta-analysis. Subgroup analyses were performed to explore the influence of factors which have been found to influence PTSD prevalence rates in neurotypical populations.

Results: After removing outliers, the findings indicate that the current prevalence of PTSD among diagnosed autistic children and adolescents was 0.8% (95% CI = 0.16; 1.94, $t^2 = 0.0016$), with a lifetime prevalence of 2.91% (95% CI = 1.76; 4.33, $t^2 = 0.0012$). For autistic adults, the current prevalence was 1.96% (95% CI = 0.013; 5.85, $t^2 = 0.0030$), with a lifetime prevalence of 2.24% (95% CI = 0.29; 5.97, $t^2 = 0.0073$). Although the rates are like those observed in the general population, they are much lower than the rates observed in other reviews that examined PTSD symptoms in autistic populations. Subgroup analysis suggests that the presence of intellectual disability within the autism sample, the type of PTSD diagnostic criteria used, and the type of informants used during PTSD assessment impact prevalence rates across both child-adolescent and adult studies.

Conclusions: This meta-analysis provides valuable insights into the prevalence of PTSD among diagnosed autistic populations. It underscores the complex relationship between autism and PTSD whilst also highlighting the importance of reconsidering diagnostic criteria to identify and address trauma in this population more accurately.

436.066 Mechanisms of Action for a Culturally and Linguistically Adapted Intervention for Latino Young Adults with Autism Spectrum Disorder

A. F. Pagan¹ and K. A. Loveland², (1)Department of Psychiatry and Behavioral Sciences, University of Texas Health Science Center, Houston, Houston, TX, (2)Louis A Faillace, MD, Department of Psychiatry and Behavioral Sciences, McGovern Medical School, University of Texas McGovern Medical School, Houston, TX

Background: Latino young adults with autism spectrum disorder (ASD) must navigate the transition to adulthood with few culturally and linguistically adapted interventions. By leveraging community based participatory research (CBPR) and identifying mechanisms of action, researchers can enhance engagement and efficacy in culturally adapted interventions. The present study seeks to fill a significant gap in the literature, as prior evaluations of group and individual interventions for adults with ASD have largely excluded Latinos. The present study is vital in addressing disparities in mental health services and outcomes for this demographic.

Objectives: The present study examines mechanisms of action in a culturally adapted therapy program for Latino young adults with autism spectrum disorder (ASD). The primary focus is to evaluate how improvements in social support, physical health, and cultural connectedness mediate mental health and adaptive functioning outcomes for young adults participating in a culturally and linguistically adapted intervention.

Methods: We conducted a pilot study involving 56 Latino autistic young adults (ages 18-25). Participants received the 12-week, *¡Iniciando! la Aduldez* intervention, which consists of telehealth-group therapy sessions for both parents and young adults. Additionally, young adults received weekly coaching therapy sessions to work on goals and family therapy sessions. Mechanisms of action—social support, physical health, and cultural connectedness—were assessed at five time points (baseline, mid-treatment, post-treatment, 3- and 6-month follow-ups). Mediation analyses will explore how these mechanisms influence changes in mental health (anxiety, depression), adaptive functioning, and caregiver burden. By adopting a CBPR approach, we ensured that the intervention remains culturally relevant and effectively addresses the specific needs of the community. This collaboration not only enhances the program's acceptance but also promotes sustainability and long-term impact.

Results: We expect that improvements in social support, physical health, and cultural connectedness will mediate positive changes in mental health, adaptive functioning, and caregiver burden among Latino autistic young adults and their families. Specifically, we anticipate that participants receiving the *¡Iniciando!* intervention will show significant reductions in anxiety and depression, enhanced adaptive functioning, and increased social and cultural support compared to the waitlist group. These mechanisms will likely explain the observed changes in outcomes we found in our pilot work in areas such as social cognition, adaptive functioning, and quality of life, reinforcing the importance of culturally tailored interventions for Latino populations with ASD.

Conclusions: Understanding mechanisms of action such as social support, physical health, and cultural connectedness will provide insights into how culturally tailored interventions can reduce mental health disparities and improve adaptive functioning in Latino young adults with ASD. This research not only aims to contribute to academic literature but also aspires to inform policy and practice, leading to improved health equity in mental health services. The findings have the potential to influence the development of future interventions, ensuring that they are grounded in the cultural and contextual realities of the communities they serve. By enhancing our understanding of these mechanisms, we aim to establish a framework that other researchers and practitioners can adopt to foster better outcomes for Latino individuals with ASD.

436.067 The Working Alliance of Parents, Young Adults, and Clinicians in a Transition to Adulthood Program

A. F. Pagan¹ and **K. A. Loveland²**, (1)Department of Psychiatry and Behavioral Sciences, University of Texas Health Science Center, Houston, Houston, TX, (2)Louis A Faillace, MD, Department of Psychiatry and Behavioral Sciences, McGovern Medical School, University of Texas McGovern Medical School, Houston, TX

Background: The working alliance, or the collaborative relationship between clients and therapists, plays a crucial role in therapy outcomes. A systematic review found that in 70.3% of studies, the working alliance mediated therapeutic outcomes, with stronger alliances correlating with greater symptom improvement. Furthermore, research suggests a bidirectional relationship between symptom improvement and working alliance: improvement in symptoms strengthens the alliance, while a stronger alliance contributes to further symptom improvement. For individuals with autism spectrum disorder (ASD), evaluating the working alliance presents unique challenges. For example, few studies have examined how working alliance may change over the course of treatment for young adults with ASD, especially within culturally and linguistically diverse populations.

Objectives: This study aims to examine the working alliance among bilingual, Latino young adults with ASD, their Spanish-speaking parents, and their clinicians during a transition-to-adulthood intervention. We sought to determine how the working alliance mediates outcomes in mental health and quality of life during this transition, exploring whether this relationship extends to diverse cultural contexts.

Methods: We conducted a pilot study involving 56 Latino autistic young adults (ages 18-25) and their Spanish-speaking parents. Participants were enrolled in the 12-week *¡Iniciando! la Aduldez* intervention, a telehealth-based group therapy program that includes group therapy for parents, group therapy for young adults, family therapy sessions, and weekly individual coaching sessions for young adults. Working alliance was assessed using the Working Alliance Inventory-Short Revised (WAI-SR) completed at week 2, mid-treatment, and post-treatment. We evaluated the relationship between several variables, including quality of life (measured by WHOQOL-BREF) and post-treatment outcomes, with mid-treatment working alliance as a mediator. Mediation analyses were conducted to assess the significance of working alliance in influencing changes in quality of life outcomes across participants. A correlation matrix was used to explore associations between cultural variables and working alliance.

Results: Preliminary analyses demonstrated that working alliance significantly mediated the relationship between baseline psychological well-being and post-treatment outcomes for both young adults and their parents. Participants who reported stronger alliances with their therapists at mid-treatment experienced greater improvements in overall quality of life by the end of the intervention. Notably, cultural variables examined (e.g., cultural connectedness, language) were not significantly associated with working alliance for any group (parents, young adults, or clinicians).

Conclusions: The findings suggest that the development of a strong working alliance transcended cultural factors within this specific intervention, underscoring the potential for culturally adapted programs to foster meaningful therapeutic relationships. The findings also highlight the central role of working alliance in promoting positive mental health and quality of life outcomes for Latino young adults with ASD and their families during the transition to adulthood. This study contributes to the growing body of research on therapeutic alliance, particularly within culturally adapted interventions, and underscores the importance of fostering strong alliances to maximize therapeutic efficacy. Despite challenges in measuring alliance within ASD populations, this study supports the potential of culturally responsive telehealth interventions to create meaningful alliances that promote successful transitions to adulthood.

436.068 Social Determinants of Health That Disproportionately Increase Mortality Risk Among Autistic Vs. Non-Autistic Older Adults: A Big Data, Machine Learning Study

B. N. Hand¹, **M. Nikahd²**, **J. M. Hyer³**, **A. Gothard⁴**, **B. Wolf⁵**, **B. W. Patterson¹** and **L. Bishop⁵**, (1)General Internal Medicine, The Ohio State University, Columbus, OH, (2)The Ohio State University, Columbus, OH, (3)Medical University of South Carolina, Charleston, SC, (4)University of Wisconsin-Madison, Madison, WI, (5)University of Wisconsin - Madison, Madison, WI

Background: Emerging literature suggests the health needs of autistic older adults require singular attention, distinct from younger autistic adults and older non-autistic adults. Prior studies found autistic older adults had significantly greater risk of mortality than non-autistic peers. However, we do not know which social determinants of health differentially impact time-to-mortality among autistic older adults relative to the general population. This is a barrier to identifying autistic older adults who would benefit from targeted preventive healthcare and support services.

Objectives: To identify social determinants of health that disproportionately increase mortality risk among autistic compared to non-autistic older adults.

Methods: In this quasi-experimental longitudinal cohort study, we analyzed inpatient and outpatient data from a 100% United States national sample of Medicare beneficiaries during 2013-2021. Medicare is a nationally administered program that provides nearly universal healthcare coverage to Americans aged 65 and older (including autistic and non-autistic older adults). Our total sample included 10,807 autistic older adults and 21,611 non-autistic older adults who were propensity score matched on sex, race, age, year, rurality, Charlson Comorbidity Index, county, and US state. The samples were divided into training (75%) and validation cohorts (25%). Our dependent variable was survival, calculated as years between age 65 and death or last observed healthcare encounter. The primary independent variable was group membership (i.e., autism vs. matched control). Social determinants of health included sex, race, rurality, and Social Vulnerability Index. We applied a machine learning technique ("Logic Forest") to identify subpopulations, based on social determinants of health, where autistic older adults had significantly higher mortality risk than non-autistic older adults. Results identified in the training cohort were validated in the mutually exclusive validation cohort.

Results: The validation cohort included 8,101 Medicare beneficiaries (n=2,701 autistic older adults). Beneficiaries were mostly male (67.9%), white/non-Hispanic (88.9%), and a majority resided in metropolitan areas (82.2%). Overall, 35.3% of autistic older adults and 17.9% of matched controls died during the observation period. Autistic older adults had 25% (95% CI=1.11-1.40) higher risk of mortality than matched controls. Multiple sub-populations were identified where autistic older adults had significantly higher mortality risk than non-autistic older adults. Among beneficiaries living in a small metropolitan area, autistic older adults had 42% (95% CI=1.09-1.84) higher risk of mortality. Among those who had low social vulnerability and were racially minoritized, autistic older adults had 50% (95% CI=1.22-1.85) higher risk of mortality. Among those with high social vulnerability and were white/non-Hispanic, autistic older adults had 54% (95% CI=1.03-2.29) higher risk of mortality. Sex did not differentially impact time-to-mortality for autistic older adults relative to matched controls.

Conclusions: Identifying subpopulations of autistic adults with disproportionately elevated mortality risk—like those living in small metropolitan areas, those with low social vulnerability who are racially minoritized, and those with high social vulnerability who are white/non-Hispanic—highlights the need for targeted preventive healthcare and support services. Future research should delve deeper into these factors to develop strategies that can effectively address health challenges faced by this growing demographic to improve health, wellbeing, and longevity.

436.069 Representation of Autism Mortality Data By Citing Authors: An Analysis of Articles Citing Hirvikoski Et Al., 2016

B. N. Hand¹, M. Nikahd², B. Wolf³, J. M. Hyer⁴, A. Longo⁵, D. Gilmore¹ and L. Bishop¹, (1)General Internal Medicine, The Ohio State University, Columbus, OH, (2)The Ohio State University, Columbus, OH, (3)Medical University of South Carolina, Charleston, SC, (4)Ohio State University, Columbus, OH, (5)University of Wisconsin - Madison, Madison, WI

Background: Understanding health outcomes across the lifespan, including mortality, is a high priority for the autistic community. High-profile publications and government reports state “people with autism die 16 years earlier” or have a “54-year life expectancy,” citing a rigorous landmark study of mortality among autistic people by Hirvikoski et al., 2016. Yet under 3% of autistic people died during the study’s observation period, making conclusions about the average age of death for the entire autistic sample, or about the life expectancy of all autistic people, a misrepresentation of findings.

Objectives: To quantify how often and describe in what ways key findings from Hirvikoski et al., 2016, a seminal work on mortality in autistic people, were accurately or misrepresented by citing authors

Methods: We conducted a systematic citation context analysis by searching MEDLINE, Scopus, CINAHL, PsychINFO, Web of Science, and PubMed to identify articles that cited Hirvikoski et al., 2016. We included articles that were available as full-text, peer-reviewed, and in English. Data extracted from each article included author, publication year, journal, Altmetric score, number of citations, and all passages of text where Hirvikoski et al., 2016 was cited. Next, two team members collaboratively reviewed citing passages from 20% of the articles to develop a codebook to guide article evaluation as incorrect/misleading, correct/accurate, or not relevant. Once finalized, we coded all remaining articles. We used descriptive statistics to summarize the characteristics of included articles.

Results: 506 articles were included. Most (n=356, 70.4%) were incorrect/misleading, 25.1% (n=127) were correct/accurate, and 4.5% (n=23) were irrelevant. Articles that cited all-cause mortality findings were significantly (p<0.001) more often categorized as incorrect/misleading, while articles that cited suicide findings were significantly (p<0.001) more often categorized as correct/accurate. Among articles that correctly represented findings (n=127), 55.9% cited the higher death by suicide rate, 37.8% cited the higher all-cause mortality rate, and 7.9% cited broad references to health inequities experienced by autistic people. Among articles that misrepresented findings (n=358), the most common misrepresentation was referring to “premature mortality” (53.7%), defined as the proportion of deaths occurring prior to the national average age of death, which was not quantified by Hirvikoski et al., 2016. Other frequently observed misrepresentations included conflating suicidality with death by suicide (17.1%), making unsupported conclusions about life expectancy of autistic people (16.6%), and over-generalizing the findings regarding mean age of death of decedents (15.7%). Other articles (17.7%) misrepresented odds ratios comparing deaths by suicide between autistic and non-autistic people, by conflating the largest odds ratio with the leading cause of death (8.4%) or by inaccurately or incompletely reporting the odds ratio (9.3%).

Conclusions: We found widespread misrepresentation of mortality findings by citing authors. Misrepresenting mortality findings may have serious unintended consequences for autistic people including psychological harm, compromised ability to obtain commercial health or life insurance, altered retirement planning decisions, and perpetuation of health disparities. As such, we assert that there is a moral imperative for authors, peer reviewers, and journals to be accountable for the accurate representation of findings from cited studies.

436.070 Life Satisfaction Outcomes for Adults with Autism and/or IDD Enrolled in Life-Long Learning and Recreation Community Program

M. R. Pepper¹, D. X. Hu², F. Zollars³ and G. Stobbe⁴, (1)*Alyssa Burnett Adult Life Center, Seattle Children's Alyssa Burnett Adult Life Center, Bothell, WA*, (2)*Department of Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA*, (3)*The University of Washington, Seattle, WA*, (4)*Seattle Children's Autism Center, Seattle, WA*

Background: Data from the CDC estimated around 28.7% of adults in the USA have a disability in 2022, 13.9% of whom have a cognitive disability (Prevention, 2024). As the population of adults with intellectual and developmental disabilities (IDD) including autism (ASD) continues to grow in the USA, research is important in understanding how services and programming designed for adults with autism and developmental disabilities contributes to positive quality of life (QOL) outcomes. Starting in 2021, selected questions from the WHO Quality of Life Intellectual and Developmental Disabilities module (WHOQOL-DIS)(Group, 2011) were used to assess QoL and life satisfaction measurements of adults 18+ with IDD and/or autism enrolled in a community-based life-long learning and recreation program.

Objectives: The primary goal of this study is to explore how participation in age-appropriate life-long learning and recreation community centers for adults with autism and IDD contributes to positive QoL outcomes over time. This study seeks to compare Life Satisfaction outcomes between participants with and without autism.

Methods: Data were collected via electronic surveys from adults with IDD enrolled in a life-long learning and recreation community program and/or their proxies, using selected items from the WHOQOL-DIS and demographic information. Baseline data were collected from returning participants upon returning to in-person services post-COVID restriction in June 2021, or at new intake appointments. The follow-up survey was administered in January 2024. Data analysis was conducted in R Studio (Version 2023.06.2). A two-way repeated measures ANOVA was employed to assess mean differences in QoL across two time points (baseline vs. follow-up) and between groups (ASD vs. non-ASD) for participants who completed both surveys. In addition, paired t-tests were conducted to compare QoL between ASD and non-ASD groups at baseline and follow-up separately.

Results: A total of 173 surveys were completed at baseline (M age = 26.21, SD = 6.72; 87 non-ASD, 86 ASD), and 94 surveys were completed at follow-up (M age = 27.82, SD = 6.91; 46 non-ASD, 48 ASD). Of these, 35 participants (21 non-ASD, 14 ASD) completed surveys at both time points, but no significant changes in QoL Life Satisfaction were observed over time. At baseline, no significant differences in QoL were observed between the ASD (M = 3.83, SD = 1.15) and non-ASD (M = 4, SD = 1.02) groups. However, at follow-up, a significant difference in overall life satisfaction was found between the ASD (M = 3.75, SD = 0.98) and non-ASD (M = 4.17, SD = 0.95) groups, with $t(92) = 2.13, p = 0.036$, and a small effect size (Cohen's $d = 0.44$).

Conclusions: This study highlights the importance of recognizing and addressing the unique needs of adults with IDD in improving QoL outcomes. While baseline QoL was similar between ASD and non-ASD groups, follow-up data revealed lower life satisfaction in the ASD group, emphasizing the importance of understanding and addressing factors that impact long-term QoL in adults with ASD. Further research is needed to explore these factors and develop strategies to promote lifelong positive outcomes for this population.

Poster Session**437 - Brain Function (fMRI, fcMRI, MRS, EEG, ERP, MEG) II**

May 3rd, 2025, 12:30 PM - 1:30 PM - Hall 4A

437.071 Longitudinal EEG Investigation of Syllable Entrainment and Word-Segmentation in Infants at Low and High Likelihood for Autism

M. Godel¹, A. Flò², L. Benjamin³, G. Dehaene-Lambertz⁴ and M. Schaer¹, (1)*Department of Psychiatry, University of Geneva, Geneva, Geneva, Switzerland*, (2)*Department of Developmental Psychology and Socialisation and Department of Neuroscience, University of Padova,, Padova, Venetia, Italy*, (3)*Aix Marseille Univ, INSERM, INS, Inst Neurosci syst, Marseille, Bouches-du-Rhône, France*, (4)*Cognitive Neuroimaging Unit, CNRS ERL 9003, INSERM U992, CEA, Université Paris-Saclay, NeuroSpin Center, Gif/Yvette, Île de France, France*

Background: Autism Spectrum Disorder (ASD) often presents with early language delay that can impact many developmental domains. To avoid those detrimental cascading effects, it is essential to detect and support early verbal difficulties early on. In this regard, implicit neuroimaging measures have the potential to assess key preverbal mechanisms for language acquisition. Previous studies of autistic individuals identified decreased cortical synchronization to syllable input, as well as difficulties in the computation of statistical properties contained within speech input - a process known as statistical learning. However, the maturation pattern of those speech processing mechanisms remain under-explored in the infant period, in ASD as well as in typical development (TD).

Objectives: We aim to define the trajectories in infants at high and low likelihood for ASD for (1) cortical entrainment to syllables, (2) word discovery within a speech input using its statistical properties, and (3) memorizing the discovered words.

Methods: We collected 83 longitudinal high-density EEGs in 44 infants (2.5-22.6 months) at high (HL) and low (LL) likelihood for ASD. We measured neural entrainment at syllable and word rates during exposure to a multi-speaker speech stream containing trisyllabic words, then collected ERPs during a word recognition procedure. Data were analyzed with longitudinal partial-least square correlation (PLS-c), a multivariate data-driven approach.

Results: We found a decreased neural entrainment to syllables in HL infants compared to LL. Moreover, this finding was associated with HL verbal outcome at 24 months. However, HL infants' ability to detect words using statistical learning was globally preserved, although it followed a different age-trajectory compared to LL. HL infants also showed reduced neural response to the presentation of learned vs novel words, possibly caused by atypical maturation of the memory system and/or reduced orientation to novelty. Our results might reflect a less precise response along the auditory processing pathway in HL, while statistical learning might represent a relatively spared mechanism on which HL infants rely.

Additionally, the multi-speaker nature of our stimulus might have played a role, HL infants paying possibly less attention to voice changes.

Conclusions: We highlighted the crucial role played by longitudinal implicit metrics of infant language processing to unveil fine-grained cascading effects involved in ASD. This prompts the development of early assessment tools using neural entrainment measures to estimate verbal outcome in HL, as well as early intervention strategies supporting the precision of brain response to syllables.

437.072 Longitudinal Stability of Neural Responses to Faces and Relation to Social Behaviors in Autistic Youth: Results from the Autism Biomarkers Consortium for Clinical Trials

C. Nozari¹, H. Borland¹, M. Santhosh¹, A. Naples², K. Chawarska³, G. Dawson⁴, J. Dziura⁵, S. Faja⁵, S. Jeste⁶, F. Shic¹, C. Sugar⁷, J. McPartland⁸ and S. J. Webb⁹, (1)Center for Child Health, Behavior and Development, Seattle Children's Research Institute, Seattle, WA, (2)Yale Child Study Center, Yale University School of Medicine, New Haven, CT, (3)Yale University, New Haven, CT, (4)Department of Psychiatry and Behavioral Sciences, Duke University, Durham, NC, (5)Boston Children's Hospital Laboratories of Cognitive Neuroscience, Brookline, MA, (6)Children's Hospital Los Angeles, Los Angeles, CA, (7)University of California, Los Angeles, Los Angeles, CA, (8)Yale Child Study Center, Yale Child Study Center, New Haven, CT, (9)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA

Background: Face processing has been proposed as a potential biomarker of social function because it is a fundamental skill related to social communication. Individuals with autism show slowed neural speed (longer N170 latencies) of face processing compared to typically developing youth (Webb et al., 2021, 2023; Hileman et al., 2011) and adults (Kang et al., 2017). Latencies of the P100 and N170 are moderately stable over six weeks in autistic youth and slower N170 latency corresponds to lower verbal and non-verbal IQ (Webb et al., 2023).

Objectives: In this Autism Biomarkers Consortium for Clinical Trials (ABC-CT) project, we (1) Examined ERP stability from T1 (baseline) to T4 (+4 years) for Faces ERP variables. (2) Examined concurrent relation of ERP to behaviors at T4. (3) Examined acquisitional, demographic, and behavioral factors predicting stability between T1 and T4 ERP latencies.

Methods: T4 data were collected from 90 autistic youth (M=12.8 yrs, SD=1.8) and 62 typically developing controls (TD) (M=12.5 yrs, SD=1.8) 4.2 years (SD=.66) after T1. At T1, ASD diagnosis was confirmed by gold-standard measures. ERP data was acquired while participants watched pictures of upright and inverted faces and houses (as in Webb et al., 2021, 2023). Analyses included participants with valid Faces ERP data at both T1 and T4. Social Behaviors were characterized using the Vineland Adaptive Behavior Scales-3 (VAB3) and the Social Responsiveness Scale (SRS-2).

Analyses were conducted separately by diagnostic group. (1) Intraclass correlation coefficients (ICC) were used to examine stability in latency of ERP components. (2) Pearson Correlations examined relationships between ERP components (upright and inverted faces) and behavior. (3) To predict T4 ERP latencies, Linear Regression was calculated using predictors: T1 ERP latency, T4 acquisition variables, demographics (age, sex), and behavioral predictors (IQ, VAB, SRS).

Results: (1) ICC values are presented in Table 1; values were poor to moderate across four years. (2) In ASD group, Face Upright N170 latency was correlated with VAB Socialization ($r=.275$) and Daily Living Skills ($r=.284$; also with Face Inverted $r=.230$). No relations were found with full scale IQ or SRS SCI score (r values $<|.078|$). In the TD group, there were no significant correlations between behavior and ERP values.

Conclusions: In contrast to previous research demonstrating moderate short-term stability, latencies of the P100 and N170 were more variable over four years in autistic youth, except for the P100 responses to upright face. In our older T4 sample, latency to faces did correspond to components of social skills and daily living behavior. In comparison to previous results, novel relations to behavior were found at older ages suggesting that brain-behavior relations may change with age. Analyses are ongoing and will further examine predictors of T4 ERP latency including adaptive skills, T1 ERP latencies, demographics, and acquisition variables.

437.073 Mirror Neurons and Theory of Mind in Autistic Youth Post-Social Skills Intervention

L. S. Caldera Aguayo¹, V. De La Rosa¹, R. Jalal¹, H. R. Gutierrez¹ and A. Nair², (1)Psychology, Loma Linda University, Loma Linda, CA, (2)Loma Linda University, Loma Linda, CA

Background: Research on imitation, a feature of the mirror neuron system (MNS) and an important facet of social interactions suggest it is less pronounced in autistic youth (Chan & Han, 2020). In autistic youth, overconnectivity in the MNS was associated with increased social difficulties in a cross-sectional study (Fishman et al., 2014). However, the impact of targeted social skills interventions on MNS connectivity and its association with ToM performance has not been fully explored yet.

Objectives: To examine whole-brain functional connectivity of the inferior frontal gyrus (IFG; MNS hub) and its relationship to ToM in autistic youth, compared to typically developing (TD) controls after a social skills intervention.

Methods: Autistic youth completed The Awareness of Social Inference Test (TASIT; McDonald et al., 2006), the Social Attribution Task-Multiple Choice (SAT-MC; Johannesen et al., 2013), and imaging scans pre- and post- the 14-weeks Program for the Education and Enrichment of Relational Skills (PEERS; Laugeson et al., 2012) social skills intervention. Resting-state functional MRI data were acquired via a Siemens 3T PRISMA scanner for 15 autistic ($M_{age} = 14$, 73.3% male) and 11 TD ($M_{age} = 15$, 58.3% male) youth. FSL (Smith et al., 2004) and AFNI (Cox, 1996) were used for preprocessing and bandpass filtering ($0.008 < f < .08$ Hz). ICA-AROMA (Pruim et al., 2015) addressed motion confounds. A bilateral IFG mask was created using the Harvard-Oxford atlas (Desikan et al., 2006). Global time series from this mask were correlated with whole-brain signal. Final connectivity maps were normalized using Fisher r-to-z transformations. AFNI's 3dClustSim (Cox et al., 2017a, 2017b) estimated the probability of false positives while running paired t-tests for group-level comparisons. Pre- and post-intervention change scores calculated from Z' (prime) scores extracted from significant clusters within the autistic youth group were used to examine correlations between IFG connectivity and change scores derived from pre- and post-intervention total raw scores TASIT and SAT-MC.

Results: Pre-intervention between group comparisons of IFG connectivity were nonsignificant, $p > .05$. Post between-group comparisons showed whole-brain underconnectivity of the IFG with the right lingual gyrus (RLG) in autistic youth compared to controls, $p = .01$. There was a significant difference between SAT-MC scores pre- ($M = 16.33$, $SD = 2.49$), and post- ($M = 17.27$, $SD = 1.71$) PEERS intervention, $t(14) = -2.36$, $p = .017$. The correlation between SAT-MC scores and IFG connectivity post-intervention were nonsignificant, $p > .05$. Differences for TASIT scores pre- to post-intervention were nonsignificant, $p > .05$. However, IFG underconnectivity in the autistic group post-intervention was negatively correlated with TASIT scores, $r = -.61$, $p = .016$. Such that, ToM performance improved on the TASIT with greater underconnectivity of the IFG to RLG.

Conclusions: Findings support previous research showing that autistic youth have difficulties in ToM, but social skills interventions can help improve ToM. Underconnectivity between the IFG and RLG visual area may be a compensatory mechanism post-intervention, which may help improve social outcomes. This research suggests integrating neurobiological insights into social skills training for more effective interventions for autistic youth.

437.074 Multimodal Brain Imaging in Autism Spectrum Disorders in Patients with SHANK3 Mutations

K. Aljabali^{1,2,3,4,5}, **A. Fabre**^{2,3,6,7,8,9}, **A. Philippe**^{10,11}, **L. Fillon**¹², **A. Saitovitch**¹³, **J. Boigontier**¹², **A. Munnich**^{6,14}, **N. Boddart**¹² and **M. Zilbovicius**¹⁵,
 (1)Cerveau, Cognition, Comportement, Université Paris cité, Paris, Île-de-France, France, (2)Image@Imagine, Institut Imagine, Paris, Île-de-France, France, (3)Pôle Autisme, Fondation Elan Retrouvé, Paris, Île-de-France, France, (4)Génétique, Consultation Mobile Régionale de Génétique, Paris, Île-de-France, France, (5)Unité 1163 & U1299, INSERM, Paris, Île-de-France, France, (6)Consultation Mobile Régionale de Génétique, Paris, Île-de-France, France, (7)Trajectoires Développementales et Psychiatrie, INSERM Unité 1163 & U1299, Paris, Hôpital Necker Enfants Malades, Service de Radiologie Pédiatrique, France, (8)Cerveau, Comportement, Cognition, Université Paris Cité, Paris, Île-de-France, France, (9)Service de Radiologie Pédiatrique, Hôpital Necker enfants Malades, Paris, Île-de-France, France, (10)Institut Imagine / UMR 1163, Paris, France, (11)Médecine, Université Paris Cité, Paris, Île-de-France, France, (12)Service de radiologie pédiatrique Hôpital Necker, Institut Imagine / INSERM U1299, Paris, France, (13)Hôpital Necker service de radiologie pédiatrique, Institut Imagine / INSERM U1299, Paris, FRANCE, (14)Service d'Histologie-Embryologie et Cytogénétique, Université Paris Descartes Paris France, Paris, France, (15)Service de radiologie pédiatrique Hôpital Necker, INSERM, Paris, France

Background: Genetic mutations can be specifically identified in approximately 30% of individuals with autism spectrum disorder (ASD) (Munnich et al., 2019). Among these, mutations in the *SHANK3* gene (22q13.3), which encodes a post-synaptic scaffolding protein, occur with higher frequency. However, brain MRI abnormalities have rarely been explored in ASD patients with *SHANK3* mutations.

Objectives: This study aimed to investigate anatomical and brain perfusion abnormalities in children with ASD and *SHANK3* mutations and to assess the relationship between these abnormalities and the type of mutation.

Methods: We conducted a retrospective study including 36 patients with ASD and *SHANK3* mutations (aged 2–22 years, mean age 6.6 ± 4.8 y) who underwent MRI at Necker Hospital, Paris. Among these, 15 had a complete deletion (Phelan-McDermid syndrome; Group A), while 21 had partial deletions or point mutations (Group B). Anatomical MRI, including 3D T1-weighted FSPGR, axial and coronal FSE T2-weighted imaging and coronal FLAIR sequences, were reviewed by an expert neuroradiologist. Arterial spin labeling MRI (ASL-MRI), a non-invasive technique for measuring cerebral blood flow (CBF) at rest, was performed on a subgroup of 7 patients (aged 2–5 years) and 21 age-matched comparison children. A whole-brain voxel-wise analysis was conducted to compare rest CBF between patients and controls. Statistical analyses were performed using SPM12, controlling for age as a confounding variable, with a significance threshold of $p < 0.05$ corrected for multiple comparisons (FWE).

Results: Clinical analysis of anatomical MRIs from the entire patient group ($n=36$) showed that 14 patients had normal MRI scans, while 15 had clearly defined abnormalities, including dysmorphic corpus callosum (14 patients), cortical atrophy (7 patients; Figure 1), and temporal pole abnormalities (5 patients). In Group A ($n=15$), all patients showed MRI abnormalities. In Group B ($n=21$), 13 patients exhibited MRI abnormalities. Additionally, cortical atrophy was significantly more frequent in Group A (6/15) than in Group B (1/21) ($p = 0.01$). Voxel-wise whole-brain ASL analysis revealed significant reductions in rest CBF in the bilateral superior temporal regions, left superior frontal gyrus, left precentral gyrus and left supramarginal gyrus in *SHANK3* patients compared to controls (Figure 2). No increases in CBF were observed in *SHANK3* patients.

Conclusions: Our findings align with previous studies that reported temporal pole MRI abnormalities in children with ASD without identified genetic mutations (Boddaert et al., 2009). Additionally, our results suggest that cortical atrophy may be specifically associated with a complete deletion of *SHANK3*. The observed hypoperfusion in the superior temporal regions, which are crucial for social cognition, are consistent with prior brain imaging studies in idiopathic ASD. This is the first study to investigate brain perfusion abnormalities in *SHANK3* patients, highlighting the importance of advanced imaging techniques for understanding the neurobiological mechanisms underlying ASD associated with genetic mutations.

437.075 Network Mechanisms Underlying Core Behavioral Features in Fragile X Syndrome

J. E. Norris¹, L. M. Schmitt², L. A. De Stefano³, E. V. Pedapati³, C. A. Erickson³ and L. E. Ethridge⁴, (1)Department of Psychology, University of Oklahoma, Norman, OK, (2)Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (3)Psychiatry, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (4)Pediatrics, University of Oklahoma Health Science Center, Oklahoma City, OK

Background:

Fragile X Syndrome (FXS) is characterized by intellectual disability, sensory hypersensitivities, executive dysfunction, and autistic characteristics. Current treatments only target specific psychiatric features (e.g., anxiety and irritability) and not cognitive features, which are more pressing for patients and families, due in part to poor insight into underlying neural mechanisms. Recent work from our group using resting state electroencephalography (EEG) has linked abnormal functional connectivity (FC) and specific microstates (i.e., transient, quasi-stable spatial patterns of brain activity across the scalp) to cognitive disruptions and lower IQ making FC an ideal target for investigation. The current study aims to evaluate the underlying functional network disruptions using EEG to examine FC in source space during resting state and during a cognitive flexibility task.

Objectives:

We aim to identify mechanisms contributing to functional disruptions in frontoparietal and temporal networks, with the goal of generating more specific, targetable biomarkers of the neurophysiology supporting cognition.

Methods:

A preliminary microstate analysis was conducted on resting state EEG data from 70 adult individuals ($N=36$ FXS and 34 typically developed controls (TDC)) ages 16-45, using the +Microstate Toolbox (K-means clustering to define microstates. Both a 4-cluster solution (i.e., replicates canonical microstates) and a 6-cluster solution were generated to replicate Takarae et al., 2023. Peak alpha frequency was also calculated as a proxy for cognition. The final results will include microstate outcomes from 80 adults ($N = 40$ FXS, 40 TDC) ages 18-36 to avoid both aging and developmental effects on cognition. Relationships between microstates and clinical measures indexing cognition will be evaluated using FC summary scores that represent whole functional networks as mediators within our statistical models. This approach aims to elucidate how specific underlying network disruptions correspond to distinct clinical features of FXS.

Results:

Preliminary results show elevated global variance explained (GEV), i.e., the amount of original EEG data explained by the microstate solution, across microstates differed significantly between groups for both the 4-microstate solution ($F(2, 67)=12.76, p<.001, ES=.16$) and the 6-microstate solution ($F(1, 68)=7.46, p=.008, ES=.1$). Individuals with FXS exhibited greater GEV (**4:** $M = 61.2\%, SD = 7.8\%$; **6:** $M=64.4\%, SD=7.1\%$) compared to TDC (**4:** $M=56.1\%, SD=8.4\%$; **6:** $M=59.3\%, SD=8.4\%$) (see figure). Further, GEV was inversely correlated with frontal peak alpha frequency ($r = -.28, p = .019$), with higher GEV associated with lower PAF. Next steps will include the FC analysis and assessment of a cognitive task where we hypothesize that there will be disruptions in the salience network, a network related to stimulus detection and attention, which will predict network stasis and difficulties with cognitive flexibility. Further, we will address whether microstates can be used as a less computationally intensive way to capture FC dynamics in FXS.

Conclusions:

The GEV findings are in alignment with prior findings in FXS where GEV elevation suggests network stasis and may reflect disruptions to underlying functional networks which may be associated with distinct cognitive and behavioral features of FXS, as suggested by the correlation with PAF.

437.076 Neural Correlates of Executive Functioning in Autistic and Non-Autistic Youth

H. Rea¹, M. Santhosh², E. Neuhaus³, S. J. Webb⁴ and G. A. Consortium⁵. (1)Center for Human Development and Disability, University of Washington, Seattle, WA, (2)Center for Child Health, Behavior and Development, Seattle Children's Research Institute, Seattle, WA, (3)Department of Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (4)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (5)Seattle Children's Research Institute, Seattle, WA

Background: Executive functioning (EF) is an umbrella term for higher order cognitive processes that underlie goal-directed behavior (Gioia et al., 2000). EF has been proposed as an endophenotype of autism (Demetriou et al., 2020). Yet, there is significant heterogeneity across EF domains and autistic individuals that may be explained with research on the underlying neurophysiological characteristics (Yeung et al., 2024).

Electroencephalographic (EEG) spectra analyses during resting-state tasks capture such neural processes (Saby et al., 2012). Theta (4-8 Hz), alpha (8-13 Hz), beta (13-30 Hz), and gamma (30-80 Hz) all relate to different EF processes (Pizzagalli, 2007; Schürman & Başar, 2001; Neuper & Pfurtscheller, 2001), but only one small study on autistic and non-autistic preschoolers (n=29) investigated the relation among theta/beta ratio and EF, with research needed on other power spectra in larger samples (Zhao et al., 2023).

Objectives: This study will investigate the relation among frontal resting state EEG power and EF in a large sample of autistic and non-autistic youth. It was hypothesized that Delta, Theta, and Beta would correlate with EF.

Methods: Data for the current analyses were collected as part of the ACE GENDAAR network, a study aimed at investigating sex and gender differences in autistic and non-autistic youth. In the current study, participants included autistic (n=136) and non-autistic (n=136) 8-to-17 year olds ($M=12.86$ years, $SD=2.90$) with $IQ > 70$ ($M=107.09$, $SD=19.03$). The sample was 46% female (n=125). High density EEG was collected while participants completed an eyes-open resting state task. Regions of interest were created to improve signal-to-noise estimates by averaging the absolute power across electrodes in the frontal left, medial, and right regions. EF was characterized using the Behavior Rating Inventory of Executive Function (BRIEF). Given differences in EF and power spectra between autistic and non-autistic youth, correlations were run separately.

Results: For autistic participants, absolute power in the Beta band was positively correlated with the Shift ($r=.20$) and Organization of Materials subscales ($r=.18$), as well as with the Behavior Regulation Index ($r=.17$) and Global Executive Composite (GEC) ($r=.17$). For the non-autistic group, the Plan/Organize subscale was negatively correlated with absolute power in the Delta band ($r=-.18$). See Table 1 for results from the non-autistic group and Table 2 for results from the autistic group.

Conclusions: As Beta relates to task engagement and alertness, autistic individuals with more global and specific EF challenges may be more engaged and alert at rest (Wang et al., 2013). Non-autistic individuals with challenges in planning/organizing may show lower attention and motivation at rest, as indicated by the correlation with Delta power (Knyazev, 2012). Although research on non-autistic individuals often reports that higher theta relates to lower EF, no correlations with Theta emerged in the current sample, likely due to the older age range in our sample (Tan et al., 2024). Future research should investigate power during EF-specific tasks.

**437.077 Neural Effects of Creative Movement, General Movement, and Sedentary Play Interventions on Interpersonal Synchrony in Children with Autism Spectrum Disorder: A Preliminary fNIRS Study**

W. C. Su¹, S. Srinivasan² and A. N. Bhat³. (1)Kinesiology, Louisiana State University, Baton Rouge, LA, (2)Kinesiology, University of Connecticut, Storrs, CT, (3)Department of Physical Therapy, University of Delaware, Newark, DE

Background: Children with Autism Spectrum Disorder (ASD) demonstrate difficulties in interpersonal synchrony (IPS)¹, which is linked to atypical activation in brain regions associated with the Observation Execution Matching System (OEMS)². Specifically, this includes hypoactivation in the Inferior Frontal Gyrus (IFG) and Superior Temporal Sulcus (STS), as well as hyperactivation over the Inferior Parietal Lobule (IPL)^{2,3}. Additionally, children with ASD fail to show enhanced OEMS activation when provided with more social information⁴. While creative movement (CM) interventions have shown promise in improving social, cognitive, and motor skills in children with ASD⁵, the underlying neural mechanisms remain poorly understood.

Objectives: This pilot randomized controlled trial (RCT) aims to explore the behavioral and neural effects of CM, General Movement (GM), and Sedentary Play (SP) interventions in children with ASD, using a drumming task to measure IPS.

Methods: Twenty-four children with ASD, aged 5 to 14 years, were recruited and randomly assigned to one of three groups: CM, GM, or SP. All groups participated in 16 training sessions over 8 weeks (two sessions per week). The CM group engaged in rhythmic musical, dance, and yoga-based activities aimed at improving whole-body coordination, praxis, and IPS. The GM group participated in exercise and locomotor games targeting coordination, strength, and endurance. The SP group, modeled on standard care, engaged in sedentary activities such as reading, building, and arts and crafts to enhance communication and fine motor skills. Before and after the intervention, participants completed a drumming task under two conditions: 1) Solo, where they matched alternating hand movements to a metronome, and 2) Social, where they synchronized their movements with an adult partner. During the task, cortical activation in the IFG, middle frontal gyrus (MFG), STS, and IPL was measured using functional Near-Infrared Spectroscopy (fNIRS). Video recordings of the sessions were analyzed for rhythmic, synchrony, and mirroring errors.

Results: After 8 weeks, children in the CM group showed significant improvements in IPS, with fewer rhythmic, synchrony, and mirroring errors ($ps < 0.05$; 75%–87.5% of children followed this trend). Additionally, the CM group demonstrated the most widespread increases in socially enhanced activation in the left IFG, STS, and MFG ($ps < 0.10$; Hedge's $g = 0.68$ – 1.34 ; 87.5%–100% of children followed this trend). The GM group showed increased activation in the left IFG ($ps < 0.05$; Hedge's $g = 1.27$; 71.4% of children), while the SP group exhibited increased activation in the left STS ($p < 0.01$; Hedge's $g = 1.07$; 71.4% of children). Children with lower baseline adaptive functioning, social responsiveness, and socially enhanced activation experienced greater IPS improvements post-intervention ($r = 0.41$ – 0.45 , $ps < 0.05$).

Conclusions: The current study supports the use of CM intervention in enhancing IPS performance in children with ASD and highlights the potential of fNIRS as a tool for tracking and predicting intervention outcomes.

437.079 Acquisition Stability of Resting-State EEG and Relation to Adaptive and Cognitive Functioning in Autistic Children: Results from the Autism Biomarkers Consortium for Clinical Trials (ABC-CT)

H. Borland¹, C. Nozari¹, M. Santhosh¹, V. Arutunian¹, A. Naples², A. R. Levin³, K. Chawarska⁴, G. Dawson⁵, J. Dziura⁶, S. Faja⁷, S. Jeste⁸, F. Shic¹, C. Sugar⁹, J. McPartland¹⁰ and S. J. Webb¹¹, (1)Center for Child Health, Behavior and Development, Seattle Children's Research Institute, Seattle, WA, (2)Yale Child Study Center, Yale University School of Medicine, New Haven, CT, (3)Neurology, Boston Children's Hospital / Harvard Medical School, Brookline, MA, (4)Child Study Center, Yale University School of Medicine, New Haven, CT, (5)Department of Psychiatry and Behavioral Sciences, Duke University, Durham, NC, (6)Yale University, New Haven, CT, (7)Boston Children's Hospital Laboratories of Cognitive Neuroscience, Brookline, MA, (8)Children's Hospital Los Angeles, Los Angeles, CA, (9)University of California, Los Angeles, Los Angeles, CA, (10)Yale Child Study Center, Yale Child Study Center, New Haven, CT, (11)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA

Background: A key metric of biomarker evaluation is understanding how factors that influence acquisition may impact generalizability of data to new populations. In a previous publication from the Autism Biomarkers Consortium for Clinical Trials (ABC-CT; Webb et al., 2023), children who did provide EEG data were older, had higher IQ scores, and greater adaptive skill compared to those that did not.

Objectives: This project extends this work to examine if child characteristics continue to influence acquisition across timepoints. Specifically, children in the ABC-CT were invited to return for 4 visits, T2 was +6 weeks, T3 was +6 months and T4 was +4 years. We examined: (1) The relationship between EEG data acquisition variables and adaptive functioning and cognition, and (2a) Short, medium and long term stability of resting alpha power (6-12.99 Hz) and then (2b) considered how acquisition performance and adaptive and cognitive skills influenced stability. **Methods:** The ABC-CT is a longitudinal study including autistic (N=280) and typically developing (TD, N=119) children aged 6-to-11 years-old. Of the original 399 participants, 226 (N_{ASD}=148, N_{TD}=78) returned for T4, 4.2yrs (SD=.66) after completing T1. (1) Pearson's correlations examined the relationship between age, verbal and nonverbal IQ, adaptive skills via the Vineland Adaptive Behavioral Scales, and EEG data acquisition variables (number of attended, artifact, and total valid trials). (2) Intraclass correlations were used to examine the stability of resting alpha (6-12.99 Hz) power. (3) We will use regression analysis to examine if T1 baseline values (acquisition variables, age, time between T1-T4, adaptive and cognitive skills) predict either T4 values or T1-T4 change; analyses for Aim 3 are ongoing.

Results: (1) Correlations between acquisition variables and IQ were present at T1 and T3, but not at T4 (see Table 1). Relation to adaptive skills was present at all timepoints. Correlation with social skills were not present at baseline but were at later time points. The pattern of results suggests similar child behavior relations for attention vs signal artifact (motion, eye movements). (2) Intraclass correlation showed moderate stability of alpha power over the four time points for the ASD group (see Table 2). While the ICC2 values for alpha power lowered over subsequent time points, they remained moderate overall, in both younger and older participants, and in the ASD high IQ subgroup.

Conclusions: In agreement with the initial findings at T1 (Webb et al., 2023), children in the ASD group who provided more valid EEG data were older and had better communication and daily living skills. Resting State alpha power maintained moderate stability throughout the multi-year study. For generalizability, the ABC-CT used a fixed acquisition protocol that did not allow for individualized behavioral support for autistic children and thus may underestimate abilities of autistic children when individualized strategies can be implemented. These data provide direction for developing better acquisition supports for children who may struggle with the procedure.

**437.080 Neurocomputational Correlates of Autism: Exploring 1/f Power and Narrowband EEG Activity across Genders**

M. L. McCleod¹, E. Malaia² and S. Borneman³, (1)Communicative Disorders, The University of Alabama, Tuscaloosa, AL, (2)Communicative Disorders, University of Alabama, Tuscaloosa, AL, (3)University of Alabama, Tuscaloosa, AL

Background: Autism Spectrum Disorder (ASD) is a neurodevelopmental disorder characterized by difficulties in social interaction and communication, with sex-based differences in presentation that complicate diagnostics, particularly for females. The power-law exponent, a key neurocomputational measure, reflects the 1/f slope of EEG spectra and may provide insights into the neural dynamics underpinning these sex differences. This study aims to investigate sex-based differences in brain organization in autistic and neurotypical populations by examining broadband 1/f characteristics and narrowband EEG power.

Objectives: This study investigates the differences in the 1/f power-law exponent between male and female autistic participants and neurotypical controls, as well as the relationship between broadband (1/f) and narrowband (theta, alpha, gamma) EEG activity.

Methods: 5 minutes of continuous resting-state (eyes-closed) EEG data was collected for 19 autistic young adults (10 F, age 18-27, M = 20.7, SD = 1.8), and 23 neurotypical controls (14 F, age 18-27, M = 21, SD = 1.8), using a 64-channel EGI Hydrocel Geodesic Sensor net and Netstation EEG acquisition system. The data was analyzed to quantify the 1/f power spectrum using Irregular Resampling Auto-Spectral Analysis (IRASA; Wen & Liu, 2016), and amplitude spectra for frequency ranges of interest were calculated using fast Fourier transforms in MATLAB; peak amplitude within each frequency range was squared to obtain band power. Recursive Feature Selection (RFE) machine learning algorithm was applied to identify electrode sites most salient for participant neurotype classification based on neurotype and sex.

Results: Female autistic participants exhibited significantly larger 1/f power-law exponents than female neurotypical participants over centro-parietal regions, coupled with significantly reduced alpha power in the same areas. Comparisons between female and male autistic participants revealed greater 1/f exponents over left anterior regions in females, alongside reduced gamma power. RFE analysis identified right anterior and left parietal electrode sites as highly salient for distinguishing between ASD and neurotypical participants, with increased delta power in ASD males relative to neurotypical males at left parietal sites ($p < .043$) and increased theta power in neurotypical males ($p < .049$).

Conclusions: Significant sex differences in the 1/f power-law exponent suggest distinct neural organizational patterns between male and female autistic individuals, particularly in the left anterior and fronto-parietal regions associated with language and executive function. These findings underscore the need for sex-specific approaches in ASD diagnostics and interventions. The correlation between broadband 1/f measures and narrowband theta, delta, and gamma band activity further indicates that functional brain organization differences captured by 1/f analysis manifest in both broadband and narrowband EEG activity.

437.081 Neuroepigenetics in Autistic Adults: An In Vivo Brain Imaging Study

C. E. Tseng^{1,2}, Y. C. Chen^{1,2,3}, E. Johnston^{1,3}, L. Nowinski^{2,3}, H. Y. Wey^{1,2}, C. J. McDougle^{2,3}, J. M. Hooker^{1,2,3} and N. R. Zurcher Wimmer^{1,2,3}, (1)Athinoula A. Martinos Center for Biomedical Imaging, Department of Radiology, Massachusetts General Hospital, Charlestown, MA, (2)Harvard Medical School, Boston, MA, (3)Lurie Center for Autism, Massachusetts General Hospital, Lexington, MA

Background:

Interactions between genes and environment, mediated through epigenetic mechanisms, are involved in autism spectrum disorder (ASD). Preclinical and human studies have implicated epigenetic mechanisms, including acetylation, in ASD (reviewed in Tseng et al., 2022). Histone deacetylases (HDACs), epigenetic enzymes that decrease acetylation of the DNA, can be measured using positron emission tomography (PET) and [¹¹C]Martinostat. [¹¹C]Martinostat binds to HDAC1, 2, and 3, which are closely associated with neuroplasticity and cognition (Wey et al., 2016).

Objectives:

Assess whether regional HDAC expression is altered in autistic adults compared to age- and sex-matched controls (CON) and assess whether HDACs are associated with ASD core symptoms in autistic adults.

Methods:

Seventeen autistic adults (11M/6F, age=25.82±6.28 years) and 22 non-autistic CON (11M/11F, age=28.32±5.55 years) completed a simultaneous PET and magnetic resonance imaging (MRI) scan with [¹¹C]Martinostat. Autistic adults met the DSM-5 diagnosis for ASD, and the scores on the Autism Diagnostic Observation Schedule, Second Edition (ADOS-2), Module 4 supported the diagnosis (ADOS-2 social interaction+communication score: 13.79±3.93, N=14). Autistic adults had to have an intelligence quotient (IQ) at or above 35.

For autistic participants, behavioral symptoms were assessed based on caregiver-report questionnaires (N=16), including the Social Responsiveness Scale, Second Edition (SRS-2), Aberrant Behavior Checklist, Second Edition (ABC-2) Social Withdrawal and Stereotypic Behavior subscales, and Repetitive Behavior Scale, Revised (RBS-R). Receptive vocabulary was measured using the Peabody Picture Vocabulary Test, 4th Edition (PPVT-4).

[¹¹C]Martinostat PET data from 60-90 minutes post-radiotracer injection were reconstructed into standardized uptake value (SUV) maps and normalized by the whole brain mean (SUVR). Whole brain voxelwise analyses were conducted using a general linear model with mixed effects and ordinary least squares ($Z > 2.3$, p-cluster corrected < 0.05). Analyses were run to i) compare [¹¹C]Martinostat SUVR between ASD and CON and ii) test for associations between [¹¹C]Martinostat SUVR and behavioral and language measures in ASD, controlling for age and sex.

Results:

Between-group analysis showed elevated HDACs in the visual cortex and lower HDACs in the insula, hippocampus, and orbitofrontal cortex in ASD compared to CON (Figure 1). In terms of associations with behavioral scales, lower HDACs in the right middle frontal gyrus were associated with higher scores on the Social Withdrawal subscale of the ABC-2, indicating more severe social withdrawal. Lower HDACs in the cerebellum and higher HDACs in the precuneus were associated with higher scores on the Stereotypic Behavior subscale of the ABC-2, indicating more severe stereotypic behavior. No other associations between HDACs and behavioral symptoms or language scores were found.

Conclusions:

In ASD, we observed regionally altered HDACs in areas involved in socio-emotional processing. The finding of lower HDACs in multiple brain regions aligns with previous findings of lower acetylation near HDAC genes in ASD (Sun et al, 2016). Regional HDACs were associated with symptoms of social withdrawal and stereotypic behavior in ASD, with lower regional HDACs in frontal and cerebellar areas being associated with more severe symptoms. Future work will expand the current sample size to assess potential sex-differences.

**437.082 Neurophysiological Indicators of Neurodevelopmental Outcomes**

E. Matsuba¹, E. F. Soto², J. Osborne³, X. Chen³, M. Shuter³, D. Major⁴, B. Prieve⁴ and N. Russo³, (1)Department of Psychology, Boston Children's Hospital / Harvard Medical School, Syracuse, NY, (2)Psychology, Syracuse University, Syracuse, NY, (3)Department of Psychology, Syracuse University, Syracuse, NY, (4)Department of Communication Sciences and Disorders, Syracuse University, Syracuse, NY

Background: Children born preterm (< 37 weeks gestational age) are at an elevated likelihood for autism (ELA) and intellectual disabilities (ID). Event-related Potentials (ERPs) are a non-invasive method of measuring brain activity and have the potential to identify important neurodevelopmental outcomes. Enhanced auditory discrimination, measured by the difference in the neural response to alternating sounds around 100ms post stimulus, is associated with autism, while reduced neurophysiological habituation to repeated sounds during an identical time period is correlated with a lower IQ. These two auditory perceptual measures can be quantified within the same experiment, allowing for an examination of the differential role of neurophysiological processes as indicators for autism and cognitive ability.

Objectives: The present study sought to examine whether early auditory discrimination and habituation could differentially predict autistic traits and cognitive abilities, respectively, among a sample of school-aged children born preterm. Secondly, we assessed brain-behaviour associations between ERPs and sensory features (i.e., sensory sensitivity).

Methods: ERPs were elicited using an auditory oddball paradigm consisting of alternating standard 1200Hz (80%) and deviant 1000Hz (20%) tones from 22 school-aged (mean age = 6 years, SD = 0.5) children born preterm (mean gestational age = 27.2 weeks; SD = 1.9 weeks). Mean amplitudes of the P1 discrimination difference wave (deviant – standard) and P1 habituation difference wave (first standard – second standard) were extracted from a frontocentral electrode cluster (E5, E6, E7, E12, and E106). Cognitive abilities (FSIQ) were assessed using the Stanford-Binet, fifth edition and autistic traits were measured with the Child Autism Quotient. Sensory features were measured using the Sensory Profile, Second Edition (SP-2). Two linear regressions were conducted with the neurophysiological measures as predictors and neurodevelopmental features as dependent variables, followed by a series of Pearson bivariate correlation tests.

Results: A larger P1 discrimination led to a greater caregiver endorsement of autistic traits ($F(2, 18) = 5.468, p = .004, R^2 = .31$), but P1 habituation did not predict FSIQ ($F(2, 19) = 0.1295, p = .6362$). Enhanced auditory discrimination was also associated with higher caregiver-ratings of sensory sensitivity ($r(20) = -.66, p = .002$).

Conclusions: This study established the P1 discrimination as an emerging neurophysiological predictor of autistic traits among ELA children born preterm. Further, the P1 discrimination may be uniquely associated with restricted and repetitive behaviors in autism. Future researchers may seek to replicate and extend these results in a longitudinal design with a large, diverse sample.

437.083 New Dynamic Facial Expression EEG Signatures Reveal Perceptual and Attentional Features Associated with Social Communication and GABA Phenotypes in Autism: A Link with the Third Visual Pathway

D. Sousa¹, A. Ferreira², H. C. Pereira³, J. A. Amaral³, J. Crisóstomo², M. Simoes^{4,5}, R. Martins², S. Mouga⁶, F. Duque⁷, G. Oliveira⁸ and **M. Castelo-Branco⁶**, (1)Institute of Nuclear Sciences Applied to Health (ICNAS), University of Coimbra, Coimbra, Portugal, (2)Coimbra Institute for Biomedical Imaging and Translational Research CIBIT, Institute for Nuclear Sciences Applied to Health ICNAS, University of Coimbra, Coimbra, Portugal, Coimbra, Coimbra, Portugal, (3)Coimbra Institute for Biomedical Imaging and Translational Research CIBIT, Institute for Nuclear Sciences Applied to Health ICNAS, University of Coimbra, Coimbra, Portugal, Coimbra, Portugal, (4)Institute of Nuclear Sciences Applied to Health, University of Coimbra, Coimbra, Portugal, (5)Center for Informatics and Systems, University of Coimbra, Coimbra, Portugal, (6)Coimbra Institute for Biomedical Imaging and Translational Research, ICNAS, University of Coimbra, Coimbra, Portugal, (7)Centro Hospitalar e Universitário de Coimbra - CHUC, Coimbra, Portugal, (8)Neurodevelopmental and Autism Unit From Child Developmental Centre, Hospital Pediátrico, Unidade Local de Saúde de Coimbra (ULS de Coimbra), Coimbra, Portugal, Coimbra, Coimbra, Portugal

Background: Autism is characterised by core differences in social communication and interaction. The underlying neurobiology can be investigated through experimental designs that capture the dynamic nature of social perception, which activates the third visual pathway.

Objectives: Here, we investigated dynamic specific facial emotion processing using a naturalistic paradigm, leading to a dynamic N170 (dN170). Our dynamic facial emotion recognition task allowed to obtain a specific face expression sensitive - dN170, with a contrast against a neutral face baseline, leading to a specific facial emotion processing signal. The paradigm we employed demonstrates ecological validity, offering a more naturalistic approach to social cognition. This allows to elucidate the role of event-related potentials (ERPs) markers, specifically the face-sensitive dN170 and a dynamic P300 (dP300) in autism, as well as across the spectrum from non-autistic to autistic individuals. We further aimed to investigate the complex interplay between neurophysiological signatures, neurometabolite profiles, as measured by magnetic resonance spectroscopy (MRS) and social communication abilities.

Methods: Sixteen autistic children/adolescents (11 males and 5 females; mean (M) age =13.31±2.182 years) were recruited from the Neurodevelopmental and Autism Unit (ULS, Coimbra, Portugal). The other group comprised 16 non-autistic (11 males and 5 females; M = 13.31±1.922 years). Autism diagnosis was assigned based on the gold standard instruments: parental or caregiver interview, Autism Diagnostic Interview-Revised and direct semi-structured proband assessment with Autism Diagnostic Observation Schedule. Participants engaged in an active task of an avatar with two temporal trajectories: morphing from neutral to happy or sad expressions and unmorphing back to neutral. We recorded ERPs and MRS in autistic and non-autistic children/adolescents in these groups matched for sex, handedness, and age. GABA and Glx (Glutamate+Glutamine) measurements were performed with the Hadamard Encoding and Reconstruction of Mega-Edited Spectroscopy (HERMES) approach.

Results: We found that the dN170 had longer latencies during unmorphing for the autistic group: a main effect was found for the dynamic conditions, $F(1, 30) = 4.336, p < .05, \text{partial } \eta^2 = .126$, and the pairwise comparisons showed that, for the autistic group, there are longer latencies in the unmorphing condition ($M = 263.813, SE = 8.893$) than in the morphing condition ($M = 226.813, SE = 8.465$). The specific timing effect identified for the unmorphing vs morphing conditions in autism suggests a stimulus trajectory dependent effect (hysteresis in autism). dP300 results demonstrated higher amplitudes in the autistic group during morphing: a statistically significant two-way interaction between dynamic conditions and group was found, $F(1, 30) = 11.572, p < .01, \text{partial } \eta^2 = .278$. Pairwise comparisons showed that the dP300 amplitude elicited by the morph condition is higher in the autistic ($M = 5.860, SE = .469$) than in the non-autistic group ($M = 3.870, SE = .469$). This suggests the presence of an attentional compensatory mechanism. Correlations between ERPs, neurochemical (GABA), and social communication abilities provided evidence of a continuum from non-autistic to autistic phenotypes.

Conclusions: These findings support the promising roles of specific dynamic facial expression ERPs by reflecting perceptual and attentional processing differences in autism.

437.084 Normative Modelling of the Functional Connectome in Autism Spectrum Disorder

H. Sweatman, Integrated Program in Neuroscience, McGill University, Montréal, QC, Canada

Background: Altered social communication in autism (ASD) impacts many aspects of life including learning and relationships. Social communication difficulties in ASD may be linked to alterations in cognitive processes such as memory and reasoning, which show altered functional connectivity (FC) in the brain in ASD. While case-control studies are common, they are flawed in assuming homogeneity of groups. ASD is known to be a highly heterogeneous population and case-control methods may mask individual differences. Normative modeling provides a solution by deriving neurotypical (NT) developmental trajectories of selected features and computing individual-level deviations. This is often done using anatomical features, and studies have shown that the extent of deviation from anatomical norms can predict ASD symptoms. Recent studies have characterized FC, rather than anatomy, and demonstrated applicability in ASD. Complex and dynamic processes in the brain such as social communication and memory are better captured by FC than anatomy. Therefore, it stands to reason that deviations from the normative functional connectome in ASD would relate to the amount of impairment in these cognitive functions. Relationships between the extent of deviation and social communication processes could inform areas for early detection or intervention.

Objectives: **1.** Compute extent of deviation from normative FC in NT and ASD samples. We expect ASD children will have a greater proportion of extreme deviations. **2.** Relate deviation to behavioural measures such as memory, theory of mind, social responsiveness, and IQ. We anticipate deviation in the ASD group to be related to these measures.

Methods: We currently have a sample of 129 participants (103 NT, 26 ASD; aged 5.95-30.00 years) with 3T multi-echo fMRI including movie-watching rather than rest data as this has been shown to reduce movement in children and to provide higher sensitivity to behavioural differences. Additionally, we measure IQ (WISC-V), social responsiveness (SRS-2), memory, and theory of mind. Data collection is ongoing. **1.** We will derive normative models of system segregation ($(FC_{\text{within-network}} - FC_{\text{between-network}})/FC_{\text{within-network}}$) for each of the 7 and 17 Yeo networks using open-access HBN movie-watching fMRI data. We will compute age- and sex-specific deviation indices for each subject and identify extreme deviations in each group. **2.** We will correlate deviation indices with each behavioural measure.

Results: Models derived in our NT sample and applied to our ASD sample (e.g. Figure 1) show positive correlations between segregation of the control network and measures of fluid reasoning ($\rho = .424$, $p = .017$, Figure 2), and between segregation of the default mode network and social responsiveness ($\rho = .404$, $p = .024$). Modeling of HBN data and comparison between these deviations and behaviour is underway.

Conclusions: Our results suggest FC deviations from normative models can predict behavioural differences associated with social communication in ASD. This advances our understanding of the development of the functional connectome in ASD and may be applied to identify areas for intervention at an individual level. These data could be used to derive ASD subtypes and characterize multiple developmental trajectories within this population for early detection before behavioural symptoms are evident.

437.085 Real-World Listening in the Autistic Brain

B. K. Lau¹, A. M. Estes², T. St. John³ and S. R. Dager⁴, (1)Otolaryngology-Head and Neck Surgery, University of Washington, Seattle, WA, (2)Speech and Hearing Sciences, UW Autism Center, Seattle, WA, (3)University of Washington, Seattle, WA, (4)Radiology, University of Washington, Seattle, WA

Background:

Histological studies conducted in postmortem human tissue samples from autistic children show dysmorphology and decreased neuronal numbers in auditory brainstem nuclei that are important for coding information from the two ears (binaural hearing). Difficulty on auditory tasks that rely on binaural hearing, such as understanding speech in noisy real-world environments, is also frequently reported by autistic individuals.

Objectives:

In this study, we obtained neural and behavioral measures of binaural hearing to test the hypothesis that deficits in binaural coding underlies the auditory processing difficulty experienced by autistic individuals.

Methods:

The participants in this study were 19 autistic 7-to-10-year-old children (13 male, 6 female) and 19 age- and biological sex-matched neurotypical comparison children. To assess binaural processing, we measured the neural encoding of timing differences between the ears using electroencephalography (EEG) as well as spatial release from masking (SRM), a binaural hearing phenomenon that improves speech perception when distracting talkers are spatially segregated from the talker of interest. To prioritize real-world relevance, we simulated an everyday classroom scenario for our speech perception measure: Listening to a teacher read a book in a sea of background noise. We recorded EEG while participants were listening to an audiobook under 3 conditions 1) Quiet, 2) Co-located Noise, and 3) Segregated Noise. To quantify how well speech is encoded in the neural response, we employed a linear modelling approach where a ridge regression model was fit from acoustic speech features including the envelope, envelope derivative, word onset, and phoneme onset, to the EEG signal to produce a multivariate temporal response function (mTRF). This mTRF method allowed us to compare the neural encoding of speech in noise across groups using machine learning, and to obtain a neural measure of SRM.

Results:

Our preliminary results show reduced neural encoding of timing difference between the ears in autistic children (Fig. 1). Furthermore, the mTRF analysis revealed the surprising finding that the neural encoding of speech is worse for autistic children when distracting talkers are moved away from the target speaker (Segregated Condition; Fig. 2). This is the opposite pattern expected. What this finding may translate to in a classroom, is that when students are listening to their teacher read at the front of the room and there are distracting talkers (e.g., other students), moving the distracting talkers away from the teacher and off to the side helps neurotypical children hear the teacher better. However, this makes autistic children do worse at hearing what the teacher is saying.

Conclusions:

These findings suggest binaural processing differences in autistic children, warranting further investigation in larger cohorts and across a wider age range.

437.086 Relationship between Early Visual Processing and Sensory Profiles in Young Autistic Children

S. Major¹, H. Akkineni², H. L. Morgan³, D. Akinsooto⁴, A. Dea⁵, A. C. Henley³, E. Peters⁵, C. Stone⁶, R. E. Aiello⁷, J. Schechter³, M. Spanos⁴, C. M. Kerns⁸, E. Ng-Cordell⁹, N. O. Davis⁴ and K. L. Carpenter⁵, (1)Duke Center for Autism and Brain Development, Durham, NC, (2)Duke University, Durham, NC, (3)Department of Psychiatry and Behavioral Sciences, Duke University School of Medicine, Durham, NC, (4)Department of Psychiatry and Behavioral Sciences, Duke University Medical Center, Durham, NC, (5)Department of Psychiatry and Behavioral Sciences, Duke Center for Autism and Brain Development, Durham, NC, (6)UNCG, Greensboro, NC, (7)Duke Center for Autism and Brain Development, Duke University, Durham, NC, (8)University of British Columbia, Vancouver, BC, Canada, (9)Psychology, The University of British Columbia, Vancouver, BC, Canada

Background:

Visual Evoked Potentials (VEP) provide insights into early visual processing mechanisms, revealing significant differences in neural responses among autistic individuals. Research consistently demonstrates reduced amplitudes in VEP components, particularly P1 and N1, suggesting constraints on local processing pathways and enhanced sensitivity to specific visual stimuli. Additionally, longer N1 latencies have been associated with executive function challenges and sensory awareness. Although sensory processing challenges—hyperresponsivity (heightened reactions to sensory input), hyporesponsivity (reduced reactions to sensory input), and sensory seeking (active engagement in sensory experiences)—are prevalent in autistic individuals, the relationship between these profiles and early VEP responses remains poorly understood. This study aims to fill that gap by examining how variations in P1 and N1 components relate to sensory behaviors in young autistic children.

Objectives:

We aim to examine if amplitude and latency of the early sensory components, P1 and N1, can predict downstream sensory behaviors in the three sensory domains. This is the first study to correlate VEP and Sensory Experiences Questionnaire (SEQ) in a sample of young autistic children.

Methods:

91 autistic children participated; of these, 43 (47%) had valid VEP data. P1 amplitude was calculated as the most positive value between 80 and 160 ms and N1 amplitude was calculated as the most negative value between 40 ms and the P1 latency in a) occipital left hemisphere, b) occipital right hemisphere, and c) occipital midline. VEP data were considered invalid if a) less than 30 trials remained after artifact detection (simple voltage threshold $\pm 200\mu V$) and removal of un-attended trials ($n=12$), or more than 1/3 of channels were interpolated overall or more than 2 interpolated within a region ($n=15$). Sensory processing was assessed via caregiver report using the SEQ. Linear regression was utilized for the full autism sample, with no subgrouping, with age and IQ as covariates, using an alpha of 0.05.

Results:

The N1 latency processing at the midline predicted both hyper-responsive behaviors ($\beta=0.009$, $p=.02$) and sensory seeking behaviors ($\beta=0.01$, $p=.02$). Whereas the latency of the P1 component in the left hemisphere predicted hypo-responsive behaviors ($\beta=-0.01$, $p=.02$). P1 and N1 amplitudes did not predict sensory profiles ($p > .05$).

Conclusions:

We observed that longer N1 latency predicts more hyper-responsive and sensory-seeking behaviors, while shorter P1 latency predicts more hypo-responsive behaviors in autistic children. The N1 component indicates varying degrees of excitatory input to the primary visual cortex, and may be related excitatory and inhibitory (E/I) changes in autism. Our findings suggest that the timing of early visual responses is associated with different sensory profiles in children with ASD, supporting research linking E/I mechanisms to sensory processing. The timing of VEP components, rather than their strength, is associated with downstream sensory behaviors. Timing of neural responses rely on properly myelinated neurons, with distinct pathways converging with millisecond precision; even slight disruptions in timing can lead to large-scale network changes. Future studies should directly compare subgroups to each other to see if amplitude/latency differences exist between the different sensory groups.

437.087 Relationship between Speech Performance and Sensorimotor and Language Network Functional Connectivity in Autism Spectrum Disorder

T. L. Luks¹, M. Lafontaine¹, Y. Li¹, C. Demopoulos² and Y. Li¹, (1)Department of Radiology and Biomedical Imaging, University of California San Francisco, San Francisco, CA, (2)UCSF Department of Psychiatry and Behavioral Sciences, UCSF, San Francisco, CA

Background: Speech impairment is common in individuals with autism spectrum disorder (ASD) and can adversely impact social interaction and communication. Both sensorimotor brain networks and language networks may play a role in the heterogeneous presentation of speech production in ASD.

Objectives: To evaluate the relationship between speech performance and sensorimotor and language network functional connectivity (FC) in ASD. **Methods:** 82 subjects with ASD and 34 typically developing control (TDC) subjects were enrolled. Speech measures included age scaled scores for the Goldman-Fristoe Test of Articulation Sounds-in-words subtest (articulation), NEPSY-II Inhibition Naming Time (rapid naming), and Diachokinetic Period (DDK) for repetitions of “Puh-Tuh-Kuh” (speech motor function) administered according to Oral Speech Motor Screening Exam-3rd Edition procedures.

Resting-state functional MRI (rsfMRI) was collected using a 32-channel coil on a 3T GE MR750 scanner and analyzed with CONN using language network seeds (left/right inferior frontal gyrus (IFG) and superior temporal gyrus (STG)) and sensorimotor network seeds (left/right lateral and midline superior sensorimotor cortex (SM)). T-tests evaluated group differences in speech measures. Multivariable linear regression models (adjusted by age and sex) compared FC between groups and evaluated the relationship between speech performance and FC within ASD subjects (false discovery rate correction for multiple comparisons).

Results: There was no significant group difference in age or sex. TDC subjects scored significantly higher in speech articulation, rapid naming, and speech motor function (Table 1).

ASD subjects had stronger FC between sensorimotor regions and the thalamus ($p < 0.005$), caudate ($p < 0.001$), and cerebellum ($p < 0.005$) but weaker connectivity within the sensorimotor network (right and left SM, $p = 0.005$; superior and right SM, $p = 0.00001$; superior and left SM, $p = 0.006$) compared to TDC subjects (Figure 1a). No significant differences between groups were found in language networks.

Among individuals with ASD, better articulation was associated with stronger FC between the SM and anterior cingulate cortex (ACC) ($p = 0.0001$; Figure 1b). Better rapid naming was associated with stronger FC between left STG and left supramarginal gyrus/angular gyrus ($p = 0.046$), and between left IFG and right precuneus/angular gyrus ($p = 0.0009$; Figure 1c). Slower DDK performance correlated with stronger FC between right STG and ($p = 0.026$; Figure 1d).

Conclusions: Results indicated that sensorimotor and language network FC was associated with speech performance in individuals with ASD. We identified stronger FC in the sensorimotor-cerebellar-thalamocortical pathway but weaker FC within cortical sensorimotor regions in the ASD. Stronger FC in the ACC, important for sensorimotor integration and error detection, was associated with better speech articulation in the ASD group. Further, the mSFC (involved in motor planning) and the STG (involved in auditory processing) are integral for speech-motor control. We found that increased right hemisphere connectivity in these regions was associated with slower DDK performance, which suggests that atypical lateralization may be involved in slower DDK performance. Our measure of rapid naming incorporated demands for both rapid speech and semantic judgments. This was the only task with semantic demands, and it was the only one to demonstrate associations with FC in the language network, with better performance being associated with stronger connectivity in ASD.

437.088 Reliability of a Novel Spatial Filtering Algorithm in the Reconstruction of MEG Cortical Auditory Evoked Responses Under Conditions of Different Paradigm Lengths and in Relation to Clinical Correlates in Autistic and Typically Developing Youth
Z. Zhang¹ and **C. Demopoulos²**, (1)Psychiatry & Behavioral Sciences, UCSF, San Francisco, CA, (2)UCSF Department of Psychiatry and Behavioral Sciences, UCSF, San Francisco, CA

Background:

Magnetoencephalographic (MEG) cortical auditory response delays have been associated with lower verbal abilities in individuals with autism spectrum disorder (ASD). Functioning in other domains that rely on auditory processing, such as verbal learning, may also be related to these delays. Participation in MEG research can be challenging, as repeated trials (long scan times) are necessary to acquire quality data.

Objectives:

To evaluate: (1) group differences in source reconstructed MEG cortical auditory response latency, (2) associations between response latency and verbal learning in ASD, and (3) whether a novel approach to MEG source reconstruction would allow for replication of results under simulated conditions of fewer trials.

Methods:

41 typically developing control (TDC) and 71 ASD participants aged 8-17.3 years were administered the California Verbal Learning Test-Children's Version

(CVLT-C) and a MEG auditory evoked field (AEF) task. The CVLT-C age-scaled total learning score was used to index verbal learning. MEG data were collected for 120 trials (2-second inter-stimulus-interval) of a 100ms 1000Hz tone burst presented binaurally at 77dB. Four MEG datasets were created from the first 80%, 60%, 40%, and 20% of the 120 trials to simulate shorter scan times. For each dataset, artifact-free trials were processed with the Champagne with baseline noise learning algorithm. AEFs were localized to auditory cortex and M50, M100, and M200 response latencies and normalized amplitudes were documented for each hemisphere of each participant for all 5 datasets. Repeated measure ANCOVA was used to examine differences between groups and within-participants across the results of the five datasets. Bivariate linear regression with bisquare weight function was conducted to compare latency and amplitude results of 100% trials dataset against each simulated dataset. Finally, hierarchical linear regressions were performed to examine associations between CVLT-C total learning score and auditory response latencies/amplitudes derived from each of the five datasets after controlling for age.

Results:

Significant between group differences were identified for bilateral M100 (LH:F(1, 58) = 4.788, $p=0.033$; RH:F(1,80)=4.25, $p=0.043$) and right hemisphere M50 (F(1,65)=6.483, $p=0.013$) response latencies with delayed responses in the ASD group. No significant differences were identified within subject across reduced trial simulations for either latencies or amplitudes; however, bivariate linear regression results suggested that only the 80% ($R^2>0.88$) and 60% trials datasets ($R^2>0.45$) could produce reliable latency results relative to the 100% trials dataset, and amplitude results of all simulated datasets were not reliable. Hierarchical linear regression analyses showed that, after controlling for age, CVLT-C total learning score was significantly associated with left hemisphere M100 ($t(48)=-2.55$, $p=0.014$) and M200 latencies ($t(47)=-3.188$, $p=0.003$) in the 100% trials dataset, and that these significant associations were sustained for the 80% trial dataset. With 60% of trials, only the left hemisphere M200 remained significantly associated with CVLT-C scores.

Conclusions:

Results indicated that auditory response delays were associated with verbal learning performance in ASD participants. Further, a novel source reconstruction algorithm produced reliable latencies with 20%-40% fewer trials, suggesting that this approach could be used in studies focused on cortical auditory response latency to make research participation more accessible to those who cannot tolerate longer scans.

437.089 Repetition Strengthens the N170 Response in Autistic and Neurotypical Children: Results from the Autism Biomarkers Consortium for Clinical Trials (ABC-CT)

B. M. Walicki¹, J. W. Griffin², A. Naples³, G. Dawson³, A. R. Levin⁴, N. Kleinhans⁵, S. J. Webb⁶, F. Shic⁷, C. Sugar⁸, J. Dziura⁹, S. Jeste¹⁰, S. Faja¹¹ and J. McPartland¹², (1)Yale Child Study Center, Yale Child Study Center, Yale University School of Medicine, New Haven, CT, (2)Yale Child Study Center, Yale University School of Medicine, New Haven, CT, (3)Department of Psychiatry and Behavioral Sciences, Duke University, Durham, NC, (4)Neurology, Boston Children's Hospital / Harvard Medical School, Brookline, MA, (5)University of Washington, Seattle, WA, (6)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (7)Center for Child Health, Behavior and Development, Seattle Children's Research Institute, Seattle, WA, (8)University of California, Los Angeles, Los Angeles, CA, (9)Yale University, New Haven, CT, (10)Children's Hospital Los Angeles, Los Angeles, CA, (11)Boston Children's Hospital Laboratories of Cognitive Neuroscience, Brookline, MA, (12)Yale Child Study Center, Yale Child Study Center, New Haven, CT

Background: Converging evidence suggests that repetition suppression, or reduced neural response to repeated stimuli, is diminished in autism. This finding has been observed across sensory modalities, experimental methods, and developmental stages. Reduced repetition suppression is associated with increased autistic traits. Despite well-evidenced face processing differences in autism and their relation to social-communicative function, no studies have specifically examined repetition suppression of the N170, a marker of early-stage face processing, in autistic children.

Objectives: To (1) compare N170 repetition effects for faces and houses in autistic and neurotypical (NT) children; and (2) examine relationships with autistic traits. We predicted NT but not autistic children would show reduced N170 amplitude across trials. We expected reduced N170 repetition suppression to correlate with greater social and sensory autistic features.

Methods: In the Autism Biomarkers Consortium for Clinical Trials (ABC-CT), 280 autistic and 119 NT children aged 6-11 passively viewed 72 upright neutral faces and 72 houses while electroencephalogram (EEG) was recorded. We measured peak amplitudes of the P100, reflecting attention allocation, and the N170. We used linear regression to evaluate the influence of repetition (first/last half of trials), stimulus category (faces/houses), and group (autistic/NT) on N170 amplitude. The analyses were repeated with the P100-N170 peak-to-peak difference as the dependent variable to rule out the possibility that between-condition differences in more general visual processing indexed by the P100 influenced the findings. Associations between N170 repetition effects and measures of social function and sensory differences were examined using Pearson correlations.

Results: There was a significant main effect of repetition [$F_{1,828.71}=27.7, p<.001$], with N170 amplitude increasing (enhancement) not decreasing (suppression) in the second half of trials compared to the first half. There was also a significant main effect of stimulus category [$F_{1,834.65}=271.5, p<.001$], such that N170 amplitude was greater for faces compared to houses. There were no group differences in N170 amplitude [$F_{1,300.03}=1.7, p=0.199$]. No interaction terms were significant, meaning that repetition enhancement did not differ between faces and houses [$F_{1,829.38}=0.025, p=0.875$] or autistic and NT children [$F_{1,828.71}=0.088, p=.767$]. Repetition enhancement was negatively correlated, albeit weakly, with scores on the Pervasive Developmental Disorder Behavior Inventory sensory subscale ($r=.18, p<.05$) and the Social Responsiveness Scale, Second Edition social cognition ($r=.18, p<.05$) and social motivation ($r=.16, p<.05$) subscales among autistic children.

Conclusions: Contrary to our hypothesis, both autistic and NT children demonstrated repetition enhancement—an increase in N170 amplitude over the course of the experiment—rather than the expected suppression. Repetition enhancement is thought to reflect a temporary increase in encoding efforts related to the formation of novel neural representations, with repetition suppression emerging only after a stable representation has been established. Accordingly, there may have been insufficient trials in this study to induce repetition suppression. Alternatively, early-stage face processing, indexed by the N170, may not exhibit the same differential repetition effects observed with other stimuli or neuroimaging techniques. These findings suggest that reduced repetition suppression in autism may not be as robust as previously thought and may depend on the specific component or processing stage being measured.

437.090 Response of Resting State Networks to Cannabidiol (CBDV) in Autistic and Non-Autistic Individuals: From Both Static and Dynamic Perspectives

Y. Ge¹, C. M. Pretzsch¹, M. Dimitrov¹, S. Fenn-Moltu¹, E. Daly¹, D. Murphy², G. McAlonan^{1,3} and D. Batalle^{1,4}, (1)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (2)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, UNITED KINGDOM, (3)NIHR-Biomedical Research Centre for Mental Health at the Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, UNITED KINGDOM, (4)Centre for the Developing Brain, Division of Imaging Sciences and Biomedical Engineering, King's College London, London, United Kingdom

Background: Resting state networks (RSNs) represent large-scale spatial patterns of neural functional connectivity. Altered RSNs are associated with cognitive and emotional difficulties, but - though widely reported in autism - very large cohorts are needed to identify even small reproducible differences. However, in these prior studies, RSN characteristics are averaged through time, possibly missing crucial information embedded in temporal fluctuations. Moreover, RSNs are regulated by neurochemical systems, yet this is under-explored in non-autistic, let alone autistic cohorts. We have previously shown that modulating the endocannabinoid system using CBDV shifts the functional connectivity of cortico-subcortical networks in autistic adults towards the pattern observed in non-autistic controls (Pretzsch et al., 2021).

Objectives: Here extended this work to examine static and dynamic data-driven RSN activity and tested the hypothesis that CBDV influences RSNs differentially in autistic and non-autistic adults.

Methods: A resting-state fMRI dataset from a randomised, double-blind, cross-over study of autistic (n=14) and non-autistic (n=17) males, was acquired following placebo or 600mg CBDV administered orally on 2 separate visits. We identified 20 RSNs with group-level independent component analysis. The static RSN activity was characterised as core network strengths - mean values across voxels of subject-specific spatial maps (dual regression stage 2). The dynamic RSN activity, was characterised using the moment-to-moment RSN activity timeseries (dual regression stage 1). All timepoints were clustered into 10 brain states with K-medoid (Figure 1). Dynamic features were computed as fractional occupancy (FO) and dwelling time (DT) of each state. Baseline differences (placebo condition), drug effects of CBDV, group×drug interaction and differences between autistic RSNs under CBDV and non-autistic baseline were examined with multiple linear regression and linear mixed models.

Results:

Static RSNs: At baseline, the core network strength of the executive control network (ECN) was higher in autistic participants than in non-autistic participants ($t=2.446$, $p=.022$). There were no main effects of CBDV nor group×drug interaction, though group differences were not present between autistic participants under CBDV and non-autistic baseline.

Dynamic RSNs: At baseline, the FO and DT of State 10 were higher in autistic adults compared to non-autistic controls (FO: $t=3.030$, $p=.005$. DT: $t=3.099$, $p=.005$). There was a significant effect of CBDV on the DT of State 6 ($\chi^2(1, 23)=5.286$, $p=.021$) and State 10 ($\chi^2(1, 23)=12.381$, $p<.001$) in non-autistic participants as well as significant group×drug interaction effects on the DT of State 6 ($\chi^2(1, 43)=6.617$, $p=.010$) and State 10 ($\chi^2(1, 43)=6.437$, $p=.011$). CBDV significantly increased the DT of State 6 ($t=2.299$, $p=.039$) (Figure 2A) and State 10 ($t=3.519$, $p=.004$) (Figure 2B) in non-autistic participants. While there was no significant drug effect in autistic participants, differences in the FO and DT of State 10 were not found between autistic participants under CBDV and non-autistic baseline (Figure 2B).

Conclusions: We have shown baseline differences in both static and dynamic RSN activity between autistic and non-autistic individuals. Moreover, CBDV modulated the RSN dynamics differently in autistic and non-autistic adults, suggesting a shift in autistic brain dynamics towards a pattern more similar to non-autistic baseline after CBDV.

437.091 Resting EEG Periodic and Aperiodic Components and Links to Language and Cognitive Skills in Neurotypical and Autistic Children

Y. Chen¹, M. Tsou², C. A. Nelson³, H. Tager-Flusberg⁴ and C. L. Wilkinson⁵, (1)Department of Psychological and Brain Sciences, Boston University, Boston, MA, (2)Boston Children's Hospital, Boston, MA, (3)Department of Developmental Medicine, Boston Children's Hospital, Boston, MA, (4)Psychological and Brain Sciences, Boston University, Boston, MA, (5)Department of Developmental Medicine, Boston Children's Hospital / Harvard Medical, Boston, MA

Background: Previous studies have shown that resting-state EEG power across multiple frequency bands is associated with language development in young autistic children, although this finding has not consistently been replicated. Most prior studies focused on absolute or relative power when examining brain-behavior association with language development. New methods have emerged to parametrize the power spectra into *aperiodic* (broad band neuronal spiking activity) and *periodic* (oscillatory activity across different frequency bands) components. However, little is known about whether aperiodic or periodic components differ between neurotypical and autistic children and how these neural activities relate to language and cognitive abilities in autistic children with a wide range of language skills.

Objectives: Aim 1: To characterize and compare whole brain resting aperiodic and periodic components between neurotypical and autistic children. Aim 2: To investigate the concurrent association between resting aperiodic and periodic activities, receptive and expressive language skills, and cognitive ability in autistic children.

Methods: Artifact-free 5-minute resting-state EEG data from 71 neurotypical and 63 autistic children (age-matched; $M_{age}=4.44$ years, $SD=1.20$, ranging from 2.04 to 6.85) were included in this study. Aperiodic and periodic activity were decomposed using SpecParam. All autistic participants have a confirmed clinical diagnosis of autism spectrum disorder. Natural language samples were used to derive two measures of expressive language: number of different words (NDW) and mean length of utterance (MLU). Receptive language was assessed using the Preschool Language Scale-Fifth Edition (PLS-5) and nonverbal IQ with the Mullen Scales of Early Learning or the Differential Ability Scales-II. ANCOVAs were used to compare resting neural activity between neurotypical and autistic children with age as a covariate. Linear regression models were used to examine the association between EEG features and language and cognitive ability in the autistic group.

Results: Aperiodic offset decreased with age across the sample, $r(134)=-.181$, $p=.036$. After controlling for age, aperiodic offset was larger in the autistic group, $F(1,131)=6.63$, $p=.011$. There were no significant differences in aperiodic slope between the two groups. Autistic children showed significantly higher aperiodic total power than their neurotypical peers, $F(1,131)=4.56$, $p=.035$. While neurotypical and autistic children did not show significant differences in peak alpha amplitude and frequency, older children demonstrated higher peak alpha amplitude, $\rho(134)=.18$, $p=.037$, and frequency, $\rho(134)=.303$, $p<.001$, in both groups.

Autistic children with higher peak alpha amplitude used more diverse vocabularies (NDW, $F(3,64)=7.69$, $p<.001$) and complex sentences (MLU, $F(3,62)=8.55$, $p<.001$) during naturalistic interactions controlling for age and had higher nonverbal IQ, $r(60)=.275$, $p=.034$. Autistic children with lower aperiodic offset ($F(2,58)=3.522$, $p=.036$) and higher peak alpha amplitude ($F(2,58)=4.78$, $p=.012$) had higher receptive language.

Conclusions: Autistic children demonstrated more broad band neural spiking activity compared to their neurotypical peers reflected by a larger aperiodic offset, and those with reduced spiking activity showed better receptive language. Neurotypical and autistic children did not show significantly distinct patterns of excitatory-inhibitory balance based on the similar aperiodic slope between the two groups. Peak alpha amplitude, an indicator of thalamocortical maturation, is important for nonverbal IQ and language development in autistic children.

437.092 Resting Gamma Power Associates with Expressive Language Skills in Autistic Youth

S. Kannan¹, A. Naples², B. E. Cairney³ and J. McPartland⁴, (1)Yale University, New Haven, CT, (2)Yale Child Study Center, Yale University School of Medicine, New Haven, CT, (3)Psychiatry, Yale Child Study Center, New Haven, CT, (4)Yale Child Study Center, Yale Child Study Center, New Haven, CT

Background: There is substantial heterogeneity in language skills among children with autism spectrum disorder (ASD). High-frequency EEG oscillations between 30–45 Hz (i.e., gamma) are associated with language ability and higher-order cognition. Gamma oscillations display a pattern of developmental maturation, increasing rapidly during early life to promote cognitive development, slowing in adolescence, and decreasing in advanced age in neurotypical (NT) individuals. Reduced frontal gamma power correlates with expressive language skills and language learning in autistic children. However, whether gamma is elevated or reduced in autism is debated, and its developmental trajectory in autistic children is unclear.

Objectives: This study aimed to examine the relationship between development, expressive language abilities, and gamma power during resting EEG in autistic and non-autistic children.

Methods: Resting EEG data was collected from 25 autistic (6–18 years; $M=11.3$, $SD=3.7$) and 41 non-autistic (6–18 years; $M=11.2$, $SD=3.3$) children. Participants in both groups had an $IQ \geq 70$ ($M=113.8$, $SD=15.1$), and groups did not differ on IQ or age. EEG was recorded while participants sat still with eyes open and closed. A one-way ANOVA measured whether gamma power, averaged across all electrodes, differed between groups. For autistic participants, Pearson correlations examined the relationship between gamma power and expressive language skills, measured by the Vineland Adaptive Behavior Scales-3, a parent interview of adaptive functioning.

Results: Gamma power over all electrodes decreased with age in both groups (ASD: $r=-0.27$, $p=0.2$, NT: $r=-0.24$, $p=0.36$). Autistic youth had elevated gamma compared to NT participants ($F(1,39)=3.493$, $p=0.07$, $\eta^2=0.08$). No correlation between gamma and expressive language was found in the NT group. However, in the ASD group, gamma power positively correlated with expressive language skills on the Vineland ($r=0.49$, $p=0.01$).

Conclusions: Consistent with extant findings among neurotypical populations, gamma power decreased with age for autistic and non-autistic participants alike. However, autistic children had elevated gamma power overall compared to the non-autistic group, possibly reflecting differences related to attention, perception, or learning. Contrary to prior research, gamma power was positively associated with expressive language skills in the autistic group which may indicate more effective neural connectivity within language-related networks in the brain. Because our sample ranged from age 6 to 18, the results may demonstrate developmental differences related to gamma power and autism, wherein the rapid increase in gamma power observed in non-autistic children during early life continues into adolescence for autistic children. Future studies with larger samples and constrained developmental ranges may further clarify the relationship between gamma power, development, and language abilities in autism.

437.093 Sex-Specific Cerebrovascular Reactivity Differences in Autistic Children

Q. N. Lee¹, J. K. Lee², D. S. Andrews³, O. J. Sargent⁴, B. Heath¹, M. Solomon², C. W. Nordahl² and A. P. Fan^{1,4}, (1)Department of Neurology, University of California, Davis, Davis, CA, (2)Department of Psychiatry and Behavioral Sciences, UC Davis MIND Institute, Sacramento, CA, (3)Department of Psychiatry and Behavioral Sciences, MIND Institute, UC Davis Medical Center, Sacramento, CA, (4)Department of Biomedical Engineering, University of California, Davis, Davis, CA

Background: Many studies use resting-state functional magnetic resonance imaging (rsfMRI) to investigate the neurobiology of autism; however, findings remain inconsistent and are often attributed to the heterogeneity of neural differences in autism. Yet, in addition to neural activity, the blood oxygen level dependent (BOLD) signal also reflects systemic vascular changes that drive oxygenated blood flow, such as local brain vascular capacity. Despite evidence of cerebrovascular differences in preclinical and postmortem studies of autism, these findings and the extent to which heterogeneity in cerebrovascular differences may contribute to disparate rsfMRI findings have not been examined in humans in vivo. In a previous study, we leveraged a novel rsfMRI analysis to measure cerebrovascular reactivity (CVR), or the capacity for cerebral blood vessels to dilate in response to a vasoactive stimulus, in the multi-site Autism Brain Imaging Data Exchange. For the first time, we identified elevated relative CVR (rCVR) in regions of the ventral attention network, specifically in autistic girls (9-12 years old).

Objectives: In this study, we leverage a longitudinal, single-site study of autistic and non-autistic children, to investigate rCVR differences in a new cohort.

Methods: RsfMRI images (TR=2s) were motion corrected and spatially smoothed (Gaussian kernel full-width-half-max=8mm). Motion parameters, a linear drift term, and imaging frames with framewise displacement (FD) greater than 0.25mm were removed using linear regression. After excluding participants with fewer than 75% of frames censored for motion, 56 autistic (16 female) and 67 non-autistic (26 female) participants (9-12 years old) were included. CVR is calculated as the change in BOLD signal per change in vasoactive stimulus (e.g. CO₂). To generate rCVR maps from rsfMRI, we used voxel-wise general linear models that regress each voxel's BOLD signal on the frequency-filtered (0.02-0.04Hz) global signal, which reflects natural changes in arterial CO₂, a vasodilator, during normal breathing (Figure 1). Resulting β maps from linear regression were normalized to global β to produce rCVR maps. CVR was calculated in native fMRI space, then transformed to T1-anatomical and MNI-standard space. Using linear models, rCVR was compared between diagnostic and sex groups in gray matter regions of the Harvard Oxford Atlas (91 regions). Nuisance regressors included age and mean FD.

Results: Autistic females had decreased rCVR in the right middle frontal gyrus (rMFG; $\beta=-0.31$, $p=0.0004$) and posterior cingulate cortex (PCC; $\beta=-0.15$, $p=0.03$) compared to non-autistic females (Figure 2). No diagnostic effects were significant in males. There was a significant diagnosis-by-sex interaction in the rMFG ($p=0.008$), where autistic females also had decreased rCVR compared to autistic males ($\beta=-0.24$, $p=0.003$). In the PCC, non-autistic females had elevated rCVR compared to non-autistic males ($\beta=0.12$, $p=0.03$).

Conclusions: In our second study of rCVR differences in autistic children, we identified rCVR differences in similar regions, specifically in autistic females. However, in this study, we found decreased, as opposed to elevated, rCVR in autistic females. Our sex-specific findings are consistent with known sex hormone mediated differences in cerebrovascular function. Further studies will examine these differences longitudinally and in relation to pubertal status, behavior, and functional connectivity to disentangle these findings.

437.094 Sleep Spindles and 40Hz Auditory Steady State Responses As Biomarkers of Thalamocortical Circuit Dysfunction in Autism Spectrum Disorder

P. Hickey Townsend^{1,2,3}, **N. Massa**^{1,2}, **L. Woodham**^{1,2}, **A. M. Neumeyer**⁴, **D. Mylonas**^{1,2} and **D. S. Manoach**^{1,2}, (1)Psychiatry, Massachusetts General Hospital, Boston, MA, (2)Athinoula A. Martinos Center for Biomedical Imaging, Charlestown, MA, (3)Lurie Center for Autism, Massachusetts General Hospital, Lexington, MA, (4)Lurie Center for Autism Massachusetts General Hospital, Lexington, MA

Background: Accumulating evidence implicates thalamocortical circuit dysfunction in autism spectrum disorder (ASD). Thalamocortical circuitry plays an important role in filtering information from the environment. Thus, disruptions in this circuitry could be related to core symptoms (i.e., sensory sensitivities) and sleep disturbances, which are common in ASD. One assay of thalamocortical circuit functioning are sleep spindles, 12-15Hz bursts of activity generated by the thalamic reticular nucleus and propagated to the cortex by thalamocortical relays. During wake, the same circuitry modulates gamma oscillations in auditory cortex, which can be indexed by the 40Hz Auditory Steady-State Response (ASSR). Reduced 40Hz ASSRs and sleep spindles are reported in people with ASD, supporting the possibility of thalamocortical circuit dysfunction. However, it remains unclear if there is a relationship between these measures in ASD, or if they are associated with clinical features of ASD.

Objectives: Here, we test the hypothesis of thalamocortical circuit dysfunction in ASD, and that this circuitry underlies sleep disturbances or core ASD symptoms. We predict that there would be reduced 40Hz ASSRs and spindle density in ASD, and that reductions in spindle density would be correlated with reductions in the 40Hz ASSR given that they arise from common circuitry. We also predict that reductions in 40Hz ASSRs and spindle density will be related to increased ASD symptom severity and sleep disturbances.

Methods: 18 adults with ASD (age: 22±3; 3 Female; Non-verbal IQ: 108±14) and 16 neurotypical (NT) adults (age: 24±4; 4 Female; Non-verbal IQ: 112±16) were given a 90-minute nap opportunity while EEG was recorded. Following the nap, participants listened to 150 40Hz click trains (500ms on, 500ms off) while EEG was recorded to measure ASSRs. ASD symptom severity was assessed using the Autism Diagnostic Observation Schedule (ADOS). We derived sleep spindle density (#/minute) and wake after sleep onset (WASO) from the nap data, and calculated inter-trial phase coherence (ITPC), a measure of phase alignment, from the ASSR task.

Results: ASD participants had reduced 40Hz ASSRs compared to NT participants ($t(25)=2.67$, $p=.01$, $d=1.03$). There were no significant differences in spindle density between groups. Reduced 40Hz ASSRs were associated with lower spindle density in frontal electrodes ($ps<.042$). Although the magnitude of this relationship did not significantly differ between groups, it was mostly driven by NT participants ($r=.71$, $p=.01$; ASD $r=.10$, $p=.76$). Within the ASD group, lower 40Hz ASSRs correlated with higher ADOS scores ($r=-.74$, $p=.002$). Worse sleep quality (increased WASO) was also associated with reduced spindle density in NT and ASD participants ($Tsum=-16.08$, $p<.001$).

Conclusions: These results provide mixed support for the hypothesis of thalamocortical circuit dysfunction in ASD. Spindles and 40Hz ASSRs were correlated in NT participants, consistent with the notion that these biomarkers arise from common circuitry, but this relationship was weaker in ASD. These biomarkers were also associated with sleep disturbances and core ASD symptom severity, highlighting their clinical relevance. Additional work is required to better understand the role of thalamocortical circuitry in ASD and replicate these findings in a larger sample.

437.096 Specific Association Patterns between Brain Glutathione Levels, Myelin Map and Functional Connectivity in Autism Spectrum Disorder

T. Iwabuchi^{1,2}, T. Hirai³, N. Umeda⁴, H. Yogo⁵, Y. Nishimiya⁵, Y. Nishigaki⁵, M. Watanabe⁵, H. Yamasue^{2,6}, M. Tsujii⁷, K. J. Tsuchiya^{1,2} and H. Matsuzaki^{2,8}, (1)Research Center for Child Mental Development, Hamamatsu University School of Medicine, Hamamatsu, Shizuoka, Japan, (2)United Graduate School of Child Development, Osaka University, Suita, Osaka, Japan, (3)Psychiatric and Mental Health Nursing, University of Fukui, Eiheiji-cho, Yoshida-gun, Fukui, Japan, (4)Maternal and Child Health Nursing, University of Fukui, Eiheiji-cho, Yoshida-gun, Fukui, Japan, (5)Kojin Hospital, Nagoya, Aichi, Japan, (6)Psychiatry, Hamamatsu University School of Medicine, Hamamatsu, Shizuoka, Japan, (7)Department of Contemporary Sociology, Chukyo University, Toyota, Aichiken, JAPAN, (8)Research Center for Child Mental Development, University of Fukui, Eiheiji-cho, Yoshida-gun, Fukui, Japan

Background: Previous studies have demonstrated reduced levels of glutathione (GSH), which is involved in the body's antioxidant defenses, in blood samples from individuals with autism spectrum disorder (ASD) (Frustaci et al. 2012; Chen et al., 2021). Although several postmortem brain studies in ASD have reported reduced GSH levels in the temporal cortex and the cerebellum (Chauhan et al., 2012; Rose et al., 2012), there has been no in vivo evidence of atypical brain GSH levels in individuals with ASD.

Objectives: This study examined whether 1) individuals with ASD have reduced GSH levels in regions suggested by postmortem brain studies, including the temporal lobe and cerebellum, 2) brain GSH levels show differential associations with myelination in autistic and typically developing (TD) individuals, 3) relationships between myelination and functional connectivity also differ in ASD and TD individuals, and 4) functional connectivity shows group differences in associations with emotion recognition ability.

Methods: In this study, regions of interest (ROIs) were defined in the bilateral temporoparietal junction (TPJ), cerebellum, and pregenual anterior cingulate cortex (pgACC), and GSH measurements were performed using ¹H-magnetic resonance spectroscopy (MRS) to compare individuals with ASD (n=30, age range 20-39, 28 males) and age- and sex-matched TD (n=27, age range 18-41, 25 males). Myelin maps were generated based on the T1w/T2w ratio to explore myelin associations with GSH across the whole brain. Functional connectivity analyses were performed based on resting-state functional magnetic resonance imaging (rsfMRI). We used the multivariate pattern analysis (MVPA) to examine group differences in associations between T1w/T2w ratio and functional connectivity. Based on the MVPA results, we also examined group differences in associations between functional connectivity and emotion recognition ability as measured by the Reading the Mind in the Eyes Test (RMET, Baron-Cohen et al., 2001).

Results: Individuals with ASD showed higher left TPJ GSH concentration than TD controls ($t = 2.1$, $p < 0.05$, uncorrected). No significant differences between groups were found in other ROIs. Myelin maps showed a significant group x GSH interaction in the left middle frontal gyrus (MFG), suggesting a group difference in the correlation between the left TPJ GSH concentration and the left MFG T1w/T2w ratio ($p < 0.05$, family-wise error [FWE] corrected at the cluster level). MVPA also identified a significant cluster in the left MFG for the interaction between group and the left MFG T1w/T2w ratio, suggesting a group difference in the association between the left MFG myelination and functional connectivity from this area. Finally, using this left MFG cluster as a seed region, a whole-brain seed-to-voxel analysis revealed that the correlation between MFG-occipital functional connectivity and emotion recognition ability was significantly different between groups.

Conclusions: The present study demonstrated ASD-specific associations between GSH levels, myelination, functional connectivity, and emotion recognition ability. Contrary to the hypothesis, brain GSH levels were not reduced but increased in the left TPJ of individuals with ASD, and GSH levels in this region were positively associated with myelination in an ASD-specific manner. These findings suggest compensatory neural mechanisms in individuals with ASD.

**437.097** Spontaneous Functional Connectivity in Subcortical Attentional Networks Driving Social Behaviors and Developmental Outcomes in Autism

N. Kojovic¹, F. Delavari², P. Hagmann³ and M. Schaer⁴, (1)Developmental Imaging and Psychopathology Lab, University Of Geneva, Geneva, Switzerland, (2)Developmental Imaging and Psychopathology Lab Research Unit, Faculty of Medicine, University of Geneva, Geneva, Switzerland, (3)University of Lausanne, Lausanne, Switzerland, (4)Department of Psychiatry, University of Geneva, Geneva, Geneva, Switzerland

Background:

Evidence from human and basic research suggests that the central issue of atypical social orienting in autism may involve dysfunction in early-maturing brain structures designed for detecting relevant environmental elements (Kleinhan et al., 2011). This ancient attention pathway, compared to neocortical-subtended attention, is responsible for the automatic detection of salient stimuli in the environment (Johnson et al., 2005) and is phylogenetically conserved across species to facilitate rapid detection of relevant signals, such as threats or conspecific cues. This route involves the superior colliculus (SC), pulvinar (PUL), and amygdala (AMY), with the SC being central. Research shows that the SC matures early, around 20 weeks gestation (Qu et al., 2006), predisposing it to salience detection early in development. This aligns with findings of early preferential orienting to faces (Simion et al., 2011) or face-like stimuli (Goren et al., 1975, Johnson et al., 1991) in human infants. In parallel, recent translational evidence from autism mouse models (SHANK3) showed that the SC-Ventral Tegmental Area (VTA) pathway, a dense site of dopaminergic (DA) neurons, was critical to encoding social orientation towards an unfamiliar conspecific (Solié et al., 2022). Converging evidence of this circuit's role in processing social information comes from a study in children with autism (7-13 years old) highlighting aberrant structural and functional connections between the VTA and nucleus accumbens (NAc) in response to social stimuli (Supekar et al., 2018). Objectives: To investigate the role of the subcortical attention route, involving the superior colliculus (SC) and its connections, in the symptomatology of autism spectrum disorder (ASD) and assess how connectivity patterns within this pathway relate to key autistic symptoms and developmental progress.

Methods:

We utilized the superior colliculus (SC) as a seed region to explore its whole-brain functional connectivity in relation to age and autistic symptom severity using partial least squares correlation (PLS-C). This approach revealed a significant multivariate component ($r = 0.64$, $p = 0.04$), indicating a primary effect of symptom severity and a secondary effect of age. To evaluate developmental changes, follow-up data from 30 children were analyzed using a "rate of change" score derived from differences between follow-up and baseline Mullen Scales of Early Learning (MSEL) results, normalized by the elapsed time.

Results: The significant PLS-C component indicated lower SC connectivity with regions involved in reward processing and attention, including the ventral tegmental area (VTA), pulvinar, amygdala, visual cortex, precuneus, vermis, and temporoparietal junction. Children with higher symptom severity exhibited hypoconnectivity within this network. Notably, SC-VTA connectivity showed a positive correlation with developmental change rates, particularly in a subgroup of children receiving early intensive behavioral intervention.

Conclusions: This study provides evidence that SC-VTA connectivity may play a crucial role in developmental gains among children with ASD, highlighting its potential as a biomarker for stratifying developmental outcomes. The findings suggest that early intervention strategies might capitalize on the plasticity of this pathway to enhance multisensory integration and developmental progress. Future studies with larger cohorts are needed to confirm the role of SC-VTA connectivity in guiding personalized interventions in ASD.

437.098 Stay Still like a Statue: Using a Brief Measure to Predict Head Motion during MEG Data Collection

M. Kim¹, L. Bloy², L. Blaskey², T. Roberts², R. Franzen², J. C. Edgar² and E. S. Kushner¹, (1)Lurie Family Foundations MEG Imaging Center, Department of Radiology, The Children's Hospital of Philadelphia, Philadelphia, PA, (2)Lurie Family Foundations MEG Imaging Center, Department of Radiology, Children's Hospital of Philadelphia, Philadelphia, PA, (3)Children's Hospital of Philadelphia, Philadelphia, PA, (4)Departments of Radiology and Psychiatry, The Children's Hospital of Philadelphia, Philadelphia, PA

Background: There has been increasing awareness of the need for the inclusion of individuals with Autism Spectrum Disorder (ASD) who have high support needs in neuroimaging research. To this end, clinical and behavioral protocols for reducing motion and increasing scan quality have been developed (e.g., Nordahl et al., 2016; Kushner et al., 2021). These protocols may also benefit autistic children with fewer support needs, but who may still demonstrate increased head motion due to repetitive behaviors, sensory sensitivity, or executive functioning difficulties, leading to a reduction in evaluable data (Bednarz & Kana, 2018). As motion training can be time-intensive, establishing methods to efficiently identify individuals who may benefit most from this training is of interest.

Objectives: To assess the use of a brief assessment (NEPSY-II Statue) for screening participants to predict head motion during magnetoencephalography (MEG) data collection.

Methods: Participants were 61 children with ASD, 6 to 12 years (54 males, mean age=9.8 years, SD=1.4; mean IQ=106.5, SD=17.7). The NEPSY-II Statue subtest was administered to participants, and caregivers completed the Child Behavior Checklist (CBCL) and the Behavior Rating Inventory of Executive Function (BRIEF). The Statue task requires children to maintain a pose with their eyes closed for 75 seconds while the examiner introduces distractions. Norms are not available for school-age children, as they are expected to achieve a perfect raw score (indicating no movement during the task; Korkman et al., 2007); thus, raw scores were used for analysis. Participants were scanned using a 275-channel CTF MEG system in a supine position with three head position indicator (HPI) coils attached to the scalp to monitor head position during a 15-minute task where they are presented auditory stimuli while watching a movie (without sound).

Results: There was a relationship between the mean raw score on Statue and the maximum amount of motion ($M=2.01$ mm, $SD=1.6$, $r=-0.27$, $p=.03$). The amount of time with motion >10mm during the MEG exam was also associated with the number of 5-second intervals during which the child opened their eyes ($r=0.27$, $p=.04$) or vocalized ($r=0.26$, $p=.05$) during Statue, but not the total raw score or intervals with body movement. There were no significant associations between the amount or duration of motion during the MEG exam and caregiver ratings on the CBCL or BRIEF ($ps>0.05$). Finally, there were no associations between motion and age ($r=-0.02$, $p=.86$) or IQ ($r=-0.13$, $p=.32$).

Conclusions: Children who had more difficulty keeping their eyes closed or staying quiet during the 75-second task had more head motion during MEG data collection. There were no associations between caregiver rating scales and motion; therefore, Statue may be an efficient and better predictor of motion during the MEG exam compared to more comprehensive measures, such as caregiver rating scales. Furthermore, motion was not predicted by age or IQ. Thus, Statue is a quick and easy-to-administer approach to identifying children who may benefit from motion training prior to neuroimaging, making it an ideal tool to integrate into neuroimaging protocols.

437.099 Subcortical Brain Volumetric Differences in Autistic Individuals across the Lifespan

D. Christensen¹, Y. S. Shin², J. Wang¹, C. Cuomo², D. J. Shirley³, S. P. Pulver⁴, A. M. Orlando⁵, W. S. McKinney⁶, C. Stevens⁷, K. E. Unruh⁸, B. Karmakar⁹, S. A. Coombes¹⁰, M. W. Mosconi¹¹ and Z. Wang³, (1)Neurocognitive and Behavioral Development Laboratory, University of Florida, Gainesville, FL, (2)University of Florida, Gainesville, FL, (3)Applied Physiology and Kinesiology, University of Florida, Gainesville, FL, (4)Marcus Autism Center, Atlanta, GA, (5)Center for Autism and Related Disabilities (CARD), University of Florida, Gainesville, FL, (6)Cincinnati Children's Hospital Medicine Center, Cincinnati, OH, (7)University of Kansas, Lawrence, KS, (8)Kansas Center for Autism Research and Training (K-CART), University of Kansas Life Span Institute, Lawrence, KS, (9)The University of Florida, Gainesville, FL, (10)Applied Physiology and Kinesiology, The University of Florida, Gainesville, FL, (11)Clinical Child Psychology Program, Schiefelbusch Institute for Life Span Studies, University of Kansas, Lawrence, KS

Background: Several subcortical brain regions underpin critical clinical symptomatology of autism spectrum disorder (ASD), including hippocampus, amygdala, thalamo-basal ganglia, and ventricular areas. However, the extent to which volumetric variations of these subcortical regions differ between autistic individuals and neurotypical controls across the lifespan, particularly during middle to later adulthood, is largely unknown.

Objectives: To bridge this critical gap, we leveraged a multi-site T1-weighted MRI dataset to examine volumetric deviations in the hippocampus, amygdala, thalamo-basal ganglia, and ventricles in autistic individuals and controls ages 7-73 years. We examined between-group differences in each subcortical region for the whole age range and Young (<30 years) and Old (≥30 years) subgroups, respectively.

Methods: Our dataset includes 122 autistic (40 female) and 92 neurotypical controls (37 female) recruited from the UT Southwestern Medical Center, University of Kansas, and University of Florida. All T1 data underwent standard postprocessing pipelines using FreeSurfer 7.2.0. Volume data of 38 hippocampal, 18 amygdala, 8 thalamo-basal ganglia, and 8 ventricular ROIs were extracted. Subfields associated with a specific subcortical region were bundled for principal component analysis (PCA). For each subcortical region, component(s) were selected when the cumulative variance exceeded 75% total variance. ANCOVA(s) were then implemented on each selected component with Group, Age, and Group *Age as predictors, total intracranial volume and sex as covariates, and the component score as the response. ANCOVA analyses were examined for the whole sample and then separately for Young and Old subgroups.

Results: The first principal component (PC1) was extracted for the ventricle and amygdala cluster. Additional PCs were extracted for the thalamo-basal ganglia and hippocampal clusters, respectively. The bilateral ventricles contributed significantly to PC1 of the ventricular cluster. For the whole and Old age analyses, autistic individuals showed greater PC1 scores compared to controls of older ages. For the amygdala cluster, PC1 primarily consisted of the bilateral lateral nucleus and basal nucleus. Autistic adults exhibited greater PC1 scores than controls when comparing the whole sample and the Young subgroup. For the hippocampal cluster, PC1 was largely associated with bilateral hippocampal head, body, and tail subfields. Young autistic individuals showed greater PC1 scores compared to young controls. For the thalamo-basal ganglia cluster, PC1 was primarily driven by the bilateral thalamus. The autistic Young group demonstrated significantly greater PC1 scores, but this was not exhibited for the whole or Older group. No significant group or group-by-age effect was identified for the remaining PCs of the hippocampal and thalamo-basal ganglia clusters.

Conclusions: Our findings highlighted accelerated ventricular volumetric increases in autistic individuals at old ages. The "Old" autistic group did not differ from controls in volumes of the hippocampal, amygdala, and thalamo-basal ganglia clusters, although this observation was associated with significant overgrowth of these subcortical regions in young autistic individuals and a faster rate of volumetric declines in ASD with older age. Together, our study offers novel insights into neurobiological substrates underlying age related volumetric differences in ASD and highlights potential earlier and accelerated neurodegenerative processes manifested in subcortical regions at young ages of ASD.

437.100 Symptoms of Persistent Depression but Not General Anxiety or Major Depression Predict Resting Alpha Power for Autistic Children: Results from the Autism Biomarkers Consortium for Clinical Trials (ABC-CT)

I. Rodden¹, J. P. Momsen², A. Naples³, K. Chawarska³, G. Dawson⁴, S. Faja⁵, S. Jeste⁶, N. Kleinhans⁷, J. Dziura⁸, S. J. Webb⁹, C. Sugar¹⁰, F. Shic¹¹ and J. McPartland¹², (1)McPartland Lab - Yale Child Study Center, Yale School of Medicine, New Haven, CT, (2)Yale Child Study Center, Yale University School of Medicine, New Haven, CT, (3)Child Study Center, Yale University School of Medicine, New Haven, CT, (4)Department of Psychiatry and Behavioral Sciences, Duke University, Durham, NC, (5)Boston Children's Hospital, Harvard, Boston, MA, (6)Children's Hospital Los Angeles, Los Angeles, CA, (7)University of Washington, Seattle, WA, (8)Yale University, New Haven, CT, (9)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (10)University of California, Los Angeles, Los Angeles, CA, (11)Center for Child Health, Behavior and Development, Seattle Children's Research Institute, Seattle, WA, (12)Yale Child Study Center, Yale Child Study Center, New Haven, CT

Background: Autistic individuals exhibit different patterns of EEG power spectra (elevations in resting gamma power, reductions in relative alpha power) compared to neurotypical individuals, representing possible biomarkers for autism (Neo et al., 2023). Distinct power spectra have also been observed in Major Depressive Disorder (MDD; increased theta power and increased alpha power; Kemp et al., 2010) and Anxiety Disorder (decreased theta power; Zhang et al., 2022). Anxiety and depression frequently co-occur in autism, thus understanding relationships among anxiety and depression and resting EEG in ASD could inform biomarker development (Mayes et al., 2010).

Objectives: The current study aimed to (1) examine how resting state EEG power varies as a function of parent-reported anxiety and depressive symptoms in autistic participants and (2) investigate possible differential relationships in autistic versus neurotypical children.

Methods: Resting EEG was collected from 260 children with ASD (31% female) and 116 neurotypical children (31% female) between the ages of 6 and 11 ($M_{age}=9.1\pm1.6$ years) in the Autism Biomarkers Consortium for Clinical Trials (ABC-CT). Log-scaled power spectral density EEG values were used as dependent variables in linear regression models that included variables to control for age, sex, full-scale IQ (Developmental Ability Scales II) and EEG data quality. Subscales from the Child and Adolescent Symptom Inventory, 5th edition (CASI-5) captured individual differences associated with symptoms of major depression (MD), persistent depression (PD), and general anxiety (GA).

Results: Regression models revealed a significant interaction between PD scores and diagnostic group to predict alpha power (10-12.99 Hz), indicating that the relationship between PD scores and alpha power differed between diagnostic groups ($\beta=0.28, p=.022$). Follow-up models within each diagnostic group revealed a main effect of PD score on alpha power for autistic participants ($\beta=-0.71, p=.049$), such that higher PD symptom report was associated with lower resting alpha power. A significant main effect of PD score in neurotypical participants indicated higher PD symptom count was associated with greater alpha power ($\beta=0.20, p=.048$). MD and GA scores exhibited no significant interactions with resting alpha power.

A significant interaction between MD scores and diagnostic group in the analysis of gamma (35-54.99 Hz) revealed that the relationship between MD scores and resting gamma power was also contingent on diagnostic status ($\beta=0.12, p=.023$). However, there was no significant main effect of MD scores on gamma power for autistic children. GA and PD scores exhibited no significant interactions with gamma power. All comparable analyses investigating theta band activity produced null results.

Conclusions: The relationships between resting alpha and gamma power and symptoms of anxiety and depression differed for diagnostic groups, confirming the between-group dissimilarity reported in prior work. Higher parent-reported PD symptomology was negatively associated with resting alpha power for autistic children, while this relationship was positive for neurotypical children. Contrary to previous literature, GA and MD symptoms were unrelated to resting state alpha or theta power for autistic participants. Results highlight the importance of considering co-occurring conditions when evaluating EEG biomarkers for autism.

437.101 Thalamocortical Gradients Reveal Atypical Thalamic-Insula Interactions in Autism

S. Park¹, P. Thomson², H. B. Cho³, S. L. Valk⁴, B. Bernhardt⁵, M. P. Milham⁶, S. J. Hong⁷ and A. Di Martino², (1)Autism Center, Child Mind Institute, New York, NY, (2)Child Mind Institute, New York, NY, (3)Center for Neuroscience Imaging Research, Institute for Basic Science, Suwon, Gyeonggi-do, Korea, Republic of (South), (4)FZ Jülich, Jülich, Germany, (5)Neurology and Neurosurgery, Montreal Neurological Institute, Montreal, QC, Canada, (6)Nathan S. Kline Institute for Psychiatric Research, Orangeburg, NY, (7)Center for the Developing Brain, Child Mind Institute, NY, NY

Background: The thalamic-cortical circuits are critical in sensory information processing and cognitive integration. Findings from our recent work over typical development, suggest that connectivity between the thalamus and the salience network is pivotal in development of the functional segregation between externally-oriented (i.e., visual, sensorimotor) and internally-oriented (i.e., default mode) networks (Park et al., 2024, Nat Neuro). As a first step to extend this line of investigation to autism, the present study examines thalamocortical connectivity in this group along with its association with autistic symptom severity.

Objectives: We aimed to examine thalamocortical functional connectivity gradient maps (CMAP) and their neocortical projections (NEOMAP) in individuals in the autism spectrum compared to an age- and sex-matched neurotypical (NT) group.

Methods: We analyzed data selected from the Autism Brain Imaging Data Exchange-I (ABIDE-I), including n=107 autistic and 113 NT individuals, (aged 6.4–50 years, all males). We derived CMAPs in the Brainspace toolbox via diffusion map embedding with a normalized angle kernel, and applied Procrustes alignment for aligning individual CMAPs to the whole sample mean. NEOMAPs were extracted by multiplying CMAPs to the thalamus-cortex correlation matrix, projecting the CMAPs onto the neocortical surface. Statistical testing of CMAPs and NEOMAPs for group differences used surface-based linear models in SurfStat, with age and head motion as covariates; site effects were controlled via ComBat harmonization. For interpretation, we sorted the NEOMAPs and significant findings by the Yeo-Krienen 7 networks. Follow-up analyses using linear regression modeling tested for associations between gradients in the NEOMAPs regions showing significant group differences and the calibrated severity total scores of the Autism Diagnostic Observation Schedule-2.

Results: For both groups, CMAP1 showed a superior-to-inferior pattern while CMAP2 ranged from anterior-to-posterior. However, significant group differences were found in CMAP1 (pFDR-corrected<0.05, Figure 1A, 1B), particularly in thalamic nuclei involved in visual (pulvinar), somatosensory (ventral lateral posterior nucleus), and auditory (medial geniculate nucleus) processing, as well as in 'gate control' of salient features (centromedian nucleus). No significant differences were observed in CMAP2 (Figure 1C). Analysis of NEOMAP1 (i.e., the neocortical projection of CMAP1), revealed a more compressed cortical gradient (i.e., reduced range) in autism (Figure 2A, 2B). This was evident in the right insula, superior temporal, and visual cortex (pRFT-clusterwise<0.05; Figure 2C). Network profiling indicated these differences were most pronounced in the visual, somatosensory, salience, and default mode networks (Figure 2D). Notably, among the regions showing significant group differences (autism<NT), the right insula, within the salience and somatomotor networks, showed a significant negative correlation with autism symptom severity (p<0.01 for vertex-wise threshold, pRFT-clusterwise<0.05 for significance); Figure 2E).

Conclusions: The present findings show that atypical thalamocortical connectivity involving part of the salience network may contribute to autism symptom severity. Given the role of thalamo-salience connectivity in differentiating externally- and internally-oriented networks, these findings suggest atypical segregation of these networks in autism.

437.102 The Developmental Trajectory of Autism from Preschool to Adulthood: Age-Dependent Shifts in Thalamic Glutamate-GABA Ratios

A. R. Thomson¹, V. Hollestein², P. Aggensteiner³, H. Roeyers⁴, T. Falck-Ytter⁵, E. Loth⁶, J. K. Buitelaar⁷, D. Murphy⁸, T. Arichi⁹ and N. A. Puts¹, (1)Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology & Neuroscience, King's College London, London, United Kingdom, (2)Cognitive Neuroscience, Donders Institute for Brain, Cognition and Behavior, Nijmegen, Netherlands, (3)Department of Child and Adolescent Psychiatry and Psychotherapy, Central Institute of Mental Health, Mannheim, Mannheim, Germany, (4)Department of Experimental-Clinical and Health Psychology, Ghent University, Ghent, Belgium, (5)Development and Neurodiversity Lab, Department of Psychology, Uppsala University, Uppsala, Sweden, (6)Department of Forensic and Neurodevelopmental Sciences, Flat 2, 116, South Hill Park, London, London, United Kingdom, (7)Department of Cognitive Neuroscience, Donders Institute for Brain, Cognition and Behaviour, Radboud University Nijmegen Medical Center, Nijmegen, NETHERLANDS, (8)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, UNITED KINGDOM, (9)Imaging Science & Biomedical Engineering, King's College London, London, United Kingdom

Background:

The excitation/inhibition (E/I) balance theory of autism proposes atypicalities in the balance between the activity of gamma aminobutyric acid (GABA) and glutamate, the brain's primary inhibitory and excitatory neurotransmitters, respectively. This shift in the activity state of neural systems may lead to differences in perception, cognition, and sensory function. Numerous lines of evidence - including genetics, preclinical research, and human investigations - support this theory. Magnetic Resonance Spectroscopy (MRS), a non-invasive MR technique, can be utilised to quantify the concentrations of GABA and glutamate in the human brain in vivo. While MRS has identified group differences in GABA and glutamate levels between autism and typical development (TD), this has predominantly been studied in adolescents and adults. Furthermore, the age trajectory of glutamate/GABA balance and its variations in autism remains largely unexplored, as well as sex differences. Gaining insight into E/I balance throughout development is crucial for pinpointing critical periods in E/I balance maturation, understanding the emergence of autism and for developing targeted support approaches.

Objectives:

To characterise thalamic GABA and glutamate concentrations in a large cohort spanning from 2-5 and 14-31 years of age, and associate these with age, sex and diagnosis (autism or TD).

Methods:

GABA and glutamate (Glx; the combined glutamate and glutamine) were quantified using PRESS and HERMES acquisitions on a thalamic voxel in two cohorts: preschool (74 participants; 24 autistic, 2-5 years of age) and adolescent/adult (141 participants; 90 autistic, 14 - 37 years of age; Table 1) from the AIMS-2-TRIALS PIP and LEAP studies. MRS data were processed using Osprey. GABA and Glx concentrations were quantified relative to creatine. Linear regression was used to explore if GABA, Glx and Glx:GABA ratios associate with sex, age and/or diagnosis, while controlling for site.

Results:

Thalamic Glx:GABA *ratios* significantly associated with age ($\beta_{\text{age}} = 0.13$, $p < 0.001$), and this further interacted with diagnosis ($\beta_{\text{diagnosis} \times \text{age}} = -0.06$, $p < 0.01$), and sex ($\beta_{\text{sex} \times \text{age}} = -0.06$, $p < 0.01$). Age-related shifts in E/I balance thus vary between autistic and TD cohorts, and across sexes. In TD males, TD females and autistic females, thalamic Glx:GABA increased throughout the developmental period studied (Figure 1). In autistic males, thalamic Glx:GABA was comparatively stable with age (Figure 1).

Conclusions:

Our findings support atypical E/I balance establishment in autism, with age, sex and diagnosis predicting Glx:GABA ratios from early childhood to adulthood. This study uniquely used a universal MRS approach across multiple sites (with identical acquisition and voxel parameters), in the largest MRS autism cohort to date. Furthermore, our work highlights the importance of looking at GABA and glutamate in relation to each other and exploring sex differences. While we did not observe direct age effects on GABA+ or Glx levels alone, existing research indicates that age-related changes in brain metabolites are pronounced during late childhood, a period not captured by the included cohorts. We plan to next explore how autism associated variations in Glx:GABA (E/I) balance associate with sensory processing differences, as these may serve as a tractable measure of E/I imbalances.

**437.103** The Neural Correlates of Sensory Overresponsivity in Adolescents with Autism Spectrum Disorder

S. H. Bolton¹ and S. E. Christ², (1)Department of Psychological Sciences, University of Missouri, Columbia, MO, (2)Psychological Sciences, University of Missouri, Columbia, MO

Background: Approximately 56-70% of youth with autism spectrum disorders (ASD) experience sensory over-responsivity (SOR), an extreme sensitivity to sensory stimuli, often paired with negative responses and avoidance of select sensory inputs. Functional magnetic resonance imaging (fMRI) evidence indicates that autistic individuals exhibit heightened activation in sensory cortices relative to their non-autistic peers, suggesting that neural hyperactivity may underlie SOR in this population (Jassim et al., 2021). Despite this, very little fMRI research has examined this hypothesis while differentiating between ASD youth with and without SOR.

Objectives: To this end, the present study aims to compare patterns of neural activation between youth with ASD and SOR (ASD_{SOR}), ASD and no sensory irregularities (ASD_{NS}), and non-ASD youth during sensory stimulation. We anticipate that ASD_{SOR} youth will exhibit greater activation in sensory regions of interest (ROIs) than ASD_{NS} and non-ASD.

Methods: A sample of 46 adolescents aged 11-15 (ASD_{SOR}: $n=17$, ASD_{NS}: $n=14$, non-ASD: $n=15$) were passively exposed to sensory stimulation (including visual and auditory) during fMRI. Visual stimuli were three flickering white-black circular checkboard wedges that rotated around a central fixation point and auditory stimuli were trains of complex tone bursts. Both sets of stimuli have been shown to elicit robust activation in sensory-related regions. Following preprocessing in SPM 12, whole brain BOLD responses were estimated separately for auditory and visual conditions. Subject-level beta weights for each condition were then extracted from a priori regions of interest (ROIs) for visual and auditory networks (Power et al., 2011) and entered into group-level analyses.

Results: A series of one-way ANOVA followed by contrast tests revealed statistically significant group differences in BOLD signal in two regions of the right visual association area (one posterior, one anterior) during the visual stimulation. In the anterior right visual association area, ASD_{SOR} exhibited greater activation than ASD_{NS} ($t[43]=2.84$, $p=.007$) while non-ASD participants exhibited greater activation than ASD_{SOR} ($t[43]=-2.19$, $p=.034$) in the posterior right visual association area. Significant group differences were also observed in the left primary auditory cortex and right superior temporal gyrus (rSTG) during auditory stimulation. In the left primary auditory cortex, ASD_{NS} participants exhibited increased activation relative to both ASD_{SOR} ($t[43]=-2.24$, $p=.03$) and non-ASD ($t[43]=2.50$, $p=.016$). In the rSTG, ASD_{NS} participants exhibited increased activation relative to non-ASD ($t[43]=2.32$, $p=.025$).

Conclusions: Only the anterior right visual association area demonstrated increased activation in ASD_{SOR} relative to ASD_{NS} while no SOR-linked hyperactivity was seen in auditory regions. Contrary to expectations, the ASD_{SOR} group exhibited decreased activation in the left primary auditory cortex relative to ASD_{NS}. In the posterior right visual association area, ASD_{SOR} participants demonstrated decreased activation relative to non-ASD participants. Taken together, these results provide partial support for the hypothesis that hyperactivity in relevant sensory cortices underlies SOR in ASD; however, the neural mechanisms of this condition may be more complex than previously thought. Although these results are preliminary, they highlight the need for further investigation into the complex brain-behavior relationship associated with SOR in autistic youth.

437.104 The Relationship between Voice Processing and Reading Ability in Young Children with Autism Spectrum Disorder

Y. Yoshimura¹, S. Tanaka² and M. Kikuchi³, (1)Research Center for Child Mental Development, Kanazawa University, Kanazawa, Japan, (2)Research Center for Child Mental Development, Kanazawa University, Kanazawa, Japan, (3)Department of Psychiatry and Neurobiology, Kanazawa University, Ishikawa, Japan

Background: Autism Spectrum Disorder (ASD) often draws attention for its behavioral and social challenges, but learning difficulties due to the co-occurrence of developmental dyslexia have also been pointed out (Nation K et al., 2006). Research on the neural basis of developmental dyslexia has shown that children aged 8 to 12 with reading difficulties exhibit reduced lateralization of brain responses to auditory stimuli (Johnson et al., 2013). In at-risk children, atypical responses to phonological stimuli at 6 and 12 months of age have been observed, suggesting that such atypical brain activity could serve as an early marker of reading difficulties (Kuhl et al., 2022). However, the neural basis and early characteristics of children with both ASD and reading difficulties remain unclear.

Objectives: The purpose of this study is to conduct a longitudinal survey of children with Autism Spectrum Disorder (ASD) before and after school entry to examine whether early physiological data related to central processing of auditory information can serve as a predictive indicator of their literacy abilities during school age.

Methods:

Twenty children with Autism Spectrum Disorder (ASD) (15 boys, 5 girls), with an initial mean age of 72 ± 15.7 months and a follow-up mean age of 136 ± 25.2 months, participated in this study. ASD was assessed using the Diagnostic Interview for Social and Communication Disorders (DISCO) and the Autism Diagnostic Observation Schedule (ADOS).

At the time of the initial participation, cortical brain responses to two types of "ne" utterances (one with a flat intonation and one with an expressive intonation) were measured using magnetoencephalography (MEG) designed for infants. In this study, auditory-evoked responses (P1m) triggered by the more frequently presented flat-intonation "ne" were detected from both hemispheres using the dipole estimation method.

At the follow-up assessment, the K-ABC II was administered, and the scores for "word reading" and "word writing" were used as behavioral indicators of literacy skills. Multiple regression analysis was conducted to examine the relationship between P1m responses and literacy abilities, using P1m amplitude and latency from both hemispheres as dependent variables. The independent variables included the initial participation age, follow-up age, and the evaluation scores for word reading and word writing.

Results:

The results of the multiple regression analysis, with the P1m latency in the left hemisphere as the dependent variable, suggested a significant negative correlation with the word reading score. No significant correlations were found with age at initial participation, age at follow-up, or the writing scale.

Conclusions: As a result of this study, the latency speed of brain responses (P1m) to human voices before school entry was found to be particularly associated with higher word reading abilities later on. These findings are consistent with several previous studies that reported phonological responses as predictors of future literacy abilities, supporting the theory that phonological processing deficits are a causal factor in dyslexia. It is suggested that children with ASD who experience reading difficulties may have underdeveloped brain regions involved in phonological processing from an early stage.

437.105 The Role of the Ventromedial Prefrontal Cortex in Neural Mechanisms Linking Autistic Traits to Alexithymia

Q. Xie¹, N. Pan¹, Z. Wang², L. Lin³, X. Weng¹ and X. Wang¹, (1)Key Laboratory of Brain, Cognition and Education Sciences, Ministry of Education; Institute for Brain Research and Rehabilitation, and Guangdong Key Laboratory of Mental Health and Cognitive Science, South China Normal University, Guangzhou, Guangdong, China, (2)Key Laboratory for Quality of Life and Psychological Assessment and Intervention, Research Center for Quality of Life and Applied Psychology, School of Humanities and Management, Guangdong Medical University, Dongguan, Guangdong, China, (3)Department of Occupational and Environmental Health, School of Public Health, Sun Yat-sen University, Guangzhou, Guangdong, China

Background: Autistic traits are distributed along a continuum within the general population and are associated with an increased risk of alexithymia. Previous research attributed the difficulties in emotion processing observed in autistic individuals to the presence of alexithymia. Nevertheless, the neural mechanisms linking autistic traits to alexithymia are undetermined. One potential explanation of this relationship is the underactivation of the ventromedial prefrontal cortex (vmPFC), which is associated with impaired affective Theory of Mind (ToM) abilities. However, the specific function of vmPFC in the relationship between autistic traits and alexithymia remains unclear.

Objectives: This study aimed to reveal the vmPFC-based neural mechanisms underlying the relationship between autistic traits and alexithymia, including its subscales.

Methods: A total of 73 neurotypical Chinese college students (51 females, age = 21.86 ± 2.32 years) completed a survey measuring autistic traits (Autism Quotient, AQ) and alexithymia (Toronto Alexithymia Scale-20, TAS-20). Brain functional images were obtained by resting-state functional magnetic resonance imaging (rs-fMRI). We conducted a Pearson correlation analysis between TAS-20 scores and whole-brain functional connectivity (FC) seeded in the vmPFC (Schmälzle et al., 2017), controlling for sex, age, and head motion (GRF corrected: cluster $p < 0.05$, voxel $p < 0.005$). The correlation between the significant FC and autistic traits was also examined. Mediation analyses accounting for the same covariates were conducted to investigate whether the significant vmPFC-based FC mediated the relationship between autistic traits and alexithymia and its subscales.

Results: Higher AQ scores significantly correlated with greater TAS-20 scores ($r = 0.563$, $p < 0.001$). Furthermore, a significant negative relationship was observed between TAS-20 scores and the FC of the vmPFC and bilateral putamen (left: $r = -0.433$, $p < 0.001$; right: $r = -0.413$, $p < 0.001$). These FC also negatively correlated to autistic traits (left: $r = -0.310$, $p < 0.001$; right: $r = -0.309$, $p < 0.001$) and mediated the effect of autistic traits on alexithymia (left: $\beta = 0.101$, 95%CI: 0.018 – 0.200, right: $\beta = 0.086$, 95%CI: 0.008 – 0.166, indirect effect) and its subscales. Specifically, the vmPFC-left putamen connectivity mediated the relationships between autistic traits and both difficulty identifying feelings (DIF, $\beta = 0.114$, 95%CI: 0.027 – 0.224) and difficulty describing feelings (DDF, $\beta = 0.070$, 95%CI: 0.004 – 0.154), but no mediation was found for externally oriented thinking (EOT, $\beta = 0.033$, 95%CI: -0.049 – 0.147). In contrast, the vmPFC-right putamen connectivity mediated the relationship between autistic traits and DIF only ($\beta = 0.097$, 95%CI: 0.019 – 0.185), with no significant mediation effects for DDF ($\beta = 0.055$, 95%CI: -0.034 – 0.126) or EOT ($\beta = 0.035$, 95%CI: -0.054 – 0.134).

Conclusions: Our findings indicated that the vmPFC-putamen connectivity mediated the relationship between autistic traits and alexithymia. Notably, the pathways mediating this relationship may differ across the dimensions of alexithymia, particularly in affective dimensions. Our findings contribute to the concept of neurodiversity by emphasizing that autistic traits exist on a continuum and may also result in alexithymia, thereby promoting understanding and mitigating social discrimination against autistic individuals.

437.106 Theta-Burst Stimulation over the Right Cerebellum Could Modulate Default Mode Network Connectivity in Autistic Adults

H. C. Ni¹ and H. Y. Lin², (1)Psychiatry, Chang Gung Memorial Hospital, Taoyuan, Taiwan, (2)Centre for Addiction and Mental Health, Toronto, ON, Canada

Background:

Recent studies have demonstrated that the lateral cerebellum, especially Crus I/II, is associated with social functions, language and emotion and thus may serve as a potential target in alleviating autistic symptoms. The reduction of cerebellar Purkinje cells in autistic people leads to impaired inhibitory function and causes excitation/inhibition imbalance in the brain. This imbalance alters functional connectivity between the cerebellum and other brain regions, especially the default mode network (DMN) in autistic people. Despite these facts, no study has investigated the effect of repetitive transcranial magnetic stimulation (rTMS) on the lateral cerebellum in autistic people.

Objectives:

Our study aimed to explore the safety, feasibility and impacts of theta burst stimulation (TBS, a modified form of rTMS) applied to the right Crus I/II (lateral cerebellum) on intrinsic brain functional connectivity in autistic adults.

Methods:

In this open-label trial, we enrolled ten intellectually able autistic adults (7 males and 3 females, assigned sex at birth, aged 18- 29 years). Participants underwent a single session of neuro-navigated intermittent TBS (iTBS; 600 x 2 pulses spaced with a 15-minute interval at 80% of the active motor threshold) over the right Crus I/II. The right Crus I/II was individually localized using resting-state functional MRI. Resting-state functional MRI scans were scheduled before and immediately after the TBS intervention.

Results:

All of the autistic adults could tolerate a single iTBS session over the right Crus I/II without severe adverse events. The retention rate is 100%. We found intrinsic functional connectivity within the default mode network and somatosensory motor network significantly decreased post-iTBS 1200, while other networks remained unchanged. Moreover, our exploratory analysis showed the inter-individual variability (idiosyncrasy) post-TBS over the ventral attention, frontoparietal, default mode network and visual networks significantly decreased.

Conclusions:

Our pilot study demonstrated the safety and feasibility of applying iTBS over the lateral cerebellum in autistic adults. Moreover, we found that iTBS could modulate several functional networks in autistic adults. Our findings provide the pilot data for a neuroscience-informed, larger-scale, randomized controlled trial in the future.

437.107 Towards a Brain-Based Biomarker of Social Attention: Altered Cortical Hemodynamics in Temporal Regions in Toddlers with Autism

A. Vernetti¹, P. G. Srinivasan², G. K. Bell², S. Macari¹ and K. Chawarska¹, (1)Child Study Center, Yale University School of Medicine, New Haven, CT, (2)Child Study Center, Yale Child Study Center, Yale School of Medicine, New Haven, CT

Background: Diminished attention to the faces of social partners represents one of the earliest measurable *behavioral* markers of autism (AUT). This decreased attention is most pronounced when children observe a person using child-directed-speech and eye contact. Over the past two decades, neuroimaging studies using fMRI or fNIRS have been conducted to identify *brain-based* biomarkers of autism. Amongst the brain regions implicated in autism are bilateral superior temporal regions typically involved in audio visual processing of social cues. However, the practical difficulties to conduct task-based rather than resting-state neuroimaging studies with young children have led to a knowledge gap in the imaging literature during toddlerhood.

Objectives: 1) Assess the feasibility of task-based cortical activation studies using fNIRS with toddlers with and without autism. 2) Examine activation in bilateral superior temporal gyrus (STG) in response to ostensive cues comprising child-directed-speech and direct gaze. 3) Investigate associations between temporal cortical hemodynamics to social cues and 3a) social attention to a speaking face, 3b) social autism symptoms and 3c) receptive language (RL) skills.

Methods: 47 toddlers with autism and typically developing (TYP) toddlers (Mage=22.5, SD=4) took part in both fNIRS (full-head coverage NIRS NIRSport2 device) and screen-based eye-tracking (SR-Eyelink) studies during which videos of an actress using speech (SP) and/or eye contact (EC) were displayed. Feasibility measures: participants retention after exclusions due to capping, inattention, and signal quality. Hemodynamics measures: difference (Hb_diff) between oxy-hemoglobin (Hbo) and deoxy-hemoglobin (Hbr) in response to speech and gaze cues in both left and right STG. Phenotypic measures: looking time to the face in the speech and gaze condition (%Face), the ADOS-2 Social-Affect scores and the MSEL RL.

Results: 1) *Feasibility:* The retention rates were 76% (n=37) of TD and 65% (n=11) of AUT groups, and the rates did not differ by group, ($\chi^2(64)=0.12, p=0.725$). 2) *Hemodynamics:* in the left STG, TD toddlers exhibited increased hemodynamic response in conditions involving speech and reduced hemodynamic response in conditions without speech. In contrast, toddlers with AUT, left STG activity was negligible across all conditions. Regarding the right STG, TD toddlers showed a similar pattern of response (although reduced) as in the left hemisphere, but AUT toddlers exhibited increased response to conditions with speech and gaze cues. 3) *Associations with phenotypic features:* There were significant associations between Hb_diff in the left STG in the speech-and-gaze condition and %Face ($r(44)=.29, p=.048$), ADOS-2 Social-Affect ($r(43)=-.32, p=.033$) and MSEL-RL ($r(42)=.32, p=.034$). No associations were found with the right STG region ($p>.223$) (Figure1).

Conclusions: Toddlers with autism and TYP controls tolerated the fNIRS procedure well. Toddlers with autism display bilaterally atypical cortical activation in the STG in response to dynamic social engagement cues. In the left hemisphere, they fail to activate the STG to speech or gaze cues, and in the right hemisphere, they show lower discrimination between speech and gaze cues than controls. In the combined sample, cortical activity in the left STG predicts social and language functioning. The fNIRS-based indices of responsivity to speech and gaze may constitute a promising candidate biomarker for social and language vulnerabilities in toddlers.

437.108 Transcranial Magnetic Stimulation Lowers Neural Activity Linked to Sensory over-Responsivity in Autistic Adults

A. Than¹, A. Kadambi², M. E. Cakar³, M. Banchik², A. Chaturvedi¹, U. Shah¹, E. Wood², M. Dapretto⁶, M. Iacoboni² and S. A. Green⁷,

(1)Interdepartmental Neuroscience PhD Program, UCLA, Los Angeles, CA, (2)University of California, Los Angeles, Los Angeles, CA,

(3)Interdepartmental Neuroscience Program, UCLA, Los Angeles, CA, (4)Psychiatry and Behavioral Sciences, UCLA - Semel Institute, Los

Angeles, CA, (5)UCLA, Los Angeles, CA, (6)Department of Psychiatry and Biobehavioral Sciences, University of California Los Angeles, Los

Angeles, CA, (7)Dept of Psychiatry and Biobehavioral Sciences, UCLA, Los Angeles, CA

Background: Sensory over-responsivity (SOR) refers to an exaggerated, aversive response to sensory stimuli, often associated with Autism Spectrum Disorder (ASD), and can disrupt daily life and communication (Carter et al., 2017). Neuroimaging studies have shown that individuals with severe SOR display heightened sensory region activity and difficulty adjusting to repeated stimuli, especially when multiple senses are engaged (Green et al., 2015, 2019). Despite the prevalence of SOR, no effective treatments exist (Yuan et al., 2022). Intermittent Theta-Burst Stimulation (iTBS), a type of non-invasive transcranial magnetic stimulation, targeted to the prefrontal cortex (PFC) induces long-lasting facilitatory effects on cortical excitability (Huang et al., 2007; Huang et al., 2005) and is already being used to treat depression (Somani et al., 2019). However, iTBS targeting non-sensory ASD-related symptoms shows inconsistent results (Oberman et al., 2015). Given that the PFC is involved in sensory regulation (e.g., Cakar et al., 2023; Green et al., 2019), stimulating the PFC with iTBS may improve SOR, and demonstrating the specific effects on sensory responses across SOR severity levels is crucial.

Objectives: This study aims to examine how brain activity changes after iTBS is delivered to the PFC and whether SOR severity predicts these changes in adults with ASD.

Methods: The study included 24 adults with ASD (ages 18-31) who self-reported SOR severity using the Sensory Processing 3-Dimensions (SP3-D) Inventory (Miller et al., 2017). Participants underwent an fMRI task at baseline and again one month later, immediately after iTBS was administered to the left dorsolateral prefrontal cortex (DLPFC). The iTBS was delivered using a Magstim Rapid 2 device with a Figure 8, 70mm coil at 80% of motor threshold intensity, consisting of 600 pulses in a 20 two-second on/8-second off cycle. The fMRI task involved six blocks each of alternating mildly aversive Auditory+Tactile and Visual+Tactile stimuli, with tactile stimulation from a scratchy glove, auditory stimulation via pink noise, and visual stimulation from a rotating color wheel. Brain activity changes pre- and post-iTBS were analyzed using FSL, and correlations between SOR severity and brain changes were explored, with statistical thresholds set at $Z>2.3$ and corrected for multiple comparisons at $p<.05$.

Results: After iTBS, brain activity decreased in primary sensory areas, including the auditory cortex and postcentral gyrus, during the Auditory+Tactile task (Figure 1A, top). Similarly, during the Visual+Tactile task, activity reductions were observed in sensory-processing areas, such as the visual cortex and insula (Figure 1A, bottom). Notably, greater SOR severity correlated with more enhanced reductions in activity in sensorimotor cortices, insula, and limbic regions (Figure 1B).

Conclusions: iTBS to the left DLPFC reduced atypical brain responses to mildly aversive stimuli in autistic adults with SOR. Participants with more severe SOR showed greater changes in sensory and limbic brain regions. These findings suggest that excitatory stimulation of the PFC may help regulate sensory processing in ASD, particularly for those with more severe SOR, positioning it as a potential non-invasive treatment for sensory processing challenges in ASD.

437.109 Unraveling Language Development Trajectories in Autism Spectrum Disorder: Electrophysiological Evidence

K. Latreche¹, M. Godel¹, F. Journal¹, V. Borghesani² and M. Schaer¹, (1)Department of Psychiatry, University of Geneva, Geneva, Geneva, Switzerland, (2)Department of Psychology, University of Geneva, Geneva, Geneva, Switzerland

Background:

Language difficulties are frequent in autism spectrum disorder (ASD) and significantly impact functioning. Autistic individuals can be classified into three language profiles: unimpaired (LU), impaired (LI), and minimally verbal (MV). In previous work, we identified these three profiles in autistic preschoolers and characterized each profile's trajectory and moderators. Building on these findings, the present study examines the associations between the language profiles and resting-state EEG (RS-EEG) power in autistic preschoolers and typically developing (TD) peers. Previous RS-EEG studies reported increased gamma and reduced alpha power in autistic children and adults. In preschoolers with ASD, increased frontal gamma power (FGP) was associated with language difficulties, emerging as a potential marker for language heterogeneity. However, no longitudinal study has focused on RS-EEG power to predict and characterize language development across the specific autistic profiles.

Objectives:

1. To investigate longitudinal trajectories of frontal alpha and gamma power in preschoolers with ASD compared to their TD peers.
2. To explore the association between FGP and language profiles in autistic children younger and older than 4 years, when global stability in language skills is typically

Methods:

Preschoolers with ASD and TD were recruited from an ongoing longitudinal cohort that includes RS-EEG recordings while quietly watching a cartoon. RS-EEG recordings were collected using a high-density EEG cap, yielding a robust dataset of 395 RS-EEG recordings from 126 children with ASD and 67 TD (age range: 1.3-7.6 years). A longitudinal subsample of 53 children with ASD and 42 TD (age range: 1.7-6.3 years), resulting in 155 RS-EEG recordings, has been analyzed. The language profiles of the 53 autistic children were: LU (N=32), LI (N=14), and MV (N=7). Due to the small MV sample, they were grouped with the language impaired. Signal oscillations were decomposed in canonical frequency bands: delta (1-4 Hz), theta (4-8 Hz), alpha (8-12 Hz), beta (12-30 Hz), and gamma (30-40 Hz). The average summed power for each frequency band was computed and normalized using a log base 10 transform.

Results:

Mixed-model analyses of frontal alpha and gamma power trajectories showed no significant differences between ASD and TD groups ($p > 0.05$). For children under 4 years, no significant differences in FGP were found among autistic children with or without language impairment, and TD peers. However, in children aged 4 and older, autistic children with impaired language exhibited increased FGP ($p = 0.035$) compared to TD children (Figure 1).

Conclusions:

Contrasting with previous studies, we did not find differences in frontal gamma and alpha activity between younger autistic and TD children. However, increased FGP was specifically associated with language impairments in autistic preschoolers older than 4 years, suggesting that FGP may vary as language profiles stabilize. We are currently investigating gamma and alpha power in a larger dataset and whether increased FGP could serve as an early marker of language impairment in ASD. These investigations hold promise for improving our understanding of the neural mechanisms underlying language trajectories in young autistic children and paving the way for personalized interventions.

**437.110** Unraveling Toddlers' Social-Emotionality and Language Interaction with Brain Network Controllability at Birth

H. Sun¹ and D. Scheinost², (1)Yale University, New Haven, CT, (2)Radiology & Biomedical Imaging, Yale University School of Medicine, New Haven, CT

Background: In infants and toddlers, language and social-emotional outcomes are intertwined. For example, “late-talking” toddlers tend to lag in social-emotional development, and children with social-emotional impairments tend to engage less in peer conversations. However, little is known about how white matter development at birth supports this intertwined relationship between language and social-emotionality development.

Objectives: This study uses edge-centric network control theory and connectome-based predictive modeling to predict social-emotional and language development outcomes at 18 months from diffusion-weighted images collected at birth. We further investigate the role of the brain network at birth involved in the development of the intertwined social-emotional and language outcomes.

Methods: First, we constructed structural connectomes (a comprehensive map of white matter connections) using standard methods and quantified the edge controllability for 348 infants from the developing Human Connectome Project (dHCP). Edge controllability measures the contribution of each white-matter connectome within the brain structural network to drive system-level brain state transitions. Next, we used connectome-based modeling (a validated machine learning approach for connectome data) with 10-fold validation to predict social-emotional and language development. The Quantitative Checklist for Autism in Toddlers (Q-CHAT) assessed social-emotional development. The Bayley Scales of Infant and Toddler Development (BSID-III) assessed language skills. Finally, we tested how each network predicted the other measures (i.e., we used the SEN to predict language scores and vice versa) and if controllability at birth mediated the associations between social-emotional and language development at birth.

Results: CPM significantly predicted Q-CHAT scores ($r=0.22$, $p<0.001$; $MAE=6.91$) and BSID-III language scores ($r=0.21$, $p<0.001$; $MAE=3.95$). 275 edges comprised the predictive model for Q-CHAT--labeled social-emotional network (SEN), which mainly connected between the visual network and the somatosensory network. 344 edges involved in predicting language scores--labeled language network (LAN), concentrating between the visual network and the dorsal attentional network. 109 edges were common between SEN and LAN, connecting between the visual network and other networks including dorsal attention, default mode and subcortical networks. The edge average controllability in SEN inversely predicted the language scores ($r=-0.30$, $p<0.001$). Similarly, edge average controllability in LAN inversely predicted the Q-CHAT ($r=-0.25$, $p<0.001$). These predictions were inversely correlated with the correlations between BSID-III language and Q-CHAT scores ($r=-0.56$, $p<0.001$). Using a bootstrapped mediation analysis, the edge average controllability in SEN partially mediated the association between BSID-III language and the Q-CHAT scores ($r=-0.13$, $p<0.001$).

Conclusions: Our study leveraged the advances in network control theory to understand how early white matter structure supports future social-emotional and language development. Our findings show that controllability at birth predicts key 18-month outcomes. Additionally, networks for social-emotional and language development cross-predict outcomes. Finally, networks mediate later behavioral associations at 18-months. Together, these results suggest that the overlapping network in early life supports social-emotional and language development. These networks may open opportunities to design individualized interventions to promote optimal outcomes in those with developmental delays.

437.111 18-Kda Translocator Protein Signaling and Reward Circuitry Functioning in Autism Spectrum Disorder

K. K. Cummings¹, E. Walsh², D. Lalush³, R. Phillips³, M. Wilder³, A. Deshpande³, N. Maheshwari³ and G. S. Dichter¹, (1)The University of North Carolina at Chapel Hill, Chapel Hill, NC, (2)Psychiatry, University of North Carolina, Chapel Hill, NC, (3)UNC Chapel Hill, Chapel Hill, NC, (4)Department of Psychiatry, School of Medicine, University of North Carolina, Chapel Hill, NC

Background: The Social Motivation Hypothesis of Autism highlights disruptions in brain systems that process rewards as a factor that contributes to autism pathophysiology. In autism spectrum disorder (ASD), impaired social communication is associated with elevated inflammatory profiles^{1,2} and atypical neural responses to social reward³, leading to theories hypothesizing that immune dysfunction is an underlying mechanism of social impairments and ASD etiology⁴. However, our understanding of the mechanism underlying this potential relationship is still limited, and would provide insight into the development of treatments targeting inflammatory processes.

Objectives: To assess 18-kDa translocator protein (TSPO) expression from young adults with ASD to examine its impact on neural response to reward and ASD symptom severity.

Methods: Participants included 10 autistic and 6 typically-developing adults (ages 18-40). All participants completed a 90-minute simultaneous positron emission tomography magnetic resonance (PET-MR) scan using the radioligand [¹⁸F]PBR111 to assess TSPO expression, an index of immune functioning. During this scan, participants also completed a monetary incentive delay task⁵ to assess fMRI responses during reward anticipation and receipt. Areas related to reward processing and immune functioning were selected as regions of interest (ROIs). To examine regional group differences in TSPO radiotracer binding, a series of linear regressions were conducted in R. BP_{ND} in each ROI was used as the outcome variable so that contributions of diagnostic group could be assessed while controlling for age, BMI, and TSPO genotype.^{6,7} To determine the unique contribution of TSPO expression on ASD symptom severity, each ROI was first assessed using stepwise selection linear regression models to determine covariates that should be included in the model. The residuals from each of these models were then used as predictors in separate linear regressions to examine how TSPO expression in each ROI contributes to ASD symptom severity (SRS Total T-scores). Finally, we assessed fMRI responses during reward processing as a mediator of the relationship between TSPO expression and ASD symptoms (SRS scores) using the R “Lavaan” package⁸ to estimate the strength of the indirect and total effects.

Results: There were no differences between the ASD and comparison groups in TSPO expression. However, TSPO expression in several brain regions related to ASD symptom severity. TSPO expression in the precuneus (after controlling for BMI) was significantly positively related to SRS scores for autistic adults after FDR correction ($p=0.04$), while TSPO expression in the orbitofrontal cortex was negatively related to ASD symptom severity ($p=0.04$). fMRI responses to rewards in all ROIs did not significantly mediate the relationship between TSPO expression and ASD symptom severity.

Conclusions: This study contributes to our understanding of the complicated role of immune functioning in social symptoms in ASD. Although we did not observe statistically significant differences in regional TSPO expression, there were significant relationships between TSPO expression and ASD symptom severity. This provides further evidence that immune functioning is a contributing factor to ASD symptom severity, providing opportunities for future research to use inflammation as a treatment outcome variable or target in translational research to improve the quality of life of autistic individuals.

437.112 Visuospatial Attention Differences during Speech-in-Noise Perception Among Children with ADHD or Autism

N. Dinesha¹, S. Mehta², Z. Brown³, R. A. Rivera⁴ and E. J. Knight⁴, (1)Developmental and Behavioral Pediatrics, University of Rochester Medical Center, Rochester, NY, (2)University of Rochester, Rochester, NY, (3)Brain and Cognitive Sciences, University of Rochester, Rochester, NY, (4)Psychology, University of Rochester, Rochester, NY

Background:

Many children with autism spectrum disorder (ASD) or attention deficit hyperactivity disorder (ADHD) have difficulty distinguishing speech in the setting of noise. This can impact learning and community participation. Prior work has implicated audiovisual integration of lip movements with speech sounds as a potential underlying mechanism, but the impact of deficits in spatial attention are important, often overlooked, confounders. Disambiguating the respective contributions of these two mechanisms to speech-in-noise perception difficulties in ADHD and ASD is a critical step in the design of mechanism-tailored supports or interventions.

Objectives:

We aimed to evaluate patterns of audiovisual integration and allocation of visuospatial attention during speech-in-noise processing among school-age children with ADHD, ASD, and TD.

Methods:

We recruited 7–12-year-old children with ADHD (n=33, Males-22/Females-11), ASD (n=22 Males-17/Females-5), and TD (n=28, Males-13/Females-15) to participate in an integrated virtual reality and electrophysiologic (EEG) speech-in-noise perception paradigm. In virtual reality, children were asked to press a button whenever a centrally-located target character spoke a target monosyllabic word, while ignoring any words spoken by two flanking distractor characters. We manipulated 1) AV content by intermixing trials containing either audio (speech sounds only), visual (lip movements only) or audiovisual (AV) representations of the three characters and 2) spatial attention demands by including trials with and without interference from the distracting speakers (See Figure 1). We measured audiovisual (AV) gain in target detection accuracy ($AV\text{ gain} = \text{Accuracy}_{AV} - \text{Accuracy}_{Audio}$). Simultaneously, steady-state visual evoked potentials (SSVEP) were continuously recorded via a 128-channel electrode array as an index of visuospatial attention allocation to each of the speakers. To elicit SSVEP, the target and distractor speakers were tagged with different visual frequency oscillations (23Hz and 15Hz, respectively). EEG signal-to-noise ratios (SNR) in the corresponding first and second harmonics for those frequency bands were measured over occipital scalp. These behavioral and EEG measures were compared between groups using mixed design analysis of variance with age as a continuous covariate and relevant post-hoc comparisons.

Results:

Children with ADHD showed reduced AV gain relative to TD controls (ADHD: $d'_{AV-Audio} = .096 \pm .078$; TD: $d'_{AV-Audio} = .502 \pm .129$, $p = 0.008$; Figure 2A,B). Children with ASD had a less pronounced reduction in AV gain relative to TD controls that did not reach significance (ASD: $d'_{AV-Audio} = 0.276 \pm .196$; TD: $d'_{AV-Audio} = .502 \pm .129$, $p = 0.180$; Figure 2A,C). TD controls also demonstrated more robust SSVEP at 23Hz and 46Hz (target speaker) than the children with developmental disabilities. Children with ADHD or ASD showed reduced selective activation in response to the target and more equivalent allocation of visuospatial attention between 23Hz target and 15Hz distractor frequencies (ADHD: $SNR_{23Hz} = 1.448 \pm .325$, $SNR_{15Hz} = 1.402 \pm .372$; ASD: $SNR_{23Hz} = .726 \pm .321$, $SNR_{15Hz} = 0.404 \pm .233$; TD: $SNR_{23Hz} = 2.993 \pm .513$, $SNR_{15Hz} = 1.738 \pm .421$; Frequency x Group interaction $F(6,237) = 5.034$, $p = .00009$; Figure 2D-F). Values reported are mean $\pm$ standard error of the mean.

Conclusions:

Children with either ADHD or ASD demonstrate a reduction in the typical perceptual benefit afforded by exposure to multisensory (AV) vs. unisensory speech stimuli, accompanied by substantial difference in allocation of visuospatial attention to the relevant speaker. Thus, dysregulation of selective visuospatial attention may impact their ability to effectively perceive language in noisy settings.

**437.113** Communication Impairment in ASD Linked to Glutamate Imbalance in N-Acetyl-Aspartyl Glutamate and Glutathione Metabolism.

C. D. Jimenez-Espinoza, Physiology, La Laguna University, Santa Cruz de Tenerife, Spain

Background: Autism spectrum disorder (ASD) shows abnormalities in cognitive, affective and sensorimotor processing, with clinical manifestations commonly associated with frontal lobe lesions represented by Brodmann cortical areas and white matter tracts (Genu, arcuate fasciculus, uncinate, cingulate). Difficulty developing language and communication skills in ASD is a hallmark and although there are subtle differences between language and communication, it cannot be denied that they are linked. According to Rosselli, Ardila and Bernal (2015), one of the networks involved includes both the anterior cingulate gyrus (involved in motor organization: motor preparation/planning, cognitive/motor inhibition and language initiative) and BA6 (middle frontal gyrus), suggesting the involvement of the insula in a brain circuit that controls verbal initiative and maintenance of speech production. Here arises the hypothesis of glutamate imbalance affecting the cingulate cortices and its relationship with the metabolism of glutathione (GSH) and N-acetylaspartylglutamate (NAAG) as a cause of communication disorders in ASD.

Objectives: To understand and interpret how glutamate is involved in synthesizing NAAG and GSH as responsible for activating the brain areas involved in the language process through the networks formed by the cingulate gyrus in ASD. To study the correlation of GSH/Glu and NAA+NAAG/Glu ratios, with the “communication” in Autism Quotient (AQ) test for adults and using magnetic resonance spectroscopy (1H-MRS).

Methods: We quantified (NAA+NAAG), Glu, and GSH signals in anterior (ACC) and posterior (PCC) cingulated cortices separately from the 1H-MRS assessed in 19 patients with ASD and 42 healthy comparison subjects, matched for age, on a 3.0 Tesla MR scanner. We used the ‘Communication’ subscale of the Autism Spectrum Quotient (Baron-Cohen et al., 2001) Statistic one-way ANOVA and Bonferroni correction were applied. Pearson correlation hallmarks the goal.

Results: Pearson correlation plotted for ASD group shows negative correlation between AQ domain ‘Communication’ and (NAA+NAAG)/Glu ratio ($r = -0.1184$; $p = 0.9069$) in ACC, and GSH/Glu ratio shows negative correlation ($r = -0.2272$; $p = 0.8224$) in PCC; whereas TD group showed that communication is positively correlated with both (NAA+NAAG)/Glu and GSH/Glu ratios in both cingulated cortices (see Table 1; Figure 1). When comparing the correlation pattern of [(NAA+NAAG)/Glu] and [GSH/Glu] ratios with ‘Communication’ in AQ2, AQ3, and AQ4, an aberrant pattern of correlation was observed in the AQ2, AQ3, and AQ4 groups; indicating that they are related to glutamate for both (NAA+NAAG) and GSH in both cingulate cortices (see Table 2; Figure 2a, b). These results suggest the relation of the local overconnectivity within the language network and global underconnectivity of language with regions outside the network in ASD per that described by (Larson, C., et al. (2023).

Conclusions: Studying the interrelations between language and social communication in ASD may further clarify the correlation patterns reported here by providing evidence on the processes involved in the acquisition of communication skills. The ability to measure and monitor glutamate concentration in the cingulate cortices creates a promising new approach to intensify research on the effects of new drug candidates in ASD.

437.114 Exploring the Impacts of Methodological Choices on Frontal Alpha Asymmetry Electroencephalography Research in Autism

J. Osborne¹, E. F. Soto², X. Chen¹, M. Shuter¹, A. León Lúa¹, D. Lynch¹ and N. Russo¹, (1)Department of Psychology, Syracuse University, Syracuse, NY, (2)Louisiana State University, Baton Rouge, LA

Background: Autism, while increasing in prevalence, is still a relatively rare diagnosis. Therefore, EEG research with this population is relatively scarce, samples are small, and replications are uncommon. Resting state frontal alpha asymmetry (FAA) has been suggested as a potential biomarker for autism, as it has been related to cortical development and research has indicated a relationship between patterns for FAA and certain autism characteristics, such as social deficits, visual analytic skills, sensory hyporesponsivity, and sensory seeking behaviors. However, research has been less conclusive when comparing neurotypical and autistic individuals, or their respective siblings, with some research indicating greater left FAA in neurotypical individuals and their siblings and others suggesting greater right FAA. Some potential methodological reasons for this inconsistency are differences across studies in data preprocessing pipelines. While these methodological choices are theorized to influence the final cleaned dataset, few studies have investigated the extent to which these decisions impact researcher interpretations. Thus, investigating how the methodological differences within EEG preprocessing and analysis pipelines ultimately impact the final dataset and interpretations within a sample of autistic and neurotypical children, could provide valuable insight into why the field of autism EEG research continues to have difficulties establishing consistent findings.

Objectives: The present study assesses the impact of preprocessing methodologies, electrode selection, and alpha band frequency range definition on the finalized data and interpretations for a dataset comparing FAA between autistic and neurotypical children and adolescents matched on age and nonverbal IQ.

Methods: Eyes open and eyes closed resting-state EEG data was collected from 56 age- and IQ-matched autistic (n=28) and neurotypical (n=28) children and adolescents. These datasets will be cleaned using 3 different preprocessing pipeline guidelines popular within EEG research, for 4 different electrode groupings used within FAA research, and 2 different definitions of the alpha frequency band, resulting in 24 cleaned datasets for both conditions (eyes open and eyes closed).

Results: Determinations regarding the null hypothesis for each of the 24 cleaned datasets across conditions will be made using a 95% high density interval + region of practical equivalence Bayesian approach. The percent of agreement with regards to hypothesis decision will then be examined under both the eyes open and eyes closed conditions to investigate how robust the findings are across methodological selection. Furthermore, Bayesian regression analyses will be implemented to investigate which factor (preprocessing pipeline, electrode grouping, alpha frequency range) appears to most greatly impact the robustness of findings.

Conclusions: Current EEG research within autism lacks standardization with regards to preprocessing and analytic methodologies. Due to the infrequency of replicated studies, there is the potential for non-robust findings to gain traction within autism EEG research if results are only shown with one preprocessing and analytic pipeline. Thus, investigating the extent to which methodological choices have on ultimate data interpretations is critical for garnering greater insight into why consistent findings have been difficult to establish within the field of autism EEG research.

437.115 Multimodal Imaging in Autistic Adolescents and Adults - Biomarker Readiness - Reproducibility

T. Roberts¹, L. Blaskey¹, L. Bloy¹, M. Melch¹, M. Saleh¹ and E. S. Brodtkin², (1)Lurie Family Foundations MEG Imaging Center, Department of Radiology, Children's Hospital of Philadelphia, Philadelphia, PA, (2)Department of Psychiatry, University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA

Background:

Multiple imaging modalities have been proposed, either alone or in combination, as representing candidate biomarkers for autism, with roles including diagnosis, prognosis, sub-population definition and treatment monitoring. However, while group distinguishing effects often appear promising there is little data on measurement precision, limiting effective planning for supporting future clinical trials, in terms of sample sizes and lower limits on resolvable changes resulting from intervention.

Objectives:

To establish the reproducibility of MEG, MRI and MRS measures in autistic adolescents and adults. To relate measurement precision to group differences (autism vs. neurotypical) as a proxy for the effect size anticipated as an upper limit in clinical trials of behavioral or pharmaceutical interventions.

Methods:

27 autistic adolescents and adults (age 14-45yrs) and 4 neurotypicals are reported. Each participant underwent MEG assessment of the auditory evoked M50 and M100 component latencies as well as MRI and MRS assessment of the excitatory and inhibitory neurotransmitters, glutamate and GABA, from bilateral superior temporal gyrus (STG) on 3 occasions (baseline, +4 weeks, +12 weeks). Analogous studies of motor related neural oscillatory activity and bilateral motor cortex MRS were also obtained. Acquisition, processing and analysis followed state-of-the-art published methods, including macromolecular-suppressed MEGAPRESS editing at 3T for the spectra. Data were considered in terms of inter-subject and intra-subject variability (coefficients of variation, CV). Additionally, group differences were assessed using linear mixed models with diagnostic group and hemisphere as fixed effects, age as a covariate and subject as a random effect.

Results:

Across the mixed cohort, mean M50 latency was 68 ± 8 ms, indicating a between-subject coefficient of variation of 12%. Intra-subject variability on the other hand was characterized by a smaller average CV of 4%, supporting the biological basis (and potential resolvability) of inter-individual differences. MRS results also indicated promising test-retest reliability with intra-subject CV's of 17% and 14% for auditory cortex and motor cortex respectively. There were not significant differences in either MEG or MRS reproducibility metrics between cohorts, although inter-subject variability tended to be greater in the autistic cohort.

Conclusions:

Establishing reproducibility metrics as well as effect sizes for candidate biomarkers is crucial. In this study, we observed intra-subject variability $\ll$ inter-subject variability for MEG-derived M50 latency measures, promising that observed inter-subject variability might be attributed to biological differences (rather than noise). Additionally, measurement precision was $<5\%$ promising sensitivity to small group differences and even smaller *intra*-individual changes arising from intervention. Knowledge of measurement precision (intra-subject variability) in conjunction with estimates of effect sizes are necessary to assess the utility of such biomarkers in resolving (and guiding the interpretation of) changes associated with interventions on an individual level.

437.116 Stimulus Preceding Negativity and Reward Anticipation to Social/Nonsocial Stimuli in 3-4 Year-Old Children

X. Li and L. Carver, *Psychology, University of California, San Diego, La Jolla, CA*

Background: Anticipating social and nonsocial rewards is a critical aspect of both typical and atypical social-cognitive development. Prior research (Engle et al., 2021) shows that preschool-aged children exhibit distinct neural responses to dynamic social and nonsocial cues, suggesting early differential processing of these stimuli. In Autism Spectrum Disorder (ASD), the predictive coding hypothesis suggests that altered expectations about incoming stimuli, particularly social ones, may explain some difficulties in social communication and motivation. Differences in reward anticipation could impact social interactions compared to neurotypical (NT) peers. Investigating these neural mechanisms is essential for understanding the social deficits in ASD.

Objectives: This study investigates the neural correlates of reward anticipation, comparing the responses of 3-4-year-olds with ASD and NT peers to social (e.g., smiling faces) and nonsocial (e.g., toy cars) stimuli. We hypothesize that children with ASD will show altered anticipatory responses to social stimuli. If present, this suggests differences in processing social rewards, potentially contributing to social engagement difficulties; if not, their reward processing may be more similar to NT children than previously thought.

Methods: Our target sample size will include 26 children with ASD and 26 neurotypical children, between the age of 3 and 4. We used a passive S1-S2 paradigm with event-related potentials (ERPs) to measure the stimulus preceding negativity (SPN), an ERP component reflecting reward anticipation. Participants were presented with visual stimuli where S1 (a colored shape) predicted the upcoming presentation of either a dynamic social stimulus (a smiling face) or a nonsocial stimulus (a moving toy car) with an 80/20 probabilistic relationship. EEG was recorded from electrodes placed according to the 10-20 system, and SPN was analyzed in the 200 ms prior to S2 onset.

Results:

We now have data from 4 autistic children and 7 neurotypical children.

Figure 1a shows NT group data ($n=7$), where the SPN (200 ms before the stimulus, gray bar) for social trials (black line) is more negative than for non-social trials (red line). In contrast, Figure 1b shows ASD group data ($n=4$), where the SPN for social trials is more positive than for non-social trials. These trends are emerging but not yet definitive as data collection continues.

Figure 2 shows data from the NT group ($n=26$) from Engle et al. (2021), displaying a similar trend to our Figure 1a, with more negative SPN for social trials compared to non-social trials. We include this to illustrate a more complete NT dataset, highlighting the typical pattern of stronger anticipatory responses to social stimuli.

Conclusions: This study is the first to explore SPN responses to social versus nonsocial stimuli in 3-4-year-olds with ASD, offering insights into reward anticipation mechanisms. Preliminary findings suggest that, unlike NT children, those with ASD do not show larger SPN responses to social stimuli. This aligns with the predictive coding hypothesis, suggesting altered social reward predictions in ASD. These results highlight the role of disrupted reward anticipation in social communication difficulties, with implications for early interventions targeting social motivation.

438.118 Influences on Suicidality and Avenues for Suicide Prevention for the Autistic Community: An in-Depth Qualitative Exploration of Multiple Perspectives

A. V. Kirby¹, **Z. Siddeek²**, K. Rodriguez², W. Lee¹, R. Kripke-Ludwig², A. Joyce³, B. Duncan-Ishcomer², A. Atisme¹, W. Clark¹, A. Darlington¹, K. J. Feldman¹, K. Murthi⁴ and C. Nicolaidis⁵, (1)University of Utah, Salt Lake City, UT, (2)AASPIRE, Portland, OR, (3)Academic Autism Spectrum Partnership in Research and Education (AASPIRE), Portland, OR, (4)Occupational Therapy, University of Utah College of Health, New York, NY, (5)School of Social Work, Portland State University, Portland, OR

Background: Suicidality is common among autistic youth and adults, and significantly elevated compared to the non-autistic population. Mental health and suicide prevention are also top concerns that the autism community wants addressed in research. Suicide prevention efforts are needed that address the broad range of potential influences on suicidality.

Objectives: In the current study, we aimed to develop an in-depth understanding of influences on suicidality and avenues for prevention based on perspectives from autistic adults, family members, and mental health providers.

Methods: We used a community-based participatory research (CBPR) approach in partnership with 7 autistic adults with diverse backgrounds and experiences. We conducted a total of 38 in-depth qualitative semi-structured interviews to gather insight from: (1) autistic adults who have experienced suicidality ($N=16$), (2) family members of any age autistic person who has experienced suicidality ($N=8$), and (3) mental health providers who have worked with at least fifteen autistic clients experiencing suicidality ($N=14$). Autistic participants were 18-68 years of age ($M[SD] = 39 [13.5]$ years), and were 37.5% women, 25% men, 56% transgender, nonbinary, and/or gender-queer [*note: since gender categories are non-exclusive, percentages do not =100%]. Furthermore, 69% of the autistic participants identified as LGBTQIA+ and 62.5% identified within one or more marginalized racial or ethnic group. Family members were parents, siblings, and partner/spouse. Mental health providers reported 2-24 years of experience ($M[SD] = 10.7 [6.6]$ years) in fields including social work, psychology, psychiatry, and music therapy. Participants chose the interview format (live chat, voice, and/or video, or email). We analyzed the data using reflexive thematic analysis to identify themes related to influences on suicidality and avenues for prevention. Once that analysis was complete, we reviewed all of the excerpted data within each theme to develop autism-specific recommendations to enhance existing suicide prevention efforts.

Results: The analysis resulted in seven influences themes and seven prevention themes (see Table 1) subsumed within the following broad thematic concepts: (1) *Pervasive negative attitudes and neurotypical standards have a lasting impact on autistic people's lives*, (2) *Challenges and stressors add strain, making life feel overwhelming and hopeless*, and (3) *Difficulty regulating and managing emotions can increase the likelihood of suicidal feelings and actions*. Table 2 contains recommendations for tailoring suicide prevention efforts for the autistic community, which include supporting neurodiversity, accommodating autistic needs, and changing institutional practices that may harm autistic people.

Conclusions: The perspectives of a diverse sample of autistic adults, family members, and mental health providers reveal a wide range of risk factors contributing to suicidality, as well as opportunities for tailored suicide prevention efforts. Findings point to opportunities for improvements in societal treatment of autistic people as well as improved services and supports to inform a broader approach to suicide prevention.

**438.119 Investigating How Underlying Mechanisms Drive Disordered Eating Among Autistic People Who Have Experienced Childhood Trauma.**

K. Gillespie-Smith, Department of Clinical Psychology, University of Edinburgh, Edinburgh, United Kingdom

Background:

Autistic people are significantly more likely to experience childhood trauma (CT), including victimisation (Ohlsson Gotby et al., 2018) and physical abuse (Mandell et al., 2005). CT has been consistently linked with eating disorder (ED) development in general populations (Brewerton, 2022). However, a lack of research has meant that it is unclear how this relationship operates within Autistic people's EDs. Autistic people with EDs have highlighted the impact of early childhood experiences and trauma within ED development as research priorities for the community (Nimbley et al., *in prep*). Therefore, comprehensive investigations of CT, including how CT interacts with core mechanisms, may provide key insights as to why Autistic people are at higher risk of developing EDs (Nickel et al., 2019).

Prior qualitative investigations show that cognitive overwhelm, stemming from monotropic tendencies, sensory sensitivity, and camouflaging all play a key role in the development and maintenance of EDs in Autistic people (Buchan et al., *in prep*; Babb et al., 2021; Bradley et al., 2024). Monotropism is theorised to be the overarching cognitive processing style of Autistic people (Murray et al., 2005), and altered sensory perception and camouflaging are estimated to impact 75% and 90% of Autistic people respectively (Kirby et al., 2021). Given the prevalence of these traits across the Autistic community, and the fact that a comparatively small subset of the community goes on to develop EDs (Petersen et al., 2024), it may be that CT is operating as a moderator of these mechanisms within Autistic ED experiences.

Objectives:

To explore the moderating role of CT in the relationships between camouflaging, sensory sensitivity, and monotropism with ED behaviours in Autistic people.

Methods:

Data collection is ongoing* 45 Autistic participants with an eating disorder (mean age of 38.1 years; SD=13.6) have completed an online survey (final sample size estimated to be 280). The online survey includes the Eating Disorder Examination Questionnaire (EDE-Q; Fairburn & Beglin, 2008), the Childhood Trauma Questionnaire - Short Form (CTQ-SF; Bernstein et al., 2003), Camouflaging Autistic Traits Questionnaire (CAT-Q; Hull et al., 2019), Sensory Perception Quotient (SPQ; Tavassoli et al., 2014) and the Monotropism Questionnaire (Garau et al., 2023), a 47-item questionnaire used to measure intense attention and interests.

Results:

- Higher levels of sensory issues and camouflaging were related to higher levels of EDs.
- Preliminary moderated mediation analysis has revealed that levels of EDs were mediated by sensory profile levels and that this mediation was moderated by childhood trauma.
- Preliminary moderated mediation analysis has revealed that EDs were mediated by levels of camouflaging and that this mediation was moderated by childhood trauma.

Conclusions:

Analysis to date supports a model in which eating disorder outcomes in trauma exposed Autistic people may be directly related to sensory profiles and levels of camouflaging. The data suggests that camouflaging may be a viable therapeutic target for eating disorders. It also shows that society must become more understanding and accepting of Autistic people so that their need to camouflage will reduce and in turn potentially reduce levels of ED behaviours.

438.120 Longitudinal Outcomes of Autistic and Non-Autistic Adolescents and Adults with Catatonia Treated Prospectively with Electroconvulsive Therapy: A Single-Site Open-Label Naturalistic Study

Z. J. Williams¹, S. Lim², D. C. Fuchs³ and J. R. Smith³, (1)Medical Scientist Training Program, Vanderbilt University School of Medicine, Nashville, TN, (2)Vanderbilt University Medical Center, Nashville, TN, (3)Psychiatry and Behavioral Sciences, Vanderbilt University Medical Center, Nashville, TN

Background: Catatonia is a severe and often overlooked psychomotor syndrome that can commonly occur in individuals on the autism spectrum, with particularly high rates in those with co-occurring neurogenetic conditions, intellectual disabilities, and psychosis. However, very little evidence is available to guide the clinical treatment of catatonia in the autistic population, particularly outside of the acute phase of treatment (i.e., when a patient is ill enough to necessitate hospitalization).

Objectives: This study, through the analysis of routine outcome monitoring data, sought to describe the effectiveness of current standard-of-care electroconvulsive therapy (ECT) practices in use at Vanderbilt University Medical Center (VUMC) for the treatment of catatonia in autistic individuals, individuals with other neurodevelopmental disabilities, and those with other forms of unrelated catatonia.

Methods: A total of 29 individuals were included in the study (Mean [SD] age 28.62 [17.77] years; range 12–79), representing 732 individual ECT treatment sessions. Of the patients included in the study, 11 [37.9%; 46.7% of visits] had a recorded autism spectrum disorder diagnosis and 15 total [51.7%; 62.8% of visits] had catatonia associated with a neurodevelopmental/neurogenetic syndrome. The study population was drawn from all individuals with relevant diagnoses who underwent at least a full induction course of 12 ECT sessions at VUMC and had catatonia-related outcome data recorded (earliest 2023). All electrode placements were bitemporal, and charge was titrated to an individualized dose based on seizure duration. Descriptive statistics were analyzed, and Bayesian hierarchical models were used to quantify individual ECT outcomes and assess for differential response by autism status.

Results: Participants were followed for a median of 20 (IQR [16, 31]) ECT sessions over a median of 146 (IQR [101, 291]) days past the initial ECT consultation. Over time, participation in ECT was associated with large standardized decreases in the clinical severity of catatonia (CGI-S; $b_{Std} = -1.011$, $CrI_{95\%} [-1.485, -0.515]$, $P_d > .999$). Although not reaching traditional statistical significance, there was >90% posterior probability of patients in the autistic group demonstrating less CGI-S improvement than non-autistic patients over time ($b_{Std} = 0.485$, $CrI_{95\%} [-0.224, 1.133]$, $P_d = .910$). Empirically-derived subscales of the Bush-Francis Catatonia Rating Scale (BFCRS) demonstrated a similar pattern, with main effects all trending towards improvement with ECT (Excited: $b_{Std} = -0.111$, $CrI_{95\%} [-0.256, 0.026]$, $P_d = .940$; Akinetic: $b_{Std} = -0.424$, $CrI_{95\%} [-0.695, -0.178]$, $P_d > .999$; Parakinetic: $b_{Std} = -0.535$, $CrI_{95\%} [-1.007, -0.031]$, $P_d = .980$) and non-significant autism*time interaction terms (Excited: $b_{Std} = 0.069$, $CrI_{95\%} [-0.125, 0.284]$, $P_d = .750$; Akinetic: $b_{Std} = 0.186$, $CrI_{95\%} [-0.272, 0.576]$, $P_d = .796$; Parakinetic: $b_{Std} = -0.044$, $CrI_{95\%} [-0.737, 0.579]$, $P_d = .676$).

Conclusions: Autistic and non-autistic individuals receiving ECT for catatonia do seemingly improve along standard symptom measures. Though not clearly replicated across measures, there is at least some evidence from the CGI-S that the autism group had a less significant rate-of-change with intervention than the non-autistic group, which would indicate that these participants are doing exhibiting poorer ECT outcomes longitudinally and/or requiring more protracted ECT courses to achieve the same outcomes. Further work, including the prediction of ECT outcomes for catatonia using existing naturalistic data, is ultimately necessary to improve the care of autistic and non-autistic patients with this often life-altering condition.

438.121 Longitudinal Trajectories of Loneliness in Autistic Adolescents: The Role of Depression and Anxiety Symptoms

A. H. Gerber¹, K. E. Sharp², A. Lopez³, L. Baczewski⁴, A. Verbalis⁵ and L. Kenworthy⁶, (1)Center for Autism, Children's National Medical Center, Washington, DC, (2)Center for Autism Spectrum Disorders, Children's National Hospital, College Park, MD, (3)Children's National Hospital, Washington, DC, (4)Center for Autism, Center for Autism Spectrum Disorders, Children's National, Washington, D.C., DC, (5)Center for Autism Spectrum Disorders, Children's National Health System, Washington, DC, (6)Center for Autism Spectrum Disorders, Children's National Hospital, Washington, DC

Background: Loneliness is a public health crisis linked to increased mortality and physical and mental health issues (Leigh-Hunt et al., 2017).

Research shows loneliness is particularly elevated in autistic youth and associated with anxiety and depression (Hymas et al., 2022). Only one study has examined its development over time, finding that loneliness increases in autistic youth from adolescence into young adulthood (Schiltz et al., 2023). No research has examined predictors of change in loneliness and as a result, little is known about its development in autistic adolescents.

Objectives: To examine the trajectories of loneliness in autistic adolescents and investigate predictors of changes in loneliness.

Methods: Participants were 23 autistic adolescents ($M_{age} = 15.98$, $SD_{age} = 1.13$; 16 male assigned at birth) with $IQ \geq 80$ ($M_{IQ} = 113.09$, $SD_{IQ} = 12.71$) with pre-existing clinical and/or school autism diagnosis supported by a Social Communication Questionnaire (SCQ) score > 7. Participant demographics are displayed in Table 1. Data were collected at two timepoints separated by 6 to 10 months ($M_{mo} = 8.71$, $SD_{mo} = 0.98$), while participants were waiting to begin an intervention study. Caregivers completed the Social Responsiveness Scale (SRS-2), a measure of autism traits. Adolescents completed questionnaires assessing quality of life, anxiety (Anxiety Scale for Children–Autism Spectrum Disorder; ASC-ASD), and depression (Beck Depression Index; BDI-2). Four items from the quality of life measure, reflecting satisfaction with relationships and social activity, were summed to create a loneliness subscale. Higher scores indicated greater satisfaction and thus lower loneliness, with good reliability ($\alpha = .84$). Correlations between loneliness and other variables were computed. Multilevel models were used to predict changes in loneliness over time. Two separate models were run, using depression or anxiety symptoms as the predictor, while controlling for age, sex assigned at birth, gender, and autism traits.

Results: At baseline, higher loneliness correlated with higher anxiety and depression symptoms (all $ps < .05$), but not with age, sex, or autism traits (all $ps > .05$). The multilevel model of loneliness revealed an ICC of 0.48, indicating that 52% of the variability in trajectories of loneliness is explained by within-person differences. Controlling for age, sex, gender, and autism traits, depression – but not anxiety – significantly predicted changes in loneliness over time. Specifically, simple slopes indicated that participants with lower depression symptoms (-1 SD) experienced significant increases in loneliness, while no other group experienced changes in loneliness (see Figure 1).

Conclusions: This represents one of the first longitudinal investigations of loneliness in autistic adolescents. Consistent with previous literature, loneliness was associated with elevated depression and anxiety. We did not find an association with autism traits, despite a considerable range of scores, suggesting that co-occurring psychopathology, rather than autism itself, drives loneliness in autistic youth. Our results also demonstrate an increase in loneliness over time, specifically for those autistic adolescents not already endorsing elevated loneliness and depression. This finding is consistent with previous research demonstrating increases in loneliness across adolescence. Further, it aligns with prior work identifying adolescence as a particularly salient period for social development, highlighting the need for targeted assessment and intervention focused on loneliness in autistic adolescents.

438.122 Examining the Relationship between Pupillary Light Response and Aggressive Behavior in School-Aged Children with and without Autism: Results from the Autism Biomarkers Consortium for Clinical Trials (ABC-CT)

E. Quin¹, S. Faja², C. Orr², G. Dawson³, S. Jeste⁴, N. Kleinhans⁵, K. Chawarska⁶, J. Dziura⁷, F. Shic⁸, A. Naples⁹, S. J. Webb¹⁰ and J. McPartland¹¹, (1)Boston Children's Hospital Labs of Cognitive Neuroscience, Brookline, MA, (2)Boston Children's Hospital Laboratories of Cognitive Neuroscience, Brookline, MA, (3)Department of Psychiatry and Behavioral Sciences, Duke University, Durham, NC, (4)Children's Hospital Los Angeles, Los Angeles, CA, (5)University of Washington, Seattle, WA, (6)Child Study Center, Yale University School of Medicine, New Haven, CT, (7)Yale University, New Haven, CT, (8)Center for Child Health, Behavior and Development, Seattle Children's Research Institute, Seattle, WA, (9)Yale Child Study Center, Yale University School of Medicine, New Haven, CT, (10)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (11)Yale Child Study Center, Yale Child Study Center, New Haven, CT

Background: Aggressive behavior is seen in a large percentage of autistic youth and can contribute to substantial impairment. Factors that contribute to aggression remain relatively unknown, including autonomic arousal and anxiety. The pupillary light response (PLR) is a physiological measure of arousal, and previous studies have indicated that autistic people demonstrate an increased latency to pupillary constriction when compared to non-autistic peers. Aggressive children have demonstrated similarly sluggish autonomic responses. In non-autistic children, anxiety has also been linked to aggression. However, this relationship has received less research attention in autism.

Objectives: To examine whether latency to pupillary constriction is related to aggressive behavior, and whether this relationship is stronger in autistic children. To explore correlations with anxiety levels.

Methods: As part of the Autism Biomarkers Consortium for Clinical Trials, parents of 399 school-aged children (280 autistic) completed the Aberrant Behavior Checklist (ABC). We examined scores on the Irritability scale (ABC-I). Participants also completed an eye-tracking battery including a PLR task, measuring their latency to minimum pupil size acceleration via 18 trials of a dark screen with a central animation, then a flash of white, followed by the return of the initial image (Shic et al., 2022). Full-scale IQ (FSIQ) scores were determined using the Differential Ability Scales-II. We computed correlations to determine which child and family characteristics related to ABC-I. We then fit a multivariable linear regression to examine whether (1) average pupillary latency (APL) and/or (2) diagnostic group predicted aggression, measured by the ABC-I. Finally, we calculated Pearson correlations to understand the relationships between t-scores on the Child & Adolescent Inventory Generalized Anxiety scale (CASI-GA) and aggression, pupillary latency, and demographic characteristics.

Results: Because both FSIQ and family income related to ABC-I, these variables were included in the first step of a regression model. We added diagnostic group and APL as the second step and an interaction term between diagnosis and APL in the third step. In this model, FSIQ and Income both significantly contributed to account for variance in the ABC-I scale. When diagnosis and APL were added, model fit significantly improved; income and diagnosis accounted for a significant portion of the variance, but APL was non-significant. The inclusion of an interaction term did not improve model fit, suggesting an effect of diagnosis but no interaction between diagnosis X APL (Table 1). In our exploration of anxiety, CASI-GA scores were significantly correlated with ABC-I, as well as age, income, and FSIQ, but not with APL (Table 2).

Conclusions: In this sample, we did not observe an interaction between autism diagnosis and pupillary latency when predicting aggression levels. There was a significant association between full-scale IQ and aggression, successfully replicating the pre-existing literature. Furthermore, annual household income was negatively associated with aggression, potentially representing decreased access to interventions and socioemotional supports. Future research could examine pupillary latency in an aroused condition, as well as select participants whose aggression scores fall above the clinical cutoff to better elucidate potential relationships between these variables.

**438.123** Mediating Effect of Anxiety on the Relationship between Sleep Difficulties and Deficits in Social Motivation Among Autistic Youth

J. Lui¹, C. R. Callaci², H. Morrell², T. R. Van Dyk², C. L. Neece² and A. Nair¹, (1)Loma Linda University, Loma Linda, CA, (2)Psychology, Loma Linda University, Loma Linda, CA

Mediating Effect of Anxiety on the Relationship Between Sleep Difficulties and Deficits in Social Motivation Among Autistic Youth

Background: Sleep difficulties have been shown to be strongly associated with increased social difficulties in autistic youth (Veatch et al. 2017). Additionally, nearly 40% of autistic youth also experience anxiety-related symptoms (van Steensel et al., 2011). Limited research has evaluated the effect of anxiety on the relationship between sleep difficulties and deficits in social motivation among autistic youth. We hypothesized that in autistic youth, greater severity of sleep difficulties would predict increased impairments in social motivation through the effects of anxiety-related problems.

Objectives: To investigate whether total anxiety-related problems mediate the relationship between sleep difficulties and deficits in social motivation among autistic youth.

Methods: Participants were youth diagnosed with autism spectrum disorder ($N = 54$; $M_{age} = 9.630$, $Range_{age} = 6-17$ years; Sex [Male %] = 75.900%). Sleep difficulties were measured using the total scores from the Children's Sleep Habits Questionnaire (CSHQ; Owens et al., 2000). Anxiety-related symptoms were measured using the total sum score from the Screen for Child Anxiety Related Disorders (SCARED; Birmaher et al., 1997). Social motivation was assessed using the social motivation subscale T -scores from the Social Responsiveness Scale (SRS-2; Constantino et al., 2012). On all parent-report measures used, higher scores indicated greater severity of symptoms. Descriptive statistics were obtained using SPSS and the mediation analysis was performed using PROCESS Macro in RStudio.

Results: Results of the mediation analysis revealed that anxiety-related problems significantly mediated the relationship between sleep difficulties and deficits in social motivation ($ab = 0.452$, 95% CI [0.104, 0.921], $p < .050$). For every one-point increase in the CSHQ total score, SRS-2 social motivation subscale T -scores increased by 0.452 through the effects of anxiety-related problems. There were also several significant direct effects. Sleep difficulties were a significant predictor of total anxiety-related problems, such that for every one-point increase on the CSHQ, scores on the SCARED increased by 0.741, 95% CI [0.308, 1.175], $p = .001$. Total anxiety-related problems were a significant predictor of impairments in social motivation, such that for every one-point increase on the SCARED, SRS-2 social motivation subscale T -scores increased by 0.610, 95% CI [0.413, 0.807], $p = .001$. Sleep difficulties were a significant predictor of impairments in social motivation. However, we found that for every one-point increase on the CSHQ, SRS-2 social motivation subscale T -scores decreased by 0.419, 95% CI [-0.760, -0.080], $p = 0.017$.

Conclusions: These findings suggest that in autistic youth, anxiety-related problems may explain the relationship between sleep difficulties and impairments in social motivation. Our model indicates two paths that are consistent with previous research: there is a positive relationship between sleep difficulties and anxiety-related problems and there is also a positive relationship between anxiety-related problems and impairments in social motivation (Briot et al., 2020; Nadeau et al., 2015). Further studies should replicate this model and aim to develop interventions that target sleep difficulties and anxiety-related problems concurrently in autistic youth, which can lead to improvements in social motivation.

**438.124 Mental Health Crisis App Usage for the Autism Community**

A. V. Kirby¹, A. V. Bakian² and B. Kious¹, (1)University of Utah, Salt Lake City, UT, (2)Psychiatry, University of Utah, Salt Lake City, UT

Background: Suicide prevention is a top priority for the autistic community. Research shows significantly higher rates of suicide death, attempts, and ideation among autistic vs. non-autistic people from childhood through adulthood. Crisis hotlines and chat services are a highly recommended suicide prevention strategy, but evidence lacks about whether they meet the needs of autistic people in crisis. Safe-UT is an app-based crisis chat and tip line based in Utah (USA) that provides real-time mental health crisis intervention for students in elementary through higher education, parents/guardians, and educators. Safe-UT is staffed by Master's-trained clinicians.

Objectives: The purpose of this study was to examine autism-related crisis app messaging in order to understand usage patterns and identify future needs.

Methods: We accessed the content of chats and tips across a 5 year period after all potentially identifying data was expunged by the Safe-UT data team. We used keyword searching to identify messages including explicit mention of autism and then applied an inductive content analytic approach to organize the data. We coded the user type and message intent, allowing new codes when new usage patterns were identified.

Results: Between 2017 and 2022, there were 170,889 encounters on the app. We reviewed these, finding 1,158 (0.7%) that included explicit mention of autism. See Figure 1 for the distribution of autism mentions. Over half ($n=700$; 60.4%) of those encounters were related to seeking help for an autistic person's mental health (inclusive of diagnosed and possible autistic identity mentions), and 88.6% of the time the autistic person was the app user. Specific topics prompting app usage included passive and active suicidality, self-harm, panic, emotional pain, abuse, distress over interpersonal/relationship difficulties, and questioning one's own autistic identity. Other frequent autism-related encounters included mental health challenges experienced by family members of autistic people (e.g., siblings, parents: $n=211$; 18.2%). A notable proportion of the encounters included mention of an autistic person within a description of someone else's mental health challenge ($n=107$; 9.2%)—examples included relationship difficulties with an autistic person or an autistic person being listed as a source of support.

Conclusions: Explicit autism mentions were relatively rare compared to the overall app usage. Given the rates of autism in the population as well as the high documented rates of suicidality, we believe the discrepancy between expected vs. actual use may reflect limited comfort with the app by autistic people and/or limited disclosure of autism diagnostic status within the chats. Despite lower than expected rates, our findings do indicate a clear need for crisis workers who have autism knowledge in order to support autistic people in crisis, as well as to discuss autism-related topics with family members and other app users who bring up autism in their chats. Future work is needed to understand potential barriers to usage for autistic people as well as the effectiveness of care provided to autistic people through crisis lines.

**438.126 Modeling a Step By Step Framework to Broaden Outcome Research Contributing to Evidence-Based Practice**

Recommendations: The Example of Sleep

P. Doehring¹ and B. Reichow², (1)ASD Roadmap, Chadds Ford, PA, (2)UConn Health, Newberry, FL

Background: Evidence-based practice (EBP) guidelines intended to translate high-quality psychosocial outcome research into effective interventions have a more limited impact when they draw only upon Randomized Control Trials (RCTs), and when they only generate very broad recommendations. Our multi-step framework (see Figure 1) draws directly from a greater range of high-quality outcome research studies to generate targeted EBP recommendations that community-based practitioners can translate confidently and directly into individualized intervention goals. We believe that, once guidelines using high-quality RCTs have broadly established a psychosocial practice as evidence-based, other high-quality outcome research studies can generate specific but qualified recommendations that can also be considered evidence-based.

Objectives: To pilot the application of this framework to EBP guidelines developed by the American Academy of Neurology (AAN) to improve sleep using psychosocial interventions. We hypothesized that this framework would increase the number of recommendations drawn directly from individual outcome research studies that target specific samples, interventions, and/or outcomes, and that can be considered evidence-based.

Methods: We applied the 8 step framework (see Figure 1) to the AAN Sleep guidelines, and related outcome research studies.

Results: The EBP recommendation related to psychosocial interventions from the AAN report (Step 1) provided few details: e.g., “Clinicians should counsel parents regarding strategies for improved sleep habits with behavioral strategies as a first-line treatment approach, either alone or in combination with pharmacologic or nutraceutical approaches”. Two RCTs meeting the AAN’s stringent quality standards (Step 2) were used to generate recommendations offering more details about who might benefit, the practices used, and the intervention targets (Step 4): e.g., “For 4-10 year olds with ASD who have mixed sleep onset and maintenance insomnia, parent-based sleep education delivered in a group format combined with behavioral strategies such as extinction should improve bedtime resistance, sleep onset latency, sleep continuity, and/or total sleep time.”. A literature search identified more than 30 related outcome research studies (Step 5); most were not RCTs, and some included children with Intellectual / Developmental Disabilities (I/DD) but not ASD. In total, these studies generated more than 35 recommendations that addressed a much broader range of sample characteristics and intervention targets (Step 8). Some also suggested the potential for more rapid, significant, and sustained progress: e.g., “In 3-7 year olds with ASD and sleep terrors, scheduled awakenings may help to reduce sleep terrors completely within 1-3 weeks, with progress maintained for more than 6 months. This progress may depend upon weekly progress monitoring by an experienced professional.”. These studies were also more likely to provide the kinds of critical details about interventions that practitioners need to implement them successfully.

Conclusions: By helping to generate a broader range of more specific recommendations drawn directly from outcome research, this framework can begin to close the significant and longstanding gaps between research and evidence-based community practice. The next step - establishing which studies meet quality standards - will confirm which of these recommendations practitioners might begin to adopt confidently, supported by more stringent progress monitoring.

438.127 Network Analysis to Examine Phenotypic and Physiological Correlates of Irritability in Autism

S. Alatrash¹, E. Anagnostou², T. Paul^{1,3}, B. Andrade⁴, S. Monga⁵, M. Penner⁶, J. A. Brian⁷, **A. Kushki⁸** and A. Roshan Fekr⁸, (1)Holland Bloorview Hospital, Toronto, ON, Canada, (2)Bloorview Research Institute, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (3)Bloorview Research Institute, Autism Research Centre, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (4)Centre for Addiction and Mental Health, Toronto, ON, Canada, (5)The Hospital for Sick Children, Toronto, ON, Canada, (6)Autism Research Centre, Bloorview Research Institute, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (7)Holland Bloorview Kids Rehab Hospital, Toronto, ON, Canada, (8)Toronto Rehabilitation Institute (TRI), Toronto, ON, Canada

Background: Irritability is a prevalent and disabling challenge for many autistic individuals. Our recent scoping review revealed significant gaps in our understanding of the demographic and phenotypic correlates of irritability that can ultimately inform approaches for support and care. In particular, we found that existing studies often consider influencing factors of irritability in siloes. This is a challenge as many of these factors, including demographic and phenotypic features, can be highly interconnected.

Objectives: This study used network analysis to characterize the multi-dimensional association between irritability symptoms and demographic and phenotypic factors.

Methods: The study sample included children aged 7-16 years with an IQ ≥ 85 , who either had a diagnosis of autism (60 participants) or were neurotypical (73 participants). Behavioral data included measures of irritability (Aberrant Behavior Checklist; ABC), autism features (Social Communication Questionnaire; SCQ), anxiety (Screen for Child Anxiety-Related Disorders; SCARED), emotion regulation (Emotion Dysregulation Inventory; EDI), externalizing symptoms and attention deficit/hyperactivity features (Child Behavior Checklist; CBCL), sensory differences (Short Sensory Profile; SSP) and temperament traits (Temperament in Middle Childhood Questionnaire; TMCQ; and Early Adolescent Temperament Questionnaire; EATQ). Network analysis was conducted using the ‘bootnet’ package in R with the ‘estimateNetwork’ function and the EBICglasso method for network estimation. Centrality analysis was performed to determine the importance of nodes, focusing on node strength, while network stability was assessed using the CS-coefficient. Community detection was carried out using the Clique Percolation Method (CPMw) to identify interconnected substructures. The reliability of strength centrality and edge weights was evaluated through bootstrapping.

Results: The original dataset included data from 193 participants. After excluding participants with missing phenotypic or demographic data, data for 133 participants were available for the full analysis. Network analysis of demographic and phenotypic variables revealed a dense network with 50 out of 91 possible connections (55%). Key correlations emerged between irritability and other variables: in one group, irritability showed direct positive correlations with externalizing problems, negative affect, and effortful control. In another, it was directly linked to emotion dysregulation, autism features (SCQ), anxiety, and negative affect. Indirectly, irritability was associated with sensory profile, surgency, and sex. Attention deficit/hyperactivity correlated positively with externalizing problems and negatively with effortful control but was not part of any community.

Overall, node strengths and edge weights were stable (CS-coefficients > 0.5).

Conclusions: This study improves our understanding of the complex relationships among demographic, phenotypic, and physiological factors linked to irritability in autism. Network analysis revealed strong direct associations between irritability, externalizing behaviors, emotion regulation, and temperament traits, with indirect links to attention deficit/hyperactivity. Additionally, the findings highlight the interconnectedness of irritability with anxiety and social communication differences. This research lays the foundation for future studies that can further explore these associations, with an emphasis on physiological factors and their role in irritability. The study’s limitations, including its correlational nature and small sample size, call for caution in interpreting the findings and highlight the need for further research to explore causality.

438.128 Neurodivergent Strengths and Wellbeing: Insights from Autism and ADHD

L. D. Hargitai¹, E. Laan^{2,3}, L. M. Schippers^{2,3}, L. A. Livingston^{4,5}, G. Fairchild¹, P. Shah¹ and M. Hoogman^{2,3,6}, (1)Department of Psychology, University of Bath, Bath, United Kingdom, (2)Department of Psychiatry, Radboud University Medical Center, Nijmegen, Netherlands, (3)Donders Institute for Brain, Cognition and Behavior, Radboud University, Nijmegen, Netherlands, (4)Department of Psychology, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (5)Neuroscience and Mental Health Innovation Institute, Cardiff University, Cardiff, United Kingdom, (6)Department of Cognitive Neuroscience, Radboud University Medical Center, Nijmegen, Netherlands

Background: Strengths-based approaches, which shift away from traditional deficit-based models, are becoming increasingly common in neurodevelopmental research. Recently, Taylor et al. (2023) showed that autistic and non-autistic adults do not differ in the strengths they report, although autistic adults recognise and utilise their personal strengths less in their everyday lives. Nonetheless, increased strengths use predicted better subjective wellbeing, improved quality of life, and lower levels of anxiety, depression and stress among both autistic and non-autistic adults. In contrast, relatively little is known about the psychological strengths that may be a feature of ADHD, a neurodevelopmental condition that often co-occurs with autism. Knowledge and use of personal strengths by adults with ADHD, and whether, like in autism, these factors play a role in their life outcomes, is also unknown.

Objectives: To address these gaps in the literature and complement the findings in autism, we conducted the first well-powered study of self-reported strengths, strengths knowledge and strengths use in ADHD. Specifically, we investigated whether: (1) strengths proposed to be particularly salient to ADHD are, indeed, more strongly endorsed by adults with ADHD than their neurotypical peers; (2) adults with and without ADHD differ in their strengths knowledge and strengths use; and (3) knowledge and use of one's strengths predicts wellbeing, quality of life, and mental health.

Methods: Adults with ($n = 200$) and without ($n = 200$) ADHD were recruited online and matched on age, sex, education level, and subjective socioeconomic status, controlling for autism diagnosis. Participants rated their endorsement of 25 putative ADHD-related strengths and completed self-report measures assessing strengths knowledge, strengths use, subjective wellbeing, physical-, psychological-, social- and environmental quality of life, and mental health. Using Frequentist and Bayesian analysis methods, we compared the ADHD and non-ADHD groups, and explored the associations of strengths knowledge and strengths use with outcomes across both groups, contrasting these findings with the associations in autism.

Results: We found that the ADHD group endorsed 10 strengths more strongly than the non-ADHD group, including hyperfocus, humour and creativity, while the non-ADHD group reported slightly greater endorsement of perseverance as a personal strength. However, adults with and without ADHD reported similar endorsement of the remaining 14 strengths, highlighting that there were more similarities than differences between the two groups. Contrary to the findings in autism, adults with and without ADHD did not differ in their strengths knowledge and strengths use. Furthermore, in both groups, increased strengths knowledge was associated with better wellbeing, improved quality of life across all domains and fewer symptoms of depression, anxiety and stress.

Conclusions: While certain strengths are more salient in adults with ADHD, they show similar knowledge and use of their personal strengths as their neurotypical peers. Our study complements the literature on autistic strengths and highlights that leveraging psychological strengths, irrespective of a neurodevelopmental condition diagnosis, has the potential to improve neurodivergent people's lives. These findings offer novel insights into the conceptualisation of ADHD and serve as a springboard for future research to explore strengths in neurodevelopmental conditions using objective measures.

438.129 Outcomes in Children at Elevated Likelihood for Autism and Early Developmental Regression: Combining Retrospective and Prospective Methods

S. Boterberg, E. Demurie, F. Vlaeminck, P. Warreyn, E. Bruyneel, C. Bontinck, N. Dewaele and H. Roeyers, Department of Experimental-Clinical and Health Psychology, Ghent University, Ghent, Belgium

Background: Developmental regression, typically defined as the loss of acquired skills before age 3, affects about 30% of autistic children according to retrospective parental reports (Tan et al., 2021). However, a prospective study of siblings at elevated likelihood (EL) for autism found that most autistic children exhibited early skill loss (Gangi et al., 2019). Additionally, reported regression is often followed by increased Restricted and Repetitive Behaviours (RRBs; Bradley et al., 2016). Considering the likely high prevalence of regression in autism and its impact, future research using both retrospective and prospective methods is crucial to better understand its characteristics and outcomes.

Objectives: The first objective is to explore the occurrence of regression before age 3 using retrospective and prospective methods, and their agreement. The second objective is to evaluate outcomes following regression at age 3 and 9.

Methods: This study comprised a longitudinal sample of 100 EL-children including younger siblings of autistic children (EL-sibs; $n=52$; 54% male) and preterm-born children ($n=48$; 56% male; gestational age <30 weeks). Regression in EL-sibs was assessed prospectively using Mullen Scales of Early Learning (MSEL) change-score analysis at 10, 14, 24 and 36 months, and retrospectively via parent report at 36 months (Autism Diagnostic Interview (ADI-R)). In preterms, regression was only measured retrospectively at 36 months (ADI-R).

Outcomes, measured at 3 and 9 years, included IQ (MSEL and Wechsler Intelligence Scale (WISC-V)), autism characteristics (Autism Diagnostic Observation Schedule (ADOS-2)), parent-reported RRBs (ADI-R RRB scale and the Repetitive Behaviour Scale (RBS-R)) and diagnosis (autism, other atypical, typical).

Results: Prospective MSEL change-score analysis showed a 21.2% ($n=11$) regression prevalence in EL-sibs. Among EL-sibs, 52.6% of those with autism had an observed regression, a significantly higher percentage compared to children with atypical development (16.7%; $\chi^2(1)=5.246, p<.05$) and typical development (20%; $\chi^2(1)=3.780, p<.05$). The ADI-R of only one parent confirmed regression based on the MSEL change-score, showing very low agreement of 2% (Cohen's Kappa=-.05; $p=.717$).

Retrospective ADI-R reports indicated a regression prevalence of 8.2% ($n=8$) in our total sample. Among EL-sibs and preterms with autism, 21.4% had a reported regression, a significantly higher percentage compared to atypically (2.5%; $\chi^2(1)=6.199, p<.05$) and typically developing children (3.44%; $\chi^2(1)=4.275, p<.05$).

With regard to outcomes (see also **Table 1**), EL-sibs with prospectively identified regression showed more social-communicative difficulties ($p<.05$) by age 3. In addition, retrospectively identified regression in both EL-sibs and preterms was linked to more reported RRBs at age 9 ($p<.01$), particularly ritualistic and compulsive behaviours ($p<.01$).

Conclusions: Consistent with previous findings, a higher prevalence of autistic regression was found using a prospective approach (53%) compared to retrospective reports (21%). Remarkably, there was almost no agreement between both methods. Regression occurred in both atypical and typical development but was most common in autism.

Although most measures show no differences in outcomes, prospective measures associated regression with increased social-communicative difficulties at age 3, whereas retrospective measures linked it to increased RRBs at age 9. These findings suggest a more challenging trajectory after regression, though further research is needed due to varying results based on how regression is operationalized.

438.130 Patterns of Mood Symptoms and Medication Use Associated with Co-Occurring Intellectual Disability Among Autistic Individuals Presenting in Crisis

W. Worsham¹, A. G. Lin² and D. A. Bilder², (1)Child and Adolescent Psychiatry, Massachusetts General Hospital/McLean, Boston, MA, (2)Psychiatry, University of Utah Huntsman Mental Health Institute, Salt Lake City, UT

Background: Autistic individuals present in emotional and behavioral distress in many ways, complicating the delivery of medical and psychiatric care. Co-occurring intellectual disability (ID) and/or impaired communication further impedes the identification of conditions that may be contributing to distress. While autism is associated with increased vulnerability to mood disorders, little is known about how autistic individuals with and without ID differ regarding mood disorder symptomatology when presenting in crisis.

Objectives: To describe differences in mood symptoms and mood stabilizer use among autistic individuals with and without ID who present to a medical setting in crisis.

Methods: A retrospective chart review was performed on autistic individuals who presented to a neurobehavior consult service from 2019 through 2023. Clinical and demographic data were abstracted from clinical records including the Sources of Distress Survey (SDS). The SDS is a validated, web-based, adaptive questionnaire that queries caregiver observations related to psychiatric and medical conditions that may contribute to distress in individuals with neurodevelopmental conditions. Symptom modules include depression and expansive mood/mania, hereafter referred to as "mania" (See Figure 1). SDS queries depressive symptoms lasting ≥ 1 week over the preceding month and manic symptoms over the preceding 6 months that are distinct from baseline, last ≥ 2 consecutive days, and have no precipitating events. Descriptive statistics, Independent T-tests, Chi Square tests, and binary logistic regression adjusted for gender and age were conducted in SPSS Version 28 with an alpha of 0.05 selected to assess statistical significance.

Results: Of the 228 autistic individuals identified, 128 had ID (95 males, 33 females; mean=18.9 $\pm$ 9.3 years, range: 6-47 years) and 100 did not (66 males, 34 females; mean = 15.3 $\pm$ 8.0 years, range: 3-49 years). The presence of ID was associated with higher likelihoods of aggression (77% vs. 61%, $\chi^2(1,228)= 6.4, p=0.01$), self-injurious behavior (SIB) (63% vs. 34%, $\chi^2(1,228)= 18.2, p<0.001$), and antipsychotic and mood stabilizer use (75% vs. 52%, $\chi^2(1,228)= 13.0, p<0.001$; 52% vs. 22%, $\chi^2(1,228)= 20.7, p<0.001$, respectively). Autistic individuals with and without ID did not differ in the number of depression items endorsed (both mean=3.3 $\pm$ 2.3; $p=1.0$) nor positive screens on the depression module (both 73%, $\chi^2(1,228)=0.003, p= 0.95$). In contrast, autistic individuals with ID demonstrated a significantly higher number of manic symptoms (mean=2.1 $\pm$ 2.2; mean=0.9 $\pm$ 1.8, respectively, $p<0.001$) and greater likelihood of screening positive on the mania module (48% vs. 20%, $\chi^2(1,228)= 18.7, p<.001$). Sleeping six or less hours per night also occurred more frequently in those with ID (31% vs. 14%, $\chi^2(1,228)= 8.5, p= 0.003$). See Figures 1 and 2.

Conclusions: Frequent aggression, SIB, and antipsychotic/mood stabilizer use reflected higher crisis acuity among autistic individuals with ID. The presence of co-occurring ID coincided with higher rates of manic symptoms; however, depressive symptom frequency was remarkably similar between groups. Because psychotropic management of bipolar disorder differs substantially from unipolar depression, study findings demonstrate the importance of systematic screening for mania during crisis evaluations for autistic individuals, particularly when ID is also present.

438.131 Patterns of Parent-Child Concordance of Anxiety Symptoms across Multiple Diagnostic Groups Using the MASC-2: A Replication Study

Z. Algaze¹, G. Emory², L. D. Yankowitz³, R. M. Benecke², C. J. Zampella², R. T. Schultz⁴, J. Pandey² and J. D. Herrington², (1)The Children's Hospital of Philadelphia Center for Autism Research, Philadelphia, PA, (2)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (3)Laboratories of Cognitive Neuroscience, Boston Children's Hospital/Harvard Medical School, Boston, MA, (4)The Center for Autism Research/CHOP, Philadelphia, PA

Background: Previous research indicates low to moderate agreement between parent and child reports of psychological symptoms (Bajeux et al., 2018), which has implications for diagnosis. Anxiety often co-occurs with autism, and previous work has suggested different patterns of parent-child concordance between autistic youth (ASD), those with co-occurring anxiety (ASD+ANX), and typically developing controls (TDC) on the Multidimensional Anxiety Scale for Children 2nd Edition (MASC-2; 2012), a widely used tool for evaluating anxiety in youth (Kalvin et al., 2020), but this work requires replication.

Objectives: Replicate findings of Kalvin et al. (2020) by examining parent-child ratings on the MASC-2 across ASD, ASD+ANX, and TDC.

Methods: 143 12-17-year-old participants were categorized as ASD, ASD+ANX, and TDC based on comprehensive evaluation supervised by a licensed psychologist. Clinicians completed the Ohio State Autism Rating Scale (OARS) to capture ASD symptom severity. Parents and children completed the MASC-2 Parent and Self-Report questionnaires. Parent-child discrepancy scores were calculated by converting Total Anxiety T-scores into z scores, and subtracting child anxiety z scores from parent anxiety z scores. Three major analyses were conducted to replicate Kalvin et al.: 1) Comparison of MASC-2 Total Anxiety T-Score across groups; 2) Comparison of parent-child discrepancy across groups, and 3) analyses of potential moderators of parent-child discrepancy (age, sex, IQ, autism characteristics).

Results: In replication of Kalvin, significant differences were observed in both parent and child Total Anxiety ratings between diagnostic groups, with highest anxiety ratings in ASD+ANX and lowest in TDC (Table 2). As in Kalvin, a significant group-by-rater interaction effect ($F(2,140)=6.24$, $p=0.003$) indicated that parent-child reporting discrepancies vary by group. However, the pattern of these discrepancies was different, with post hoc *t*-tests finding that TDC children rated their anxiety higher than their parents ($t(126.17)=-4.05$, $p<0.001$, replicating Kalvin), whereas there was no difference between parent and child ratings in ASD ($t(57.68)=0.92$, $p=0.36$, children>parents in Kalvin) or ASD+ANX ($t(89.57)=0.33$, $p=0.74$, parents>children in Kalvin). Correlations between parent and child ratings (Table 2) partially replicated Kalvin, with moderate relationships in ASD+ANX and TDC. Unlike Kalvin, which reported parent-child discrepancy was related only to autism severity, we found a significant association between parent-child discrepancy and IQ only (Table 2).

Conclusions: Overall, this study partially replicated Kalvin et al. Across parent and child report, we find a similar rank ordering of reported anxiety across ASD+ANX, ASD, and TDC. While we also found that the relationship between parent and child report of anxiety varied across groups, the nature of those differences was not consistent. We also did not replicate associations between potential moderators of parent-child reporting discrepancies. These findings support the conclusions that anxiety may be experienced and reported differently in ASD and that both parent and child report are useful, but discrepancies with prior work indicate the need for further investigation of the factors influencing parent-child anxiety rating discrepancies (e.g., sample differences, autism severity measure differences). For the project's presentation, we will extend Kalvin's study to two additional diagnostic groups (anxiety-only, and non-anxiety diagnoses; 155 additional children) and six additional MASC-2 subscales.

**438.132** Performance of Autism Diagnostic Tools in Preschoolers with Cerebral Palsy

G. Perez Liz¹, J. R. Maldonado Coronado², A. B. Vega-Rivero³, A. B. Narcizo³, F. Alcalde³, M. Batarce³, R. Contreras³, S. Garcia³, C. Ibarra⁴, A. Sagastegui⁵, S. Villarreal⁶, E. H. Sheridan⁶, D. A. Berger⁶ and D. L. Robins¹, (1)A.J. Drexel Autism Institute, Drexel University, Philadelphia, PA, (2)Universidad de Celaya, Celaya, GJ, Mexico, (3)Universidad de Monterrey, Monterrey, NL, Mexico, (4)Instituto Nuevo Amanecer, Monterrey, NL, Mexico, (5)AJ Drexel Autism Institute, Drexel University, Philadelphia, PA, (6)Psychological Sciences, University of Connecticut, Storrs, CT

Background: Cerebral palsy (CP) is the most frequent motor disorder in childhood; movement, posture, and muscle coordination impairment may range from I (minimal support) to V (greatest support) on the Gross Motor Functional Classification System (GMFCS; Palisano, et al., 1997). Cohorts of children with CP have been found to have an autism prevalence of 3% to 16% (Craig et al., 2019). Most studies aiming to identify autism in children with CP have focused on school age children with CP (Pålman, 2021) but identification of autism in preschoolers with CP remains to be investigated (Rackauskaite et al., 2020).

Objectives: To describe the performance of two autism diagnostic tools, the Toddler Autism Symptom Inventory (TASI, for parent/caregiver report; Coulter et al., 2019) and the Autism Diagnostic Observation Schedule, 2nd ed. (ADOS-2, for direct observation; Lord et al., 2012) during autism diagnostic assessment in preschoolers with CP identified through screening or caregiver/teacher concern.

Methods: Sixteen children ($N_{\text{male}}=10$) ages 18-60 months, with CP underwent an autism diagnostic assessment, based on screening status or on caregiver concern. Demographic characteristics (age, sex, maternal education) were collected. Additional information included GMFCS classification of the children at the time of screening and co-occurring medical conditions. Autism diagnostic assessments included the administration of the TASI and ADOS-2 (modules Toddler or I), and a clinical estimate was established based on DSM-5 criteria. Scores from TASI and ADOS-2 were compared across nonASD (did not meet autism diagnostic criteria) and ASD (met diagnostic criteria) groups using a Mann-Whitney U test.

Results: All children had a GMFCS level between III and V. Scores for TASI were of 'Low likelihood' (<7 points) for two children, and of 'High likelihood' (≥ 7 points) for 14 children. ADOS-2 scores were within the 'Not consistent with autism' range for three of the children, and within the 'Consistent with autism' range for 13 children. Of the 14 and 13 children whose scores indicated likelihood of autism on TASI and ADOS-2, respectively, only four met diagnostic criteria for an autism diagnosis (ASD). The average score of the nonASD group on the TASI was 11.17 ($SD=4.43$), and 20.75 ($SD=5.50$) for the ASD group ($p=0.02$). The average score on the ADOS-2 was 13.75 ($SD=4.65$) for the nonASD group and 23.50 ($SD=5.69$) for the ASD group ($p=0.001$). Although TASI and ADOS-2 scores were above the cut-off on both groups, these correctly identified all four cases of autism, and the scores in the ASD group were higher than the nonASD group. However, both tools miscategorized most of the children who did not meet clinical criteria for autism ($n=10$, and $n=9$, respectively). Nine of these 10 children were miscategorized by both tools.

Conclusions: Autism diagnostic assessments using TASI and ADOS-2 in children with cerebral palsy will likely yield scores above the established cut-off. While these tools correctly identified children who met criteria for an autism diagnosis, potential modifications in scoring and cutoff points when administering to children with CP could lead to better accuracy in discriminating non-autism cases.

438.133 Physiological Responses to Stranger Approach in Autistic Children, Non-Autistic Siblings, and Neurotypical Peers: Insights into Early Social Fear

M. Norozi¹, A. L. Hogan¹ and J. Roberts², (1)Department of Communication Sciences and Disorders, University of South Carolina, Columbia, SC, (2)Department of Psychology, University of South Carolina, Columbia, SC

Background: Autistic children are at elevated risk for social anxiety, which can lead to increased social avoidance and communication difficulties. Non-autistic siblings of autistic children (NA-Siblings) are also at elevated risk for social anxiety, due to environmental and genetic factors associated with autism. While early social fear has been shown to robustly predict later social anxiety in non-autistic (NA) children, much remains unknown about social fear in autistic children and NA-Siblings, especially in early childhood when preventative interventions could be most beneficial. Heart activity during the approach of a stranger can provide critical insight into the physiological mechanisms underpinning social fear in young children, as it reflects how the autonomic nervous system responds to stress in social contexts.

Objectives: To determine whether physiological responses during a stranger approach differ in autistic children and NA-siblings contrasted against NA children.

Methods: Participants included 39 autistic children ($M[SD]=3.72[0.65]$ years, 82% male), 20 NA-Siblings ($M[SD]=4.14[1.03]$ years, 60% male), and 30 NA children ($M[SD]=3.81[0.90]$ years, 76.6% male), ranging from 2-6 years of age. The groups were similar in age, $F(2,86)=1.69$, $p=.189$. Electrocardiogram (ECG) was measured during two tasks: (1) A baseline phase in which participants watched a five-minute animation; and (2) the Stranger Approach (SA) press of the Laboratory Temperament Assessment Battery, which consisted of three distinct phases: Approach, Kneel, and Withdraw. Two variables were derived from the ECG: (1) Interbeat interval (IBI), the time elapsed between consecutive heart beats, which indexes overall arousal; and (2) Respiratory sinus arrhythmia (RSA), the variability in IBI that corresponds with spontaneous breathing, which indexes parasympathetic regulation. Repeated measures ANOVAs were used to examine the effect of group, phase, and group*phase interaction on IBI and RSA. Bonferroni-corrected post-hoc analyses were conducted to identify specific differences.

Results: For IBI, significant main effects of phase, $F(3,258)=43.96$, $p<.001$, and group, $F(2,86)=3.29$, $p=.041$, were observed. The group*phase interaction was non-significant, $F(6,258)=0.78$, $p=.584$. IBI was shorter during the three SA phases than during baseline, $ps<.001$, but IBI did not differ between the SA phases, $ps\geq.90$. Autistic children exhibited shorter IBI than NA-Siblings and NA children, $ps\leq.015$. The NA-Siblings children exhibited longer IBI than the NA children, $p<.001$. For RSA, the main effect of phase was significant, $F(3,258)=18.48$, $p<.001$, but the main effect of group and the group*phase interaction were non-significant, $Fs\leq 2.82$, $ps\geq.064$. RSA was lower during all three SA phases than during baseline, $ps<.001$. RSA was lower during the approach phase than during the kneel phase, $p<.01$. All other SA phase differences were non-significant, $ps\geq.11$.

Conclusions: Findings suggest that autistic children exhibit heightened physiological arousal (i.e., shorter IBI) overall but normative patterns of IBI reactivity during a stranger approach, while NA-Siblings exhibit lower arousal (i.e., longer IBI) overall, highlighting distinct physiological profiles despite increased risk for social anxiety. Surprisingly, groups did not differ in parasympathetic regulation (i.e., RSA), and all groups exhibited the adaptive physiological response of RSA suppression when approached by a stranger. Future longitudinal studies should explore the long-term implications of physiological responses on the development of social anxiety symptoms.

438.134 Predictors of Aggression in Autistic and Non-Autistic Youth: The Role of Anxiety and Executive Functioning

N. Altinordu¹, L. Mancell¹, Q. Lanza¹, M. Santhosh², E. Neuhaus³, S. J. Webb⁴, H. Rea⁵ and G. A. Consortium⁶, (1)University of Washington, Seattle, WA, (2)Center for Child Health, Behavior and Development, Seattle Children's Research Institute, Seattle, WA, (3)Department of Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (4)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (5)Center for Human Development and Disability, University of Washington, Seattle, WA, (6)Seattle Children's Research Institute, Seattle, WA

Background: Aggressive behaviors are prevalent among autistic children and are associated with social-emotional challenges (Reid et al., 2020). Aggression, anxiety, and executive functioning challenges often co-occur in autistic children but are usually examined separately (Sullivan et al., 2019). Further, aggression is typically studied cross-sectionally. Therefore, a longitudinal model that examines aggression alongside mental health is essential for understanding the trajectory of aggression.

Objectives: We investigated the relationship between anxiety, executive functioning, and aggression as predictors of later aggression measured 3 to 8 years later in autistic and non-autistic youth. As IQ and age correlate with aggression (Neumeyer et al., 2019), those were included as covariates.

Methods: Participants included 57 autistic (40% female) and 84 non-autistic (49% female) youth ages 8 to 17 years who participated in the GENDAAR study at both T1 ($M=12.82$, $SD=2.81$) and T2 ($M=18.17$, $SD=2.76$). The ACE GENDAAR network investigated sex and gender differences in autistic and non-autistic youth with average or above IQ. Separate models were run for autistic and non-autistic participants due to significantly higher levels of aggression in autistic participants at T1 ($t(209)=-9.63$, $p<.001$) and T2 ($t(89)=-5.05$, $p<.001$). IQ was assessed using the Differential Abilities Scale. Aggression and anxiety were measured using the age-appropriate form of the Achenbach System of Behavioral Assessments (Child Behavior Checklist or Adult Behavior Checklist). EF was measured using the Behavior Rating Inventory of Executive Function. Multiple linear regressions were performed to examine whether T1 aggression, anxiety, and executive functioning, controlling for age and IQ, predicted T2 aggression in autistic and non-autistic participants separately.

Results: Regression models were significant for autistic ($F(5,51)=11.08$, $p<.001$, $R^2=52\%$) and non-autistic ($F(5,78)=18.95$, $p<.001$, $R^2=55\%$) participants. For autistic participants, T1 aggression and anxiety were significant predictors of T2 aggression. For non-autistic participants T1 aggression, anxiety, and executive functioning were significant predictors of T2 aggression. See Table 1 for results.

Conclusions: Overall, findings suggest key group differences in predictors of aggression. Variability may arise from the distinct developmental trajectories and social experiences of autistic and non-autistic youth. Autistic youth face unique social challenges, including difficulty navigating social interactions, communication challenges, and sensory sensitivities, which may contribute to heightened anxiety and aggression. Conversely, challenges with executive functioning, (e.g., poor impulse control, difficulty regulating emotions) may contribute to aggression in non-autistic youth. These findings highlight the importance of tailoring interventions that target aggression to address the unique needs of each group. Future research should explore how predictors of aggression evolve and impact long-term outcomes. Additionally, investigating the interplay between anxiety, executive functioning, and aggression in more diverse populations could provide a broader understanding of these dynamics.

438.135 Predictors of Internalizing and Externalizing Behaviors Among Autistic Adults

K. Garcia Alday¹, **N. Sheikh²**, **M. Armstrong³**, **N. Toumanios⁴**, **E. T. Crehan⁵** and **S. Faja⁶**, (1)Developmental Medicine-Laboratories of Cognitive Neuroscience, Boston Children's Hospital Laboratories of Cognitive Neuroscience, Brookline, MA, (2)Laboratories of Cognitive Neuroscience, Boston Children's Hospital, Brookline, MA, (3)Labs of Cognitive Neuroscience, Boston Children's Hospital, Boston, MA, (4)Tufts University, Boston, MA, (5)Eliot-Pearson Department of Child Study & Human Development, Tufts University, Medford, MA, (6)Boston Children's Hospital, Harvard, Boston, MA

Background:

Co-occurring mental health conditions are more prevalent among autistic individuals compared to the general population. Yet, diagnosis and treatment of these conditions based on clinical practice designed for the general population often leads to uncertainties in the efficacy of identifying and targeting the specific needs of the autistic population. To reduce risk factors associated with mental health conditions such as suicidality among the autistic community, there is a critical need to understand the unique intersection of autism and mental health outcomes. The identification of predictors of mental health outcomes could inform the development of new assessments and interventions tailored to address the specific needs of the autistic community.

Objectives: To identify predictors of internalizing and externalizing behaviors among autistic adults to support their mental well-being.

Methods: 21 autistic adults (52.3% female), ages 18-29 ($M_{age}=23.22$ years) participated so far in this ongoing study. Diagnoses were confirmed using the Autism Diagnostic Observation Schedule and Autism Quotient (AQ). Cognitive skills were measured using the Wechsler Abbreviated Intelligence Scale ($M_{FSIQ}=117.57$). Participants completed the Adult Repetitive Behavior Questionnaire to measure repetitive behaviors and the Achenbach Adult Self Report (ASR) to measure adaptive functioning and mental health. Linear regression models were run to examine whether overall AQ, cognitive skills, and RRBQ totals contributed to internalizing and externalizing total and subscale scores from the ASR.

Results: For internalizing behaviors, AQ total scores significantly predicted internalizing total scores ($\beta=.787$, $p<.016$). Additionally, AQ predicted withdrawal subscale total scores ($\beta=.855$, $p<.001$); depressive total scores ($\beta=.629$, $p<.042$); and scores for the anxiety/depression subscale ($\beta=.698$, $p<.043$). For externalizing behaviors, none of the predictors showed statistical significance. Cognitive skills and repetitive behaviors were not related to internalizing or externalizing behaviors.

Conclusions:

These findings indicate that the presence of self-reported autistic traits predicts mental health outcomes such as levels of anxiety and depression. These results are consistent with what has been reported in previous studies, indicating that autism increases the risk of poor mental health outcomes. Various factors might explain this co-occurrence, including shared underlying mechanisms cutting across autism and mental health conditions, as well as distinct life experiences associated with being on the spectrum. Having autism and co-occurring mental health conditions might negatively impact long-term outcomes such as adaptive functioning, social skills, and risk of suicidality. Our analysis explored concurrent relations between mental health outcomes and autism features, cognitive skills, and repetitive behaviors; however, prospective longitudinal analysis will allow us to further examine these relationships over time. Additionally, we aim to include other potential predictors in a larger sample, such as psychosexual functioning and masking of autistic traits. Our findings may further the understanding of the intersectionality of autism and mental health conditions, which may inform intervention and diagnosis services to improve autistic quality of life.

438.136 Predictors of Satisfaction with Mental Healthcare for Autistic and Non-Autistic Adults

R. C. Ball¹, **A. L. Richdale²**, **L. P. Lawson³** and **E. Morris⁴**, (1)Dept. of Psychology Counselling and Therapy, Latrobe University, Bundoora, VIC, Australia, (2)Olga Tennison Autism Research Centre, La Trobe University - OTARC, Bundoora, VIC, AUSTRALIA, (3)Department of Psychology, Counselling & Therapy, La Trobe University, Melbourne, VIC, AUSTRALIA, (4)Department of Psychology, Counselling & Therapy, La Trobe University, Melbourne, VIC, Australia

Background: Autistic individuals experience high rates of mental ill-health and are over-represented amongst mental health service users. However, they often report dissatisfaction with their mental healthcare experiences. While research on improving physical healthcare for autistic people emphasizes improving accommodations for sensory and communication needs, limited mental healthcare research suggests other factors are important for positive mental healthcare outcomes, including the therapeutic relationship and practitioners' openness and knowledge about autism. **Objectives:** To identify the most important factors predicting satisfaction with mental healthcare for autistic adults (self-reported diagnosis: "D-Aut"; self-identified: "S-Aut") and compare these factors with those of non-autistic ("N-Aut") adults. We hypothesized all groups would similarly prioritize factors beyond accommodations as the main predictors of satisfaction.

Methods: Australian adults (N=426, M_{age} = 38 years, 72% female gender identity; D-Aut n=153; S-Aut n=134; N-Aut n=139) participated in an online survey about their mental healthcare experiences. Thirty-six items, developed from existing literature and advice from five autistic consultants, were categorized into four factors: Accommodations, Positive Practitioner Qualities, Knowledge, and Treatment Tailoring and Effectiveness. Participants rated their satisfaction with their most recent mental health practitioner and the 36 experience items using 5-point Likert scales (1=Very Low or Untrue; 5=Very High or True). Averages were calculated for each factor and groups were compared using Analysis of Variance. Standard multiple regression analyses were conducted to determine the significant predictors of satisfaction for the entire sample and within each group.

Results: Table 1 shows there were no significant differences in mean *Satisfaction* ratings between groups, with all mean factor ratings being similar across groups except for *Accommodations* where D-Aut gave significantly higher mean ratings than S-Aut. Table 2 shows all regression models were significant, explaining large proportions of variance in *Satisfaction*. For the entire sample, all four factors significantly predicted *Satisfaction* although *Accommodations* was a weak predictor. The significance and strength of predictors differed across groups. *Practitioner Qualities* was the strongest predictor for D-Aut and N-Aut groups, whereas *Treatment* was the strongest predictor for S-Aut, with *Practitioner Qualities* being a weaker predictor in this group. *Treatment* was also a strong predictor for D-Aut and N-Aut participants. *Knowledge* was a strong predictor for both autistic groups but was weaker for N-Aut participants. *Accommodations* was only a significant predictor for the S-Aut group but was a weak predictor.

Conclusions: Overall, participants reported moderate satisfaction with their practitioners. Across groups, all factors except Accommodations strongly predicted satisfaction. Notably, Treatment was the strongest predictor for the S-Aut group rather than Practitioner Qualities, and Knowledge was less influential for the N-Aut group compared to the two autistic groups, perhaps indicating that practitioners' knowledge about autism is crucial for autistic clients' mental healthcare outcomes. These findings suggest accommodations may be important pre-requisites for effective mental healthcare, but once provided, factors related to practitioner expertise, personalized treatment and therapeutic relationship quality are more important in determining satisfaction. Therefore, practitioners should focus on improving their knowledge, providing individually tailored treatments, and fostering strong therapeutic relationships to enhance satisfaction for all clients, whether autistic or not.

438.137 "My Answer Doesn't Fit Your Options": Measuring Self-Harm and Suicidality with Autistic Adults Using the Self-Harm Injurious Thoughts and Behaviours Inventory (SITBI)

I. Gordon¹, M. Pelton², J. Goodwin³, R. Herrington⁴, J. Rodgers⁵ and S. A. Cassidy⁶, (1)University of Nottingham, Nottingham, Nottinghamshire, United Kingdom, (2)University of Cambridge, Cambridge, Cambridgeshire, United Kingdom, (3)Other, Newcastle Upon Tyne, United Kingdom, (4)Newcastle University, Newcastle, Tyne and Wear, United Kingdom, (5)Population Health Sciences Institute, Newcastle University, Newcastle, Newcastle upon Tyne, United Kingdom, (6)School of Psychology, University of Nottingham, Nottingham, Nottinghamshire, UNITED KINGDOM

Background: Autistic people are a high-risk group for suicide and self-harm is one of the strongest predictors of death by suicide amongst autistic people. New tools have been validated to capture the suicidal experiences and meet communication preferences of autistic people, but there are no validated measures to assess self-harm. The SITBI is a widely used outcome measurement tool in clinical research about self-harm in the general population but has not yet been comprehensively validated in autistic people. There is currently no guidance for researchers to support autistic participants to complete questionnaires measuring suicidality and self-harm that are designed for non-autistic people.

Objectives: We aimed to describe the challenges reported by autistic participants when completing the SITBI and researchers' experiences of supporting them to provide recommendations for future research.

Methods: The final meeting with autistic collaborators of a pilot randomized controlled trial of autism adapted safety plans stressed the importance of collaborative research to explore how best to capture self-harm and suicidality in future trials. To address this, we undertook thematic analysis of 46 feasibility interview transcripts (participant mean age = 39, 49% female, 29% not male or female) from the final stage of data collection.

Results: As shown in Figure 1, we identified an overarching theme 'Identifying an authentic response: "My answer doesn't fit your options"' in which participants described working in trusting partnership with researchers to overcome ambiguous language and a lack of meaningful response options. Sub-themes described how these challenges extended into descriptions of autistic experiences of suicidal plans, suicidal ideation and self-harm. Firstly, the sub-theme 'Conceptualising suicidal experiences' described how questions about suicide plans required detailed definition to delineate plans from thoughts and actions. Secondly, the sub-theme 'Defining parameters of suicidal ideation' described how participants' frequent and enduring *suicidal ideation* made it difficult to calculate required numeric responses and items did not capture fluctuations in intensity in a meaningful manner. Thirdly, the sub-theme 'Capturing self-harm' describes participants seeking clarification whether self-harm within the SITBI includes instances of self-neglect, eating difficulties and autistic experiences such as stimming and meltdown.

Conclusions: Researchers should develop trust with autistic participants, validate their experience and work collaboratively to best fit experience to the available response options. Researchers can support participants by clarifying meaning of key terms, such as suicidal thoughts, suicide plans and self-harm and provide strategies to support participants to estimate numeric responses. Future research studies can work with autistic collaborators to decide the most valid approach to capture self-harm and suicidality experiences of autistic people depending on study design and aims. Future research could consider developing an autism-specific module to supplement the SITBI to capture autistic experiences of self-harm.

438.138 Relationship between Food Selectivity, Sleep Problems and Irritability in Autistic Youth

P. D. Radoeva^{1,2}, **R. G. McDonald**³, **C. Elizardo**⁴, **E. A. Li**¹, **C. H. Legere**¹, **J. M. Saletin**^{1,2}, **J. I. Hunt**^{1,2}, **S. Deoni**⁵, **S. J. Sheinkopf**⁶, **C. A. Mazefsky**⁶, **N. S. Philip**⁶ and **D. P. Dickstein**^{7,8}, (1)Bradley Hospital, East Providence, RI, (2)Warren Alpert Medical School of Brown University, Providence, RI, (3)Department of Psychology, Montclair State University, Montclair, NJ, (4)Thompson Center for Autism & Neurodevelopment, University of Missouri, Columbia, MO, (5)Department of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, PA, (6)VA Providence Healthcare System, Providence, RI, (7)McLean Hospital, Belmont, MA, (8)Harvard Medical School, Boston, MA

Background: Problems with feeding, sleep and emotional reactivity have been independently described in autistic children and adolescents, and frequently occur at a higher rate in autistic youth than in their neurotypical peers. Yet, the relationship between these difficulties has not been well characterized. Better understanding of these relationships could pave the way for the development of additional and more comprehensive treatment strategies.

Objectives: Our study sought to examine factors associated with emotional reactivity in autism: specifically, focusing on the relationship amongst food selectivity, sleep problems and emotional reactivity.

Methods: Children and adolescents with autism ($N=27$, Age : 14.5, SD_{age} : 1.91, Range 11-17 years; 3.7% Asian, 3.7% Black, 7.4% Multiracial, 81.5% White, 3.7% Not Reporting; 7.4% Hispanic or Latino; 37% female; $IQ > 80$) were recruited for an IRB-approved study, conducted in the northeastern United States. Parents completed the Brief Autism Mealtime Behavior Inventory (BAMBI), Sleep Disturbance (Patient Reported Outcomes Measurement Information System [PROMIS]) and Sleep-Related Impairment (PROMIS) questionnaires, and the Emotion Dysregulation Inventory (EDI). Shapiro-Wilk tests of normality were used to assess the distributions of the following variables of interest: BAMBI food selectivity sum score, sleep disturbance PROMIS t-score, sleep-related impairment PROMIS t-score, and EDI emotional reactivity t-score. For normally distributed variables, Pearson correlations were conducted.

Results: The BAMBI food selectivity sum score was positively correlated with the sleep-related impairment PROMIS t-score ($r=.42$, $p<0.05$), but not with the sleep disturbance PROMIS t-score ($r=.27$, $p=.19$). The sleep disturbance PROMIS t-score and sleep-related impairment PROMIS t-score were each positively correlated with the EDI emotional reactivity t-score ($r=.63$, $p<0.001$ and $r=.52$, $p<0.01$, respectively). A positive correlation emerged between the BAMBI food selectivity sum score and the EDI emotional reactivity t-score ($r=.49$, $p=0.01$).

Conclusions: Our results suggest that more pronounced food selectivity and sleep problems are associated with more severe emotional reactivity in autistic youth. While our small sample size is a limitation, it is important that additional studies are conducted to evaluate (1) the relationship between problems with feeding, sleep and emotional reactivity in autistic youth; and (2) the direction of the effects (e.g., in longitudinal studies), which could help identify appropriate treatment targets.

438.139 Relationship between Sleep Disturbances, Sensory Sensitivities, and Anxiety Problems in Preschool Children with Autism Spectrum Disorder

L. Y. Lin and **S. C. Yang**, Department of Occupational Therapy, National Cheng Kung University, Tainan, Taiwan, Taiwan

Background: Rest and sleep play vital roles in our daily lives, enabling us to function at our best. However, inadequate sleep quality can have adverse effects on children's development, impacting their behavior, learning, language, and immune systems. Children with Autism Spectrum Disorder (ASD) are particularly susceptible to sleep disturbances, with up to 89.7% experiencing such issues. Furthermore, sensory sensitivities are commonly observed in children with ASD and have been linked to emotional challenges. Previous studies conducted in the Western context have shown that sensory sensitivities and anxiety problems are frequently associated with sleep disturbances in preschool children with ASD.

Objectives: This study seeks to delve into the connections between sleep disturbances, sensory sensitivities, and anxiety problems in preschool children with ASD in Taiwan.

Methods: The study involved 47 preschool children with ASD, comprising 39 boys and 8 girls, who scored above 30 (mean = 32.8) on the Childhood Autism Rating Scale-Second Edition (CARS2-ST) and above 70 on the Peabody Picture Vocabulary Test-Revised (PPVT-R).

Caregivers were tasked with completing three questionnaires: Children Sleep Habits Questionnaires-Chinese version (CSHQ-C), Sensory Profile 2-short form (SSP), and Children Behavior Checklist, 1.5-5 years version (CBCL). Pearson correlation analysis was utilized to explore the relationships between sleep disturbances, sensory sensitivities, and anxiety problems.

Results: The results from CSHQ-C revealed that 97.9% of preschool children with ASD experienced a higher prevalence of sleep disturbances. The average total raw score in CSHQ exceeded the cut-off score of 41, indicating a mean total raw score of 57. Additionally, 80.9% of children scored higher than most people in sensory sensitivities, and over 61% of participants reported a moderate or severe level of anxiety problems using a cut-off score of 65. Significant correlations were found between sleep disturbances and sensory sensitivities ($r = 0.506$, $p < 0.001$), as well as between sleep disturbances and anxiety problems ($r = 0.524$, $p < 0.001$). Sensory sensitivities also demonstrated a moderate correlation with anxiety problems ($r = 0.594$, $p < 0.001$). Regression analyses revealed that children with sleep disturbances reported more sensory sensitivities and anxiety problems, with anxiety problems mediating the relationship between sensory sensitivities and sleep disturbances.

Conclusions: This study emphasizes the importance of considering sensory processing difficulties and sleep disturbances when addressing anxiety problems in preschool children with ASD. Anxiety problems act as a mediator, reducing the significant relationship between sensory sensitivities and sleep disturbances. Therapeutic interventions should consider the presence of sensory sensitivities and anxiety problems in addressing sleep disturbances among preschool children with ASD.

438.140 Relationship between a Gatekeeping Function during Sleep and Specific Sensory Issues in Children with Autism

T. Ishii¹, **P. T. Taweessedt**¹, **A. Nguyen**², **S. E. Chen**², **E. Gropman**¹, **Z. Li**¹, **B. Kim**¹, **C. F. Chick**¹, **I. Cotto**¹, **J. M. Phillips**¹, **B. Jo**¹, **M. Kawai**¹, **R. O'Hara**¹ and **J. F. Hallmayer**¹, (1)Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA, (2)Stanford University, Stanford, CA

Background: Among the most common symptoms in patients with autism are sleep disturbances and sensory issues. Sleep disturbances are reported to occur in 50-80% of patients, and sensory issues in 60-90%, both of which are known to affect the quality of life of patients and their families. While disruption of sensory gating mechanisms in the thalamus has been proposed as a background for sensory issues in patients with autism, it is also known that the thalamus plays an important role in sleep-wake control. However, whether sensory issues and sleep problems in autism coexist on a common neural basis or whether a causal relationship exists between them remains to be clarified.

Objectives: This study aimed to evaluate the impact of sensory issues on sleep problems in patients with autism by assessing sleep disturbances in detail using subjective and objective measures.

Methods: Forty-eight patients with autism (10 Females; age: 9.9 ± 3.8 years; age range: 4-17 years) participated in the study. The Sensory Profile, 2nd Edition (SP-2) and Children's Sleep Habits Questionnaire (CSHQ) were used to assess sensory issues and subjective sleep problems, respectively. After a desensitization period of several weeks, ambulatory polysomnography (PSG) was conducted at each participant's home for an objective sleep assessment. Whole-night PSG data was obtained from 35 participants. PSG was scored using the American Academy of Sleep Medicine criteria, and regression analyses were performed to assess the relationship between SP-2 and sleep parameters.

Results: The major findings are summarized as follows. 1) CSHQ scores were positively correlated with scores from all SP-2 quadrants (Registration, Seeking, Sensitivity, and Avoiding) but particularly strongly associated with Sensitivity ($r=0.53$, $p=0.0001$). 2) In each sensory subsection of the SP-2, scores for touch, oral, and auditory processing were significantly correlated with CSHQ scores ($r=0.38$, $p=0.01$; $r=0.47$, $p=0.0007$; and $r=0.40$, $p=0.005$, respectively) 3) Among PSG sleep parameters, wake after sleep onset (WASO) was positively correlated with touch processing scores ($r=0.28$, $p=0.04$).

Conclusions: The strength of the correlation between sensory issues and sleep problems varied with the type of sensory property, indicating specific sensory issues may be related to sleep disturbances in patients with autism. Furthermore, PSG analysis results suggest that sensory issues are more strongly associated with difficulties in sleep maintenance than sleep onset problems, suggesting the disruption of the gatekeeping mechanism during sleep shares a common neural basis with sensory issues in autism. These results indicate that sensory issues are at least partly responsible for sleep problems in patients with autism and that interventions for sensory issues may improve sleep problems commonly observed in patients.

438.141 Self-Reported Factors Underlying Suicidal Thoughts and Feelings in Autistic People

R. L. Moseley¹, S. J. Marsden², C. Allison³, T. Parsons⁴, S. A. Cassidy⁵, T. L. Procyshyn⁶, M. Pelton⁷, E. M. Weir⁸, T. A. Chikaura⁹, D. Mosse¹⁰, I. Hall¹⁰, L. Owens¹¹, D. Crichton¹², J. Rodgers¹² and S. Baron-Cohen¹, (1)Department of Psychology, Bournemouth University, Poole, United Kingdom, (2)United Kingdom, (3)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, Cambridgeshire, United Kingdom, (4)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, Cambridge, United Kingdom, (5)School of Psychology, University of Nottingham, Nottingham, Nottinghamshire, UNITED KINGDOM, (6)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, NA, United Kingdom, (7)University of Cambridge, Cambridge, Cambridgeshire, United Kingdom, (8)Psychiatry, Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, Cambridgeshire, United Kingdom, (9)Department of Anthropology and Sociology, SOAS University of London, London, United Kingdom, (10)East London NHS Foundation Trust, London, London, United Kingdom, (11)EdmissionUK, London, London, United Kingdom, (12)Population Health Sciences Institute, Newcastle University, Newcastle, Newcastle upon Tyne, United Kingdom

Background:

Suicide is a leading cause of death for autistic people worldwide, with lifetime prevalence of suicide ideation and attempts estimated at 1 in 3 and 1 in 5, respectively (Newell et al., 2023). While numerous correlates of suicidal thoughts and behaviours have been identified (Brown et al., 2024), understanding of the factors facilitating the ideation-to-action trajectory, which is essential for risk assessment and intervention, remains in its infancy. Since theories developed in neurotypical populations do not appear to operate equivalently in autistic people (Pelton et al., 2023), it is essential to examine autistic people's accounts and factors identified by those with experience of suicide ideation and attempts.

Objectives:

In a mixed-methods approach, we explored ratings of the most important contributing factors in a large autistic sample with different degrees of suicidal experience. Through thematic analysis of free-text responses, we hoped to derive deeper conceptual understanding of contributing factors. We examined whether ratings differed by age and gender, and whether self-reported contributing factors were useful predictors of varying levels of lifetime suicidality.

Methods:

Via an online survey designed with input from autistic people, autistic adults without intellectual disabilities (n=1369, 94% British) rated the importance of 19 pre-defined factors contributing to their suicidal thoughts and feelings, with some (n=544) adding their own factors. All participants (718 cisgender women, 326 cisgender men, 325 transgender/gender-divergent participants) had experienced some degree of suicidal thoughts, and almost 40% had attempted suicide at least once. Following thematic analysis of free-text responses, we compared ratings of contributing factors by age and gender, and used multinomial regression to examine contributing factors as predictors of lifetime suicidality.

Results:

Loneliness, feelings of worthlessness/failure, hopelessness and mental illness were consistently the highest rated contributing factors (Figure 1); analysis by gender suggested particular weighting to these factors by autistic women and gender-divergent individuals, and effects of age suggested hopelessness most strongly affected those aged 26-40. While qualitative responses (Figure 2) indicated contributions of some experiences and feelings identified as relevant to suicide in non-autistic people (e.g. abuse), being autistic appeared to heavily colour both the proximal stressors (e.g. societal rejection) and cognitive-emotional states (e.g. feelings of difference distancing one from other people) underpinning suicidal feelings. Greater importance of bullying, hopelessness, being unable to access support, mental health problems and past trauma differentiated between participants with different degrees of suicidal experience, while greater importance of difficulties accessing support and past trauma differentiated between participants with and without suicide attempts.

Conclusions:

Our findings offer three essential implications for suicide research, assessment and intervention. First, contributing factors for suicide differ by age and gender in autistic people. Second, while factors derived from autistic people's descriptions of suicidal experiences partially resemble those reported in neurotypical people, they differ in fundamental aspects, apparently augmented by common experiences and psychological differences associated with being autistic. Three, experiencing barriers to support and trauma appear as particular predictors of suicidal behaviour among autistic people.

438.142 Sex Differences in Social Anxiety Symptoms and Social Attention Among Children with and without ASD: Results from the Autism Biomarkers Consortium for Clinical Trials (ABC-CT)

M. Reninger¹, J. McPartland², R. A. Bernier³, N. Kleinhans⁴, G. Dawson⁵, S. Jeste⁶, S. Faja⁷, S. J. Webb³, A. Naples⁸, C. Sugar⁹, J. Dziura¹⁰, K. J. Dommer¹ and F. Shic¹, (1)Center for Child Health, Behavior and Development, Seattle Children's Research Institute, Seattle, WA, (2)Yale Child Study Center, Yale Child Study Center, New Haven, CT, (3)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (4)University of Washington, Seattle, WA, (5)Department of Psychiatry and Behavioral Sciences, Duke University, Durham, NC, (6)Children's Hospital Los Angeles, Los Angeles, CA, (7)Boston Children's Hospital Laboratories of Cognitive Neuroscience, Brookline, MA, (8)Yale Child Study Center, Yale University School of Medicine, New Haven, CT, (9)University of California, Los Angeles, Los Angeles, CA, (10)Yale University, New Haven, CT

Background: Social anxiety is a common co-occurring condition with autism spectrum disorder (ASD) (Spain et al., 2018), and there is evidence of increased social anxiety symptoms (SAS) in girls compared to boys in both ASD and typically developing (TD) children (May et al., 2014). Increased social anxiety has been associated with atypical and increased initial attention to faces (Gregory et al., 2019). It has been shown that children with ASD show decreased attention to faces compared to their TD peers (Shic et al., 2022) and that ASD girls have increased attention to faces compared to ASD boys (Harrop et al., 2020).

Objectives: Explore the effects of SAS and biological sex on attention to faces using eye-tracking, based on two hypotheses: ASD-females exhibit higher SAS levels as compared to other groups and higher levels of social attention compared to ASD-males.

Methods: Children 6-11-years-old with ($n=280$) and without ($n=119$) ASD participated in a longitudinal observational study involving 3 visits with clinical measures and an eye-tracking battery. We evaluated the percentage of time spent looking at the actresses' faces, %Face, during the eye-tracking Activity Monitoring paradigm (videos and still images of two actresses engaging in a shared activity). We divided participants into high- and low-SAS based on symptom count (≥ 2 being high-SAS) as reported on the Child and Adolescent Symptom Inventory (CASI-5) during any visit. Chi-squared tests were used to evaluate proportional differences in SAS between Diagnosis-Sex groups. Linear mixed models evaluated %Face~Sex*Diagnosis and %Face~Sex*(combined SAS-Diagnosis) with covariates of IQ and age and random participant intercept. Due to its underpowered size ($n=2$), the high-SAS TD group was removed and the second model used combined SAS-Diagnosis group.

Results: Chi-squared tests showed that ASD-females had higher proportions of high-SAS as compared to ASD-males ($p=0.012$), TD-females ($p<0.001$), and TD-males ($p<0.001$) (Table 1). ANOVA of the first %Face model indicated main effects of Sex (females>males), Diagnosis (TD>ASD), and age (all $p<0.001$), and no interactions. ASD-females showed greater %Face than ASD-males ($p=0.037$) (Figure 1). ANOVA of the second %Face model indicated main effects of Sex (female>male), SAS-Diagnosis group (low-SAS TD>high-SAS ASD>low-SAS ASD), and age (all $p<0.001$), and no significant interactions. High-SAS ASD-females showed higher %Face than low-SAS ASD-females ($p=0.014$) and ASD-males with low- ($p=0.001$) or high-SAS ($p=0.015$), lower %Face compared to low-SAS TD-females ($p=0.003$), and no significant difference compared to low-SAS TD-males.

Conclusions: The results provide support for the existence of both Sex and Diagnosis differences on SAS and social attention and supported the two hypotheses. For ASD-females, having higher-SAS was associated with increased %Face compared to their ASD peers (male and low-SAS female). Yet TD-females showed higher %Face than TD-males even though they were low-SAS. Together, this may suggest mechanisms underlying increased %Face in girls with ASD may differ from that in TD girls. Future analyses could explore item-level scores to identify specific symptoms associated with increased social attention in girls with ASD.

438.143 Sex, Race, and Ethnicity Predict Patterns of Comorbid Autism Spectrum Disorder and Mental Health Diagnoses in Childhood and Adolescence

E. E. Long and M. S. Gaffrey, Pediatrics, Medical College of Wisconsin, Milwaukee, WI

Background:

Mental health disorders commonly co-occur with autism. However, the sequencing of these comorbid diagnoses has not been well studied. Given evidence for sociodemographic differences in rates of diagnosis and average age at diagnosis for both autism and numerous mental health disorders, patterns of comorbidity may differ across groups.

Objectives:

We investigated whether sex, race, and ethnicity impact the likelihood that a child receives an autism diagnosis before, after, or concurrently with a mental health diagnosis, and whether these factors impact the likelihood of receiving internalizing versus externalizing diagnoses.

Methods:

Data were extracted from the medical records of 3414 youth (959 girls). Children with diagnoses of both autism and a mental health disorder (i.e., mood disorders; anxiety disorders; disruptive, impulse-control, or conduct disorders; obsessive-compulsive disorder) were included. As the Benjamini-Hochburg False Discovery Rate correction for multiple comparisons was applied, q-values are reported.

Results:

Autism was diagnosed first for 39.1% of children. A mental health disorder was diagnosed first for 42.4% of children. Autism and a mental health disorder were diagnosed concurrently for 18.5% of children.

Sex predicted the sequencing of diagnoses ($\chi^2(2)=28.97, p<.001$). Girls were 1.37 times more likely than boys to receive a mental health diagnosis first compared to concurrent autism and mental health diagnoses ($q=.01$), and 0.64 times less likely to receive an autism diagnosis first than a mental health diagnosis first ($q=.005$). When mental health disorders were diagnosed first, girls were 1.79 times more likely than boys to receive an internalizing diagnosis ($q=.005$). Regardless of the sequencing of diagnoses, girls were diagnosed with autism on average 1.16 years later than boys ($q=.005$) and mental health disorders 0.67 years later than boys ($q=.005$).

Race and ethnicity also predicted the sequencing of diagnoses ($\chi^2(16)=31.91, p=.01$). Multiracial Hispanic children were 1.37 times more likely than White children to receive an autism diagnosis first than a mental health diagnosis first ($q=.03$), and 1.97 times more likely to receive an autism diagnosis first than concurrent diagnoses ($q=.005$). Race and ethnicity also predicted the likelihood that children would be diagnosed with an internalizing versus externalizing disorder when a mental health disorder was provided first ($\chi^2(8)=45.67, p<.001$). Black children ($OR=2.77, q=.005$) and multiracial Hispanic children ($OR=1.58, q=.05$) were more likely than White children to receive an externalizing diagnosis.

Conclusions:

Findings indicate that diagnostic patterns are associated with sex, race, and ethnicity. Girls are diagnosed with both autism and mental health disorders later on average than boys. Further, girls are more likely than boys to receive a mental health diagnosis, particularly an internalizing disorder, before an autism diagnosis, suggesting that the experience of anxiety and/or depression delays or overshadows the identification of autism in girls. Multiracial Hispanic children are more likely than White children to be diagnosed with autism first rather than a mental health disorder first or concurrent autism and mental health diagnoses, suggesting that mental health concerns may be overlooked in this population. Finally, results highlight significant racial and ethnic disparities in the likelihood that autistic children will receive an externalizing diagnosis.

438.144 Sleep Patterns of Children with a Family History of Autism Are Cyclically Associated with the Lunar Month

G. Rodríguez Ferrante¹, J. Munson², T. St. John³, J. Pandey⁴, L. Zwaigenbaum⁵, S. R. Dager⁶, N. Marrus⁷, R. T. Schultz⁸, H. Hazlett⁹, J. Piven⁹, H. de la Iglesia¹ and A. M. Estes¹⁰, (1)Biology, University of Washington, Seattle, WA, (2)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (3)University of Washington, Seattle, WA, (4)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (5)University of Alberta, Edmonton, AB, Canada, (6)Radiology, University of Washington, Seattle, WA, (7)Washington University in St. Louis, St. Louis, MO, (8)The Center for Autism Research/CHOP, Philadelphia, PA, (9)University of North Carolina, Chapel Hill, NC, (10)Speech and Hearing Sciences, UW Autism Center, Seattle, WA

Background: Our recent study indicates that during the days prior to the full moon human activity is extended into the nighttime in communities without access to electric light and, surprisingly, in young adults living in Seattle¹. During the nights prior to the full moon, sleep onset is delayed and sleep duration is shortened. This lunar modulation of sleep has been associated with switches between manic and depressive episodes in bipolar disorder patients^{2,3}. It is currently unknown whether the lunar regulation of sleep may represent a risk factor in other disorders associated with sleep dysfunction. In particular, sleep is impaired in autistic individuals, and disrupted sleep may, in turn, lead to greater impairments in functioning, but it is unknown whether this bidirectional relationship may be partially explained by the moon's effect on sleep.

Objectives: To test whether sleep-related outcomes are cyclically associated with the lunar month in children with a family history of autism.

Methods: Participants were 157 children between 7-12 years old with an autistic sibling (higher familial likelihood; HL n=102) or no familial history of autism (lower likelihood; LL n=55) from the multisite Infant Brain Imaging Study (IBIS) network. 31 HL children were diagnosed with ASD (HL-ASD). Participants wore an actimeter for 10 days. Sleep onset and duration were extracted from these recordings. We performed sinusoidal non-linear least squares models to test whether there was an association between these sleep variables and the day in the moon cycle in the HL-ASD, HL-noASD, and LL groups.

Results: We observed an association between the moon cycle and children's sleep patterns regardless of group (Figure 1), evidenced by the fact that the 30-day component of the fitted sinusoidal model showed a significant amplitude in all groups for both sleep onset (HL-ASD: $a=16\text{min}$, $p<0.001$; HL-noASD: $a=19\text{min}$, $p<0.0001$; LL: $a=26\text{min}$, $p<0.0001$) and duration (HL-ASD: $a=12\text{min}$, $p<0.0001$; HL-noASD: $a=11\text{min}$, $p<0.001$; LL: $a=13\text{min}$, $p<0.0001$). On average, variations through the lunar month (difference between maximum and minimum) were 44min for sleep duration and 68min for sleep onset. Interestingly, there were some differences in the shape of the sinusoids and the phase relationship between these two sleep-related variables and the moon cycle. For example, sleep duration was shorter during the full moon in non-autistic children, but autistic children showed shorter sleep duration during the new moon. Given our results, it is not clear whether moon cycle effects are disorder-specific, endophenotypic or familial.

Conclusions: These preliminary results show an association between sleep and the lunar month across all groups, regardless of diagnosis or familial history of ASD. This supports the idea that the lunar modulation of sleep may be conserved in typically developing children and those with neurodevelopmental disorders. Future studies are needed to determine the impact of the moon's modulation of sleep on children's functioning, and whether this impact is greater in autistic children than children with familial history of ASD or no family history of ASD. Understanding this effect could potentially reduce the cost and effort of sleep interventions by focusing on specific nights every lunar month.

**438.145 Social Anxiety Meets Social Virtual Environments: Perspectives and Adaptive Strategies of Autistic Adults**

V. D. Grillo^{1,2} and P. Venuti¹, (1)Department of Psychology and Cognitive Science, Laboratory of Observation, Diagnosis, and Education (ODFLab) - University of Trento, Rovereto, Trento, Italy, (2)Fondazione Bruno Kessler, Povo, Trento, Italy

Background:

Social anxiety, or social phobia, is marked by a fear of negative evaluation, often resulting in avoidance behaviors triggered by perceived social threats (see: DSM-5-TR; APA, 2022). Recently, growing recognition of co-occurring mental health conditions with their own distinct symptoms (Renno & Wood, 2013) has helped address the issue of "diagnostic overshadowing" (Kerns et al., 2016). This awareness prevents these symptoms from being minimized or misattributed to broader neurodevelopmental diagnoses like Autism Spectrum Conditions. Moreover, it has been found that social anxiety is more prevalent among autistic individuals, with up to 50% affected (Spain et al., 2018). Importantly, studies show social anxiety can hinder outcomes in social skills training (Spain et al., 2017), while camouflaging behavior, which correlates positively with autistic traits (Hull et al., 2018), poses as a significant risk factor for mental health challenges among autistic adults without intellectual disabilities, with no observed moderating effects related to gender (Hull et al., 2021). Consequently, there is a need for the development of specific, validated assessment tools and targeted intervention programs. As noted by Acker and colleagues (2018), there remains a substantial gap in the literature regarding the lived experiences of anxiety among autistic individuals, calling for further exploration in this area.

Objectives:

The current exploratory study aimed to gather insights into how autistic adults engage in social virtual environments, with the goal of identifying key factors that could inform the development of a tailored virtual intervention to support the needs and preferences of autistic users as articulated by them.

Methods:

We first conducted desk research. Following, we applied an adapted PRISMA framework (Moher et al., 2009) to systematically identify, screen, and select our sample. This included thirty publicly available, self-generated content pieces from autistic individuals, comprising over 450 minutes of audio/video recordings and more than 1,500 written comments and materials from online platforms, such as forums like Reddit. PRISMA was chosen to ensure a structured and transparent process in gathering comprehensive data. We then analyzed the data using thematic analysis (Braun & Clarke, 2023) with a reflexive approach (Braun & Clarke, 2021), incorporating theoretical and investigator triangulation for robustness.

Results:

One of the sub-themes identified in this study, derived from the autistic VRChat user community, is the shared experience of social anxiety and the perception that the platform has helped many in alleviating these feelings (e.g., "it cured my social anxiety"). The findings also explored various social adaptive strategies that were self-reported by more experienced users to assist less experienced autistic individuals in navigating the online environments. These behaviors were categorized into over thirty distinct strategies, grouped into three main areas which provide interpersonal and communication insights in regards to digital, virtual and In-Real-Life social interactions.

Conclusions:

Future research should further investigate the potential of digital and virtual platforms as a clinical tool for interventions to alleviate social anxiety within the autistic population.

438.146 Social Anxiety in Autistic Adults: The Role of Mental Imagery and Fear of Negative Evaluation

J. Lei¹, J. Attwood² and A. Russell³, (1)Department of Psychiatry, University of Oxford, Oxford, Oxford, United Kingdom, (2)Essex Partnership University NHS Trust, Basildon, Essex, United Kingdom, (3)Centre for Applied Autism Research, Psychology, University of Bath, Bath, UNITED KINGDOM

Background:

The Clark and Wells (1995) model of social anxiety (SA) underpinning cognitive therapy for SA proposes that fear of negative evaluation (FNE) from others and increased self-consciousness may result in individuals forming more negatively biased images of how one comes across to others in social situations. To date, the role of mental imagery in the maintenance of SA in autism remains poorly understood, especially when accounting for co-occurring generalised anxiety. Understanding maintenance mechanisms of social anxiety can inform treatment adaptations.

Objectives:

The following hypotheses were examined to explore the role of mental imagery in SA in autistic adults:

- Imagery will be more distressing in social versus relaxed condition
- FNE will be more positively associated with SA than generalised anxiety symptoms
- Greater SA and FNE may be associated with more distressing aspects of social imagery (e.g., upsetting, wanting to escape and greater anxiety elicited by the image)

Methods:

62 autistic adults (18-64 years; 35 female) recruited from social media and local autism services completed questionnaires online including Autism Quotient-10, Social Phobia Inventory, Brief Fear of Negative Evaluation Scale, Generalised Anxiety Disorder-7. Participants completed a structured Mental Imagery Interview (Hackmann et al., 1998) reported mental images in a relaxed versus socially anxious scenario. Participants rated the extent to which they experienced the image as vivid, controllable, realistic, upsetting, and making them want to escape, and how anxious they felt on a 0-10 scale. Friedman tests and Wilcoxon signed-ranks tests explored differences in imagery characteristics across social versus relaxed conditions (H1). Response Surface Analyses explored the extent to which: 1) assumed similarity in ratings of SA and GAD were associated with FNE, when controlling for autistic traits (H2); 2) assumed similarity in ratings of SA and FNE are associated with social imagery characteristics, when controlling for GAD (H3).

Results:

Participants self-reported a range of SA (M(SD): 34.18 (14.21)) and GAD (M(SD): 12.68 (5.57)) symptoms. Participants found social imagery more upsetting ($\chi^2(2) = 113.68, p < .001$), more likely to escape from/avoid ($\chi^2(2) = 90.70, p < .001$), more anxiety-inducing ($\chi^2(2) = 101.27, p < .001$), and less controllable ($\chi^2(2) = 35.49, p < .001$) compared to relaxed imagery (H1) (Table 1). FNE was significantly associated with both SA ($r = .56$) and GAD ($r = .40$) (H2). Greater SA was associated with wanting to escape from and experience of greater anxiety during social imagery. Greater GAD symptoms were associated with finding social imagery more upsetting and anxiety provoking. FNE was not associated with social imagery characteristics (H3) (Figure 1).

Conclusions:

The current study found that when controlling for generalised anxiety, only SA, not FNE, is associated with autistic adults finding social imagery to be more anxiety provoking and wanting to escape. For autistic adults, social imagery may be less associated with anticipated negative judgment from others, and more with general distress and bodily discomfort accompanying anxiety. Social imagery might maintain social anxiety in autistic adults through associated somatic and sensory discomfort, and related avoidance strategies, beyond FNE from others.

**438.147** Surveying the Diagnosis of Visual Impairment in Children with Autism

S. Quezada and J. R. Root, Special Education, Florida State University, Tallahassee, FL

Background: There is minimal empirical guidance for assessment or evidence-based interventions for children with autism (ASD) and visual impairment (VI) (Pili et al., 2021), particularly those with profound ASD and VI who have complex communication needs. Additionally, there is scarce research on the experiences of culturally diverse students and families impacted by ASD and VI comorbidities in the United States. Yet, blindness including total congenital blindness is a dominant risk factor for ASD (Jure et al., 2016) and is independent of other risk factors like cognitive disability and gender (Kiani et al., 2019). This pilot survey explored the diagnostic experiences of children with autism and visual impairment reported by parents and caregivers as a first step to examining the population's early assessment, diagnosis, and overall access to appropriate educational services.

Objectives: To identify factors impacting early assessment, diagnosis, and educational services among school-age children in Florida with dual ASD and VI.

Methods: The study is an exploratory pilot survey which used non-probability purposive and snowball sampling (Gay, 2011) to recruit parents/caregivers of school-age children with ASD and VI (ages 3-21 years) in the state of Florida to complete an on-line survey instrument developed by the presenter to identify factors contributing to the underdiagnosis of children with ASD and VI in the United States. Correlational analysis was used to determine the relationship between explored factors.

Results: The preliminary data presents findings on diagnosis and service experience of parents of children with ASD and VI in the state of Florida across **intersecting identities** (e.g., primary disability, race, ethnicity, gender), **culture** (e.g., language, custom, beliefs), **communication modes** (e.g., non-English-speaker, multilingual, augmentative alternative communication user), and **demographics** (e.g., geographic location, family composition) of **parents** and their **children** with ASD and VI. Our results show how these factors affect **special education eligibility, placement, performance, and the timeliness of services** for which the family and children qualify.

Conclusions: Researchers examining the prevalence of co-occurring ASD with medical and behavioral conditions routinely exclude visual impairment in their analyses (Soke et al., 2018; Cardinal et al., 2020). As a result, children with dual ASD and VI continue to be understudied, underdiagnosed, and underserved. The findings from this preliminary survey study contribute to a larger body of research aimed at identifying disparities and systemic barriers in services and support of children with co-occurring vision loss and ASD living in the United States. The collective data can then inform future efforts to reduce disparities in access to early intervention and appropriate family educational services.

438.148 The Anxiety Disorders Interview Schedule with Autism Spectrum Addendum: Inter-Rater Reliability, Convergent Validity and Discriminant Validity for Assessing Anxiety and ADHD in Autistic 4-8 Year-Olds

E. Ng-Cordell¹, R. E. Aiello², D. Akinsooto³, A. Dea³, N. O. Davis², A. C. Henley⁴, H. L. Morgan⁴, E. Peters³, J. Schechter⁴, M. Spanos⁵, C. Stone⁵, E. Tenenbaum⁶, K. L. Carpenter⁷ and C. M. Kerns⁸, (1)Psychology, The University of British Columbia, Vancouver, BC, Canada, (2)Department of Psychiatry and Behavioral Sciences, Duke University Medical Center, Durham, NC, (3)Department of Psychiatry and Behavioral Sciences, Duke Center for Autism and Brain Development, Durham, NC, (4)Department of Psychiatry and Behavioral Sciences, Duke University School of Medicine, Durham, NC, (5)Department of Psychiatry and Behavioral Sciences, University of North Carolina Greensboro, Durham, NC, (6)Department of Psychiatry and Behavioral Sciences, Duke University, Durham, NC, (7)Department of Psychiatry and Behavioral Sciences, Duke University Medical Center, Durham, NC, (8)University of British Columbia, Vancouver, BC, Canada

Background:

Autistic children commonly experience co-occurring anxiety and/or ADHD. Complexities due to symptom overlap and distinct manifestations of symptoms of each condition in autistic individuals necessitate tailored assessment methods. The Anxiety Disorders Interview Schedule – Parent version (ADIS-P) with Autism Spectrum Addendum (ADIS/ASA; Kerns et al., 2024) is a diagnostic interview that was designed to (1) differentiate anxiety and autism, and (2) assess DSM specified (“traditional”) and unspecified (“distinct”) anxiety presentations, including fears related to social confusion, uncommon phobias, focused interests, and change. The ADIS/ASA has demonstrated inter-rater reliability and convergent / discriminant validity in 8–13-year-old autistic children (Kerns et al., 2017), and preliminary evidence indicates inter-rater reliability and convergent validity for assessing anxiety in autistic preschoolers (Vasa et al., 2024).

Objectives:

An important extension of existing work will be to incorporate supplementary interview probes that enhance differentiation of ADHD and autism into the ADIS administration (Davis et al., 2022), and to establish interrater reliability, convergent and discriminant validity of the ADIS/ASA for assessing anxiety and ADHD in 4–8-year-old autistic children.

Methods:

Participants were 93 autistic children aged 4-8 years ($M_{age}=73.00$ months, $SD_{age}=14.14$ months; $M_{DQ}=96.03$, $SD_{DQ}=16.63$; 31% females; 75% white) in an ongoing study exploring anxiety and ADHD in autism. Interviewers administered and scored the ADIS/ASA, including supplemental ADHD interview questions, while a second rater independently listened to and scored interview recordings. Parents also completed standard (Child Behaviour Checklist [CBCL], ADHD Rating Scale [ADHD-RS]) and autism-tailored (Parent-Rated Anxiety Scale for Autism Spectrum Disorder [PRAS-ASD]) behavioral questionnaires.

We calculated inter-rater agreement regarding diagnostic status (Prevalence-Adjusted, Bias-Adjusted Kappa; PABAK) and severity (intra-class correlation; ICC) for all assessed conditions. Correlations between clinician-rated anxiety and ADHD severity per the ADIS/ASA and parent-reported anxiety (CBCL Anxiety and PRAS-ASD) and ADHD symptoms (ADHD-RS and CBCL ADHD) assessed convergent and discriminant validity.

Results:

There was moderate to excellent inter-rater reliability for traditional (ICCs: 0.74–0.94, PABAK: 0.83-0.94) and distinct anxiety (ICCs: 0.66–0.86, PABAK: 0.91-0.98), as well as ADHD (ICC: 0.91, PABAK: 0.83) (Table 1). Convergent and discriminant validity (Table 2) were supported for ADIS/ASA traditional anxiety, distinct anxiety, and ADHD. ADIS/ASA traditional anxiety was more strongly associated with parent-reported anxiety than ADHD measures ($Z_s: 2.74–4.09$, $ps < .006$), and ADIS/ASA ADHD was more strongly associated with parent-reported ADHD than anxiety symptoms ($Z_s: 5.59–6.48$, $ps < .001$). ADIS/ASA distinct anxiety was also more strongly associated with parent-reported anxiety than ADHD ($Z_s: 2.05–3.09$, $ps < .04$).

Conclusions:

Findings support the ADIS/ASA – with additional probes for assessing ADHD symptoms woven into its administration – as a reliable and valid measure of anxiety and ADHD in autistic children during the pre-school and early school years, and demonstrate the measure’s ability to differentiate anxiety and ADHD symptoms. Used during this developmental period, the ADIS/ASA may guide accurate and early identification of autistic children with co-occurring mental health and neurodevelopmental concerns. This may aid clinicians in delineating and supporting autistic children’s needs, and facilitate research on the prevalence, development, and underlying mechanisms of co-occurring anxiety and ADHD with greater precision.

**438.149** The Impact of Anxiety on Emotional Dysregulation in Children and Adolescents with Autism Spectrum Disorder

G. S. Brito de Oliveira¹, T. C. Nascimento², R. Lowenthal³, T. Rezende⁴, J. C. Chung⁵, K. Woodcock⁶, M. C. V. Teixeira⁴ and **C. S. de Paula⁷**, (1)School of Psychology, Mackenzie Presbyterian University, sao paulo, SP, Brazil, (2)Mackenzie Presbyterian University, sao paulo, SP, Brazil, (3)Mental Health, Santa Casa de São Paulo School of Medical Sciences, Sao Paulo, Brazil, (4)Human Developmental Sciences Graduate Program, Mackenzie Presbyterian University, sao paulo, SP, Brazil, (5)School of Psychology, University of Pirmingham, Birmingham- England, West Midlands, United Kingdom, (6)University of Birmingham, Birmingham- England, West Midlands, United Kingdom, (7)Human Developmental Sciences Graduate Program, Universidade Presbiteriana Mackenzie, São Paulo, SP, Brazil

Background:

Approximately 70% of individuals with Autism Spectrum Disorder (ASD) present at least one comorbidity, with anxiety disorders being among the most prevalent (29%). Anxiety is associated with impairments in adaptive functioning, health, and quality of life, as well as emotional dysregulation. One behavioral problem strongly linked to emotional dysregulation in ASD is emotional outbursts, defined as highly emotional and explosive episodes characterized by challenging behaviors that vary across individuals and over time. Understanding the profiles of children and adolescents with ASD and anxiety, as well as the consequences for emotional regulation, is crucial for informing targeted interventions and support strategies. By identifying the interplay between anxiety and emotional dysregulation, practitioners can develop more effective therapeutic approaches that address both the psychological and behavioral challenges faced by these individuals, ultimately improving their overall well-being and quality of life.

Objectives:

To describe the frequency of anxiety episodes among children and adolescents with ASD, and to investigate the associations between the presence of anxiety and the type, frequency, and antecedent events of severe emotional outbursts.

Methods:

Sample: N = 193 children and adolescents (ages 8-16) with ASD. **Instruments/Data Collection:** Parents and caregivers were recruited via social media and responded online to Brazilian versions of two questionnaires: (1) Anxiety Scale for Parents of Children with ASD (ASC-ASD): This scale consists of 24 items with numerical values ranging from 0 to 3, where 0 = Never, 1 = Sometimes, 2 = Frequently, and 3 = Always. The total anxiety score, obtained through a simple sum of the items, can range from 0 to 72, with higher scores indicating greater anxiety levels. A total score ≥ 20 may indicate significant anxiety, while scores above 24 are more specific. (2) Emotional Outburst Questionnaire: This instrument contains 133 items divided into blocks of more and less severe topographies, based on parents' opinions, such as self-injurious behavior, aggression, verbal aggression, motor agitation, and physiological responses, among others. For each topography, three conditions are assessed: frequency, location, and antecedents.

This study was approved by the Mackenzie Ethics Committee (CAAE 29428620.4.0000.0084).

Results:

A high prevalence of anxiety (19%) was observed in this study sample. The most commonly reported severe emotional outbursts included verbal and physical aggression towards others, property destruction, and self-injury. These emotional outbursts were infrequent, occurring mostly less than once a month. The most frequent antecedents of these outbursts were children/adolescents being in a bad mood (61.3%), experiencing pain (47.2%), or feeling hungry or thirsty (40.6%). Interestingly, children and adolescents with anxiety were nine times more likely to experience emotional outbursts compared to those without anxiety.

Conclusions:

This study underscores the high prevalence of anxiety in children and adolescents with ASD and its link to emotional dysregulation, particularly severe emotional outbursts. The findings highlight the need for targeted interventions that address both anxiety management and contextual factors influencing emotional regulation, ultimately promoting better outcomes for this population.

438.150 The Impacts Associated with Autism: An Umbrella Review.

B. French^{1,2}, V. E. Newell³, G. Nalbant⁴, H. Wright⁵, D. Daley⁴ and S. A. Cassidy⁵, (1)Institute of Mental Health, University of Nottingham, Nottingham, Nottinghamshire, United Kingdom, (2)School of Psychology, University of Nottingham, Nottingham, Nottinghamshire, United Kingdom, (3)University of Nottingham, Nottingham, Nottinghamshire, United Kingdom, (4)Nottingham Trent University, Nottingham, Nottinghamshire, United Kingdom, (5)School of Psychology, University of Nottingham, Nottingham, Nottinghamshire, UNITED KINGDOM

Background:

Autistic people are at increased risk of experiencing a range of difficult life events. For example, up to 79% of autistic adults meet diagnostic criteria for a psychiatric condition at some point in their life, as well as an increased risk of a range of physical health conditions. However, there has not been a comprehensive synthesis of all the varying outcomes autistic people may experience.

Objectives:

To identify the outcomes and risks associated with autism which have been comprehensively studied in the research literature to date.

Methods:

A protocol for this review is registered with the International Prospective Register of Systematic Reviews (PROSPERO; CRD42023475389). An umbrella review was conducted. This involved conducting a systematic search of five databases (PsycINFO, Embase, Scopus, Medline, ERIC), to identify quantitative and qualitative reviews of any design exploring the impacts, long-term outcomes or risks associated with autism (including, but not limited to narrative reviews, systematic reviews (with and without meta-analysis) or scoping reviews). Searches were conducted with an unlimited start date up to 14th of January 2024. Qualitative and quantitative findings were aggregated into a narrative synthesis.

Results:

After duplicates were removed, 6079 records were screened for eligibility, with 133 records included in the final synthesis. 50 reviews covered mental health in autistic people. Results showed a significantly increased risk of anxiety and mood disorders, eating disorders, psychotic and personality disorders, substance misuse, suicide and self-harm. 62 reviews covered physical health in autistic people. Results showed consistent evidence for significantly increased risk of mortality, epilepsy, sleep disorders, obesity, feeding problems, gastrointestinal problems, poorer oral health, and atopic dermatitis, but not asthma, diabetes, impaired vision or hearing. 29 reviews covered social and lifestyle factors in autistic people. Results showed consistent evidence for significantly increased risk of body image and identity issues, bullying, victimisation and interpersonal violence, problematic gaming and internet use, lower quality of life, difficulties with relationships, social connection and sexual outcomes (such as behaviour, knowledge and education), but not offending behaviour and criminality. Many areas have not been extensively researched or have consisted of largely poor-quality research, precluding ability to make definitive conclusions regarding risk. For example, offending behaviour, diabetes, catatonia, incontinence, autoimmune disease, school absenteeism, ageing, and unemployment.

Conclusions:

Autistic people experience a wide range of negative outcomes covering mental and physical health and social and lifestyle factors. Many areas have not been comprehensively researched, despite negatively impacting autistic people's lives. Future research should focus on aiming to better understand and support autistic people experiencing these issues.

438.151 The Intersection of ADHD and Autism in Adulthood: Assigned Sex Differences in Symptom Profiles

E. Escobar Gomez¹, G. A. McQuaid², J. Le³, E. A. Kaplan-Kahn⁴, N. R. Lee⁵, G. L. Wallace⁶ and B. E. Yerys¹, (1)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (2)George Mason University, Fairfax, VA, (3)George Washington University, Washington, DC, (4)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (5)Department of Psychological and Brain Sciences, Drexel University, Philadelphia, PA, (6)The George Washington University, Washington, DC

Background: ADHD frequently co-occurs with autism, yet understanding of ADHD in autistic adults is limited. Our recent large-scale study of Medicaid-enrolled adults found that 27% of autistic adults have ADHD, matching the prevalence rate observed in autistic children. ADHD symptoms in autistic adults are linked to less independence in activities of daily living and lower quality of life, highlighting the significant impact of ADHD on adult outcomes. ADHD is prevalent in both people assigned female and male sex at birth, but females are often underdiagnosed due to fewer visible symptoms of hyperactivity. We know little about sex differences in co-occurring ADHD symptom frequency and symptom profiles among autistic adults.

Objectives:

1. Evaluate sex differences in total ADHD symptom scores and positive ADHD screens among autistic adults
2. Examine sex differences in symptom profiles among autistic adults

Methods: 724 autistic adults (M=40.47 years; range: 18–83; 58% identified as assigned female) were recruited through the Simons Powering Autism Research (SPARK) Research Match service. Participants completed the 18-item Adult ADHD Self-Report Scale (ASRS), which assesses the presence and frequency of ADHD symptoms. We first compared total ASRS scores between assigned sexes using an independent samples t-test and then utilized chi-square analyses to examine sex differences in ADHD screen positivity rates (using Part A, which is the first 6 items from the ASRS). To analyze symptom profiles, we conducted a MANOVA, treating sex as the between-group factor and ASRS item-level scores as the within-group factor. Secondary analyses controlled for age and ADHD medication use to demonstrate the robustness of our findings.

Results: Autistic females reported significantly greater ADHD symptoms than autistic males overall (see Table 1), although screen positivity rates were similar: 48% for females and 43% for males ($\chi^2=1.65$, $p=0.20$). Profile analysis revealed that females scored higher across all ASRS domains. T-tests showed females had a mean difference of 2.94 points more than males on the total ADHD symptom scale ($t(722) = -3.096$, $p<0.01$) and 0.16 points more than males on the mean ADHD score ($t(722) = -3.102$, $p<0.01$). ANOVA confirmed a significant main effect of sex ($F(3,720) = 3.546$, $p=0.01$). Interactions between sex and age were non-significant. Findings remained significant after controlling for age and ADHD medication use.

Conclusions: Our study emphasizes the need to consider sex differences in ADHD among autistic adults. While both autistic males and females had similar ADHD screen-positivity rates, females reported significantly greater symptom frequency. ADHD symptoms are associated with worse adult outcomes, which means autistic females with ADHD may face greater challenges in daily life than autistic males with ADHD.

These findings highlight the necessity for increased clinical attention and effective treatment for ADHD in autistic adult females. Further research is needed to explore factors contributing to these sex differences, including coping strategies, social expectations, and diagnostic practices. Additionally, examining treatment response differences is crucial for developing tailored interventions for this population.

**438.152** The Prohibited Connection between Selective Mutism and Autism

A. Nordahl-Hansen¹ and I. Helgesen², (1)Østfold University College, Halden, Norway, (2)Department of Education, ICT and Learning, Østfold University College, Fredrikstad, Østfold, Norway

Background: An autism-diagnosis is an exclusion criterion for selective mutism (SM) in the ICD- 10 and 11. Still, studies show significant overlap between these conditions. The diagnostic manuals DSM-5 and ICD-10/11 have different approaches to the relationship between autism and SM, creating a challenge in the diagnostic process. In DSM- 5, there is somewhat broader acceptance of overlap between various conditions, including SM and autism (Muris & Ollendick, 2021). Contrarily, in ICD-11, autism is an exclusion criterion for the diagnosis of SM. This means that if a child shows clear signs of autism, they cannot be diagnosed with SM according to the criteria in ICD-11. This study challenges the diagnostic manuals' criteria for selective mutism regarding autism as an exclusion criterion.

Objectives: The purpose of this study was to explore diagnostic practices of the overlap between autism and selective mutism using data from the Norwegian Patient Register (NPR). Specifically, the aim was to quantify conditions (ASD, ADHD, Developmental Language Disorder, Social Anxiety Disorder, Social Phobia, Generalized Anxiety Disorder, Tourette Syndrome, and Major Depressive Disorder, with a primary focus on autism, and to address the gender distribution in this SM sample.

Methods: We identified a sample ($n=1,682$), aged 3 to 18 years in Norway, who during the period from January 1st, 2008, to April 30th, 2023, have had at least one documented episode where the diagnosis of selective mutism was registered in NPR. Diagnostic criteria followed the ICD-10 guidelines for selective mutism. The data were descriptively analyzed and presented using graphical figures showing the number of individuals with selective mutism with co-occurring autism diagnosis. Statistical analyses aimed to explore trends in co-occurrence, and analyzed the time interval between each diagnosis to assess how long it took for both diagnoses to be made.

Results: Many individuals have overlapping diagnoses of selective mutism and autism (11.7%). The average number of months before autism is registered after SM is -21.4 months, with a standard deviation of 40.93 months. The figure of -21.4 months is an average, and actual experiences may vary considerably. SM seems to be identified before autism in most cases.

Conclusions: Overlap between SM and autism can be challenging to detect in a school context if silence is very prominent. Like masking, the silence in SM may conceal the autistic characteristics at school but may be more evident in the home environment. It is important for healthcare workers and educators to know about SM, because starting intervention early leads to better outcomes (Rozenek et al., 2020), and the knowledge of causes, because like Cengher et al. (2021) indicates; children with both selective mutism and autism may be more challenging to give tailored help. As seen in our data, the overlap between selective mutism and autism is at 11.7%, despite the exclusion criteria in the ICD-diagnostic system.

438.153 The Relationship between Mental Health and Quality of Life for Fathers of Children with Autism and ADHD

A. Li¹, A. S. Rabba², A. Ure³ and B. Johnson¹, (1)Monash University, Notting Hill, VIC, Australia, (2)Monash University & Monash Health, Melbourne, VIC, Australia, (3)Paediatrics, Monash University Department of Paediatrics, Clayton, VIC, Australia

Background: Fathers' involvement in child-rearing positively influences children's developmental outcomes. Most investigations on parental quality of life (QoL) have been extensively conducted on mothers, including mothers of children with neurodevelopmental conditions. As a result there is an under-representation of fathers in studies of parental QoL, especially those raising children with neurodevelopmental conditions such as autism and ADHD.

Objectives: This study aimed to investigate the relationship between father mental health and neurodevelopmental traits, child neurodevelopment, emotional and behavioural factors, and socio-economic factors that influence the QoL for fathers of children with autism and/or ADHD.

Methods: Fathers of children with autism and/or ADHD (n = 105) completed an online questionnaire about their own mental health (BDI, BAI) and neurodevelopmental traits (SRS-2, ASRS), their children's autism (SRS-2), ADHD (Conners parent rating scale) and socio-emotional symptoms (SDQ), and socio-economic factors. Multiple regression analyses were conducted for father and child-related factors and ANOVA tests for the comparison of father's QoL (WHO-QOL) and socio-economic factors.

Results: Fathers with lower depression (Beta = -0.007 [95%CI -0.013, -0.002], p = .009) and anxiety symptoms (Beta = -0.013 [95%CI -0.022, -0.005], p = .003) predicted significantly greater QoL, whereas parent and child neurodevelopment traits, and socio-economic factors were not significant. QoL did not significantly differ between fathers of children with autism, ADHD, and co-occurring autism+ADHD.

Conclusions: Findings indicate that father's mental health is a strong predictor of their QoL. This highlights the need for clinicians to support the inclusion of fathers to enhance child-rearing engagement, individual and family wellbeing.

438.154 The Relationship of Camouflaging Strategies to Anxiety in Autistic Children and Adolescents

V. Sierakowski¹, A. Dakopoulos², B. Heath¹, D. S. Andrews³, M. Solomon¹, D. G. Amaral¹ and C. W. Nordahl¹, (1)Department of Psychiatry and Behavioral Sciences, UC Davis MIND Institute, Sacramento, CA, (2)Teachers College, Columbia University, New York, NY, (3)Department of Psychiatry and Behavioral Sciences, MIND Institute, UC Davis Medical Center, Sacramento, CA

Background: Autism is characterized by persistent alterations of social communication and interaction, as well restricted and repetitive behaviors. Camouflaging refers to a group of strategies used by an individual to diminish their autistic characteristics and appear less autistic in social situations. These strategies include masking (i.e., efforts to hide autistic characteristics); compensation (i.e., compensating for difficulties in social interactions such as social cuing and copying others); and assimilation (i.e., attempting to fit in with others in social situations including avoiding or forcing social interactions). Camouflaging has been shown to be related to poorer mental health outcomes in autistic people, with higher self-reported camouflaging associated with depression and anxiety, especially among autistic females.

Objectives: 1) To characterize patterns of camouflaging behaviors across autistic males and females; 2) to examine whether camouflaging behaviors predict clinical diagnoses of anxiety in autistic children and adolescents.

Methods: Participants included 28 primary caregivers and their children (ages 9–19 years; n = 12 females, 16 males) with a diagnosis of autism, confirmed using the ADOS-2 and ADI-R by licensed clinical psychologists. All participants were enrolled in an ongoing longitudinal study focused on neurobiological and behavioral development in autism, and data collection is ongoing. The Camouflaging Autistic Traits Questionnaire (CAT-Q) measures 3 domains of camouflaging: compensation, assimilation and masking. Parents were asked to complete the CAT-Q for children aged 9–13 (n = 19), while children aged 14–19 completed the CAT-Q as a self-report (n = 9). Clinical anxiety was diagnosed using the Anxiety and Related Disorders Interview Schedule for DSM-5 (ADIS) by a licensed clinical psychologist.

Results: There were no statistically significant differences in camouflaging behaviors between males and females, likely due to insufficient statistical power. Below, we describe the observed patterns in our small dataset that provide important initial descriptive information about our sample. Autistic females compared to autistic males displayed different patterns of camouflaging behaviors across the domains of masking, assimilation, and compensation. Autistic females reported more masking than autistic males (females M=26.83, SD=6.79; males M=24.67, SD=3.52), but less compensation (females M=27.83, SD= 7.63; males M= 36.00, SD= 3.46) and assimilation (females M= 29.17, SD=6.15; males M=33.67, SD=3.06) than males. These descriptive patterns were preserved across both parent- and child-report. Contrary to our hypotheses and prior literature, autistic males tended toward higher average CAT-Q total scores than females. Regarding associations with anxiety, 9 individuals met criteria for clinical anxiety. Results from a logistic regression indicated that assimilation may be the factor of camouflaging that most strongly predicts a clinical diagnosis of anxiety (p = 0.08).

Conclusions: Previous investigations into autistic camouflaging have focused specifically on autistic females. Although conclusions drawn from the present study are limited due to our small sample size, differential patterns of camouflaging behaviors that were observed between autistic males and females provides an important area of future examination. Future research should focus on differences between how camouflaging behavior presents in autistic males and females, which could provide insights into more effective, targeted and individualized supports through therapeutic or community approaches.

438.155 Agreement across Depression Measures in Adolescent Girls with and without Autism Spectrum Disorder

C. I. Parenteau¹, K. Dennison² and S. Zheng³, (1)Psychiatry and Behavioral Sciences, Center for ASD and NDDs, UCSF Dept of Psychiatry, San Francisco, CA, (2)University of California, San Francisco, San Francisco, CA, (3)Psychiatry and Behavioral Sciences, The University of Texas at Austin, San Francisco, CA

Background:

Prevalence rates of depression among adolescent girls are on the rise (Daly, 2022), with autistic girls at even higher risk (Schwartzman et al., 2022). Assessing depression in autism is challenging given diagnostic overshadowing (Hinze et al., 2024) and the limited number of valid measures of depressive symptoms in this population (Pezzimenti et al., 2017). Clinicians often gather information on mood challenges from both the adolescent and their caregivers. While discrepancies in reporting depressive symptoms have been well documented in the general population literature (De Los Reyes, 2011), this phenomenon has not been well studied in individuals with autism. Given the challenges in diagnosing depression in autism, it is important to examine how well different informants and modes of information gathering agree with each other in the process of determining a diagnosis of depression.

Objectives:

To understand the level of agreement of reported clinical-range depression across measures, informants, and data collection modes in adolescent girls with and without an autism diagnosis.

Methods:

Ten adolescent girls with a diagnosis of autism and nine non-autistic girls between the ages of 13.8 to 16.8 years old ($M=15.1$, $SD=1$) were recruited to participate in a pilot study on social and emotional experiences (see Table 1). Inclusion criteria were assigned female at birth, identify as female, and had the ability to independently complete surveys and interviews. Adolescents completed the Beck Depression Inventory-II (BDI-II), the Center for Epidemiologic Studies Depression Scale for Children (CES-DC), and a clinical interview using DSM-5 criteria to assess symptoms of Major Depressive Disorder. Caregivers reported whether their child had formerly received a depression diagnosis from a professional and completed the Child Behavior Checklist 6-18 (CBCL), where the Internalizing Problems subscale was used in analyses. Frequencies of meeting the clinical cut-offs on the BDI-II, CES-DC, and CBCL internalizing problems were generated. Agreement of clinical range depression of the measures with each other, and the DSM-5-based clinical interview and reported clinical diagnoses were assessed using Cohen's Kappa.

Results:

For autistic participants, the CES-DC showed moderate agreement with the BDI-II ($k=.444$) and DSM-5 criteria ($k=.545$; see Table 2). The CBCL showed poor agreement with all other measures. The remaining measures showed fair agreement with each other.

Conversely, for non-autistic girls, we observed fair to substantial agreement for the CBCL with all the other measures. The CES-DC showed less agreement in the non-autistic sample compared to the autistic sample when examining agreement with the DSM-5 criteria ($k=.341$) and caregiver-reported diagnosis of depression ($k=.182$). The remaining pairings fell into the same agreement categories as in the autistic sample.

Conclusions:

The CBCL showed the worst agreement with other measures for the autistic sample, indicating that we should not solely rely on parent-report of internalizing symptoms when assessing for mood challenges in this population. This further supports that more research is needed on a larger sample of autistic adolescent girls to understand what factors may be contributing to the lack of agreement across raters and measures, and how we can accurately capture depression symptoms in this population.

438.156 Toilet Training Proficiency and Diaper Usage Patterns in Children with Autism Spectrum Disorder and Its Association with CARS Score

D. Jain¹, J. Bhatt² and L. Sanghvi², (1)Developmental Paediatrician, Shishu Child Development & Early Intervention Centre, Ahmedabad, Gujarat, India, (2)Narendra Modi Medical College, Ahmedabad, Gujarat, India

Background: Although there are variations, children usually show readiness for toilet-training around 18-24 months and most children achieve day-time continence by 30-36 months. Along with the core deficits in social-communication skills and restricted/repetitive behaviour patterns, many kids with ASD have difficulties in achieving independence in daily-living adaptive skills, including toilet-training. As being toilet-trained is one of the most important functional goals, delays in the domain hampers child's independence and causes variable levels of parental stress.

Objectives: A study on various levels of toilet control and diaper usage patterns in 3-12 years old children and its association with CARS score.

Methods: The study was conducted in a semi-structured interview format with families of 205 children diagnosed with ASD. Detailed evaluation and CARS-2-ST scoring was done and data for urine & stool indication, diaper usage, willingness to sit on potty-seat, place of defecation was collected. IBM SPSS software was used for statistical analysis.

Results: The mean age for study population was 5.26 ± 1.80 years, with 82% males and 18% female children. 79% kids were in mild-moderate and 21% in severe range on CARS score.

40.0% kids indicated urine before passing, 29.8% after, 1.0% either before/after and 29.3% gave no indication. 19.0% of kids didn't use diaper, 18.5% at home, 27.8% outside home and 34.6% were always wearing diapers. 40.4% kids defecated in diaper, 47.3% in washroom and 12.2% in either washroom or diaper. 59.5% kids informed about potty need before defecation, 29.8% told after and 10.2% didn't indicate at all. 72.2% kids had no set-time for defecation. 25.4% kids were scared of sitting on potty seat. 62.9% did potty sitting/squatting, 19.1% standing and 18% either standing or sitting.

In pre-school age group, 43.8% didn't give prior indication for stool and 64.2% for urine. 36.5% were always in diaper and 26.3% were scared of sitting on potty seat. For school-age (6-12 years), 27.9% didn't give prior indication for stool, 50% for urine, 30.9% were always in diaper and 23.5% were scared of sitting on potty seat.

There was significant association ($p < 0.05$) of CARS-score with stool indication, timing of urine indication, place & position of defecation. The variable urine indication, diaper usage, set time for stool, child scared of sitting on potty seat were not significant. Gender was not significantly associated with any variable. Age group (pre-school/school-age) was significantly associated with diaper usage, place, timings and position of defecation.

Conclusions: Toilet-training is one of the most important ADL skills for functional independence. In our study, in school-age kids 50 % were not indicating urine & 27.9% stool in advance. There was significant association between CARS scores and toileting proficiency, with children with more severe autism symptoms being less likely to indicate their toileting needs.

The results emphasize the need for early, individualized interventions to improve toileting outcomes and reduce reliance on diapers. Further research is needed to explore the long-term impact of sensory interventions and parental involvement on toilet training success in children with ASD.

438.157 Apps and Digital Resources for Child Neurodevelopment, Mental Health and Wellbeing: A Review, Evaluation and Reflection on Current Resources

K. A. Boulton¹, M. Hilton¹, E. Sutton¹ and A. J. Guastella², (1)Brain and Mind Centre, Children's Hospital Westmead Clinical School, Faculty of Medicine and Health, University of Sydney, Sydney, NSW, Australia, (2)Faculty of Medicine and Health, University of Sydney, Sydney, NSW, Australia

Background: An increase in prevalence of neurodevelopmental conditions, such as autism, worldwide, alongside resource constraints within existing clinical assessment and diagnosis services, has led to increased interest in health information technologies, such as apps and digital resources. Digital tools are often viewed as a solution to bridge this divide and to increase supports for families. There is, however, a paucity of research that has evaluated digital health tools, their potential benefits for child neurodevelopment and associated concerns (e.g., mental health and wellbeing) and their benefit for families.

Objectives: The objective of this study was to conduct the first review of existing mobile apps and digital resources that are targeted at supporting the transdiagnostic needs of children with developmental concerns or neurodevelopmental conditions.

Methods: In this study, we identified 3435 separate resources, of which 112 (43 apps and 69 digital resources) met criteria. These resources were categorised according to their purpose or target, and were then reviewed based on their utility, information quality and evidence base using the Adapted Mobile App Rating Scale (A-MARS).

Results: The most common condition of concern targeted by apps and digital resources was autism (17%; 19/112 resources), with retrieved resources focusing on supporting challenging behaviours, promoting speech, language and social development, and providing options for alternative and assistive communication. Other common areas of concern targeted by apps and digital resources included language and communication (14.3%; 16/112) and ADHD (9.8%; 11/112). Results showed that reviewed resources were engaging, with high levels of accessibility and functionality. Resources had various functions, including developmental or behavioural tasks targeted at children, assistive communication support, scheduling support, journalling, and advice, activities and strategies for parents. The information quality of resources, such as credibility of source and evidence base was, however, mostly low. Mobile apps and digital resources that showed good credibility and had an existing evidence base were largely developed in partnership with research, health or government institutions, and were rated significantly higher on overall quality compared to apps and digital resources not developed in partnership with such institutions (mobile apps: $t(41) = -4.35, P < .001$; digital resources: $t(67) = -4.95, P < .001$).

Conclusions: The lack of evidence base across resources means that it is extremely difficult to provide recommendations to families with respect to apps or digital resources that may support their needs. Frameworks for the development of new tools are discussed, highlighting the novel approaches required to demonstrate efficacy of tools for improving outcomes for children and families. Such a framework requires collaboration with multiple stakeholders (software developers, researchers, regulatory bodies, clinicians, children and families) and engagement across multiple levels of expertise (app development, implementation and dissemination within services, policy and clinical regulations), to harness the potential of digital health for improving outcomes and promoting support in child neurodevelopment, which at this juncture remains largely underdeveloped.

438.158 Traumatic Experiences and Mental Health Among Autistic Children

T. A. Chikaura¹, E. M. Weir², S. Griffiths³, T. L. Procyshyn⁴, M. Pelton⁵, C. Allison⁶, S. White⁷, T. Ford⁷ and S. Baron-Cohen⁶, (1)Psychiatry, Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, Cambridgeshire, United Kingdom, (2)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, Cambridge, United Kingdom, (3)University of Cambridge, Cambridge, United Kingdom, (4)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, NA, United Kingdom, (5)University of Cambridge, Cambridge, Cambridgeshire, United Kingdom, (6)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, Cambridgeshire, United Kingdom, (7)Psychiatry, University of Cambridge, Cambridge, Cambridgeshire, United Kingdom

Background: Autistic children are more likely to experience trauma and poor mental health than non-autistic children. Autistic adults are more likely to report suicide-related behaviours and traumas related to education, victimization, and criminal justice. However, there are no large-scale studies that consider these types of traumas among autistic children.

Objectives: To explore whether autistic children are more likely to experience specific types of traumas compared to non-autistic children.

Methods: We administered a cross-sectional anonymized parent-report survey, which included questions on demographics, neurodevelopmental and psychiatric diagnoses, 44 different traumatic experiences, and the Mood and Feelings Questionnaire (MFQ), to measure autistic and non-autistic children's traumatic experiences and mental health outcomes. Our final sample included reports on n = 290 children (n = 196 autistic) aged 6-17 years. We used the Mann-Whitney U and chi-square tests to compare group differences, and Fisher's exact tests, unadjusted and adjusted binomial logistic regression models to compare the likelihood of each trauma between groups. All adjusted analyses controlled for type of education, country of residence, and sex. Adjusted models were fitted for 32/44 traumas due to perfect separation. To reduce Type I errors, the Benjamini-Hochberg method was applied.

Results: The sample was largely composed of children who were assigned male at birth, UK residents, and 41% of the autistic children did not attend mainstream schools (Table 1). Autistic children were more likely than non-autistic children to have two or more co-occurring neurodevelopmental and psychiatric conditions (46% vs 17%). Additionally, autistic children had higher levels of depression symptoms than their non-autistic peers (W = 5804, p = <0.001). A significantly greater number of parents of autistic children reported that their children had experienced 10/44 traumas. Parents of autistic children were more likely to report that their child had no friends at school, had been tricked or pressured into breaking rules or giving someone money or possessions, and was excluded from activities by their peers. Autistic children were also more likely to experience a mental health condition that affected their daily life, miss more than two weeks of school due to poor mental health, move school because the school was unable to cater for their needs, avoid school because it was too stressful, and self-harm. Additionally, parents of autistic children were more likely to report that their child had been refused additional support at school when requested. Full results are shown in Table 2.

Conclusions: This study bolsters existing evidence on the risks of trauma, poor mental health, and self-harm among autistic children and shows for the first time that autistic children are more likely to miss more than two weeks of school due to poor mental health, move schools due to unmet support needs, and be refused additional support at school upon request. Our findings highlight the importance of training for parents and teachers on how to best support autistic children experiencing trauma and mental health difficulties. These findings underline the importance of designing and implementing needs-based and trauma-informed mental health initiatives in all schools that focus specifically on supporting autistic children.

438.159 Treatment for Bowel Disease Improves Core ASD Symptoms in Children with ASD-Associated Enterocolitis

A. Krigsman¹, G. Pandolfi², P. Lee², S. J. Walker² and Y. Fernandez Figuerero², (1)Pediatric Gastroenterology Resources of New York and Texas, Austin, TX, (2)Wake Forest Institute for Regenerative Medicine, Winston Salem, NC

Background: Chronic gastrointestinal (GI) symptoms, common in children with an autism spectrum disorder (ASD) diagnosis, are difficult to properly diagnose and effectively treat. The paucity of published information regarding specific therapeutic strategies and corresponding treatment outcomes in this unique patient population continues to complicate an already challenging situation. The treatment study described here was undertaken to address this information gap by providing a longitudinal assessment of the efficacy of standard-of-care treatment on GI symptoms and ASD characteristics in a group of GI-symptomatic children with ASD.

Objectives: The clinical effect of treating ASD-associated inflammatory bowel disease (IBD) has not yet been systematically evaluated, documented, analyzed, or reported. The objective of this study was to determine whether conventional treatment of IBD in children with ASD positively impacts both GI symptoms and core ASD behaviors and cognition. The overall goal of this pilot trial was to obtain data that would be exceptionally beneficial in generating a uniform "standard of care" for children with ASD who were being evaluated for chronic GI symptoms and shown to have treatable intestinal inflammation.

Methods: Following diagnostic assessment by a pediatric gastroenterologist and confirmation of eligibility (i.e., evidence of enterocolitis at endoscopy, capsule endoscopy, and/or biopsy), children with ASD were enrolled in the study and evaluated for one year during their ongoing treatment regimen which included induction corticosteroids followed by non-steroidal 5-ASA agents (and immunomodulators or biologics - as clinically warranted). Patient caregivers completed baseline GI symptom and ASD questionnaires at various time points over a 12-month period: at baseline just prior to treatment initiation, weekly (GI questionnaires; (1) Gastrointestinal Symptom Survey Bowel Movement Chart (GiSS-BMC), and (2) Gastrointestinal Symptom Survey Externalizing GI Behaviors (GiSS-EB)), quarterly (Autism Behavior Checklist (ABC)), semiannually (Social Responsiveness Scale (SRS-2)), and annually (Vineland Adaptive Behavior Scale II (VABS II)). Non-parametric Wilcoxon Signed-Rank Test was used to compare data between time points; $p \leq 0.05$ was considered statistically significant.

Results: Twenty-five participants completed the 52-week study. Average age of the participants was 134.48 (± 70.44) months (range = 29-338 months). The most frequently reported symptoms were abdominal pain (84%; 21/25), constipation (72%; 18/25), and diarrhea (52%; 13/25). The study population was predominantly Caucasian (N = 19; Asian = 3; Hispanic = 1; African American = 1; AA/Caucasian = 1). Although outcomes (i.e., magnitude of change) varied from individual to individual, data from all participants indicated significant improvements in both GI symptoms (**Figure 1**) and ASD behaviors and cognition (**Figure 2**) during, and following, one year of treatment.

Conclusions: This pilot study provides compelling preliminary evidence for the efficacy of standard-of-care treatment in children with ASD and co-occurring enterocolitis to improve both the gastrointestinal symptom profile as well as ASD-associated behaviors and cognition. Treating enterocolitis in children with ASD also improves core ASD features such as communication, socialization, and motor skills. This is perhaps the most exciting finding of the study because it implies that treating enterocolitis in individuals with ASD is a means of treating *autism*, not just gastrointestinal disease.

438.160 Understanding Self-Harm in Autistic Young People: A Scoping Review

E. O. Dawe Lane, Research Department of Clinical, Educational & Health Psychology, University College London, London, United Kingdom

Background: Autistic young people are at increased risk of self-harm. However, existing literature on self-harm in autistic young people (aged 10 to 24) is limited and further research will be required to promote early identification and the development of effective intervention strategies for self-harm in autistic young people.

Objectives: This scoping review aimed to (i) generate an overview of current knowledge of self-injurious behaviour and self-harm in autistic young people, (ii) identify gaps in the literature and (iii) make recommendations for future research.

Methods: The literature search was conducted using Medline, Embase, PsychINFO, PsychArticles, Scopus, and Web of Science between March and June 2024. Research articles were included if they met the eligibility criteria for the scoping review.

Results: Fifty-four studies were included in the scoping review; one mixed-method and fifty-three quantitative. Of these, fifty-one examined self-harm in autistic people and three explored the relationship between autistic traits and self-harm. We present the findings in terms of (i) prevalence, (ii) associated factors, (iii) clinical outcomes and (iv) interventions for self-harm in autistic young people.

Conclusions: This scoping review highlights that although previous research has investigated self-harm in autistic young people, substantial gaps in knowledge still exist. Future research on this topic will need to address several methodological issues, particularly how to: (i) define and measure self-harm in autistic young people, (ii) produce findings that increase our understanding of self-harm and account for heterogeneity in the autistic population and (iii) use causal inference to identify risk and protective factors associated with self-harm in autistic young people. We discuss how to future research can address these challenges and inform the development of effective, evidence-based intervention strategies to support the mental health and wellbeing of autistic young people.

438.161 Understanding the Links between Age at Autism Diagnosis and Co-Occurring Mental Health: Insights from Autistic, Birth, and General Population Cohorts

X. Zhang¹, J. Grove², A. D. Borglum³, H. C. Martin⁴, T. Bourgeron⁵, S. Baron-Cohen⁶ and V. Warrier⁷, (1)Autism Research Centre - University of Cambridge, Cambridge, Cambridgeshire, United Kingdom, (2)Aarhus University, Aarhus, Denmark, (3)Department of Biomedicine-Human Genetics, Aarhus University, Aarhus, Denmark, (4)Wellcome Sanger Institute, Cambridge, Cambridgeshire, United Kingdom, (5)Human Genetics and Cognitive Functions, Institut Pasteur, Paris, France, (6)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, Cambridgeshire, United Kingdom, (7)University of Cambridge, Cambridge, Cambridgeshire, United Kingdom

Background: Autism is marked by significant heterogeneity, but the role of age at diagnosis in explaining variability in co-occurring psychiatric conditions remains underexplored. Our previous research explored this axis of heterogeneity, identifying two differing epidemiological trajectories for early and late diagnosis.

Objectives: The present study examines how the timing of autism diagnosis, both epidemiologically and genetically, influences mental health outcomes across autistic cohorts, birth cohorts, and the general population.

Methods: In autistic children from **birth cohorts**, Millennium Cohort Study (MCS, N = 188), Longitudinal Study of Australian Children (LSAC) Baby Cohort (N = 125), and Kindergarten Cohort (N = 89), we used regression models to explore associations between previously identified trajectories for Strengths and Difficulties Questionnaire (SDQ) total scores and psychiatric outcomes, including mental health diagnoses and self-harm thoughts, adjusting for covariates. In MCS and ALSPAC, we evaluated the association between polygenic scores (PGS) for earlier and later diagnosed autism and trajectories of social, emotional, and behavioural traits.

In the **autistic cohort SPARK**, we assessed the relative prevalence of nine common mental health and neurodevelopmental conditions (e.g., ADHD, anxiety, depression) among autistic individuals over 9 years old. PGS based on iPSYCH GWAS for early- (before age 11) and late-diagnosed autism (after age 10). Regression analyses were performed to assess associations between these PGS and all the conditions, with controls for confounders.

Using genomicSEM, we analysed six minimally overlapping GWAS for autism, focusing on variations in age at diagnosis in **general populations**. Then we examined genetic correlations between these factors and mental health conditions and traits, such as depression and trauma.

Results: Late emergent difficulties trajectories were linked to higher rates of depressive symptoms ($P = 3.84 \times 10^{-4}$), anxiety ($P = 5.54 \times 10^{-7}$), and self-harm ($P = 0.018$), particularly in adolescence, reflecting higher internalising disorders in later-diagnosed individuals. Age-by-PGS interactions in MCS showed that PGS for later diagnosed autism was significantly associated with increasing emotional symptoms, peer problems, and SDQ total scores, while decreasing prosocial behaviours with age. In ALSPAC, PGS for earlier diagnosed autism was linked to decreasing hyperactivity/inattention.

In SPARK, we found different relative prevalence of conditions among autistic people diagnosed at different ages — anxiety and depression were more prevalent in later-diagnosed individuals. PGS for earlier and later diagnosed autism showed differing associations, particularly in mood disorders such as depression ($\beta = -0.08$, 95% CI [-0.131, -0.029], $P = 2.06 \times 10^{-3}$ for Autism_{earlierdiagnosed} PGS, $\beta = 0.045$, 95% CI [-0.006, 0.097], $P = 0.08$ for Autism_{laterdiagnosed} PGS).

Genetic correlation analyses showed later-diagnosed autism had larger genetic correlations with ADHD, depression, trauma, and self-harm. The genetic correlation between earlier and later diagnosed autism was moderate ($r_g = 0.38$, $se = 0.07$).

Conclusions: These findings collectively demonstrate that the profiles of co-occurring mental health conditions differ by age at autism diagnosis, with genetic differences partly explaining these variations. Understanding the complex socio-biological mechanisms linking genetics and mental health profiles is critical for future research.

438.163 Using Electronic Health Record Data to Understand the Impact of Co-Occurring Neurodevelopmental Conditions on the Timing of an Autism Diagnosis

M. Coffman¹, A. Huang², M. Engelhard², A. Scheer³, G. Maslow^{3,4}, G. Dawson⁵ and B. A. Goldstein⁶, (1)*Duke University, Durham, NC*, (2)*Department of Biostatistics and Bioinformatics, Duke University School of Medicine, Durham, NC*, (3)*Department of Psychiatry, Duke University School of Medicine, Durham, NC*, (4)*Department of Pediatrics, Duke University School of Medicine, Durham, NC*, (5)*Department of Psychiatry and Behavioral Sciences, Duke University, Durham, NC*, (6)*Department of Biostatistics & Bioinformatics, Duke University, Durham, NC*

Background:

Autism commonly co-occurs with other neurodevelopmental conditions (NDCs), with over 95% of autistic children having at least one co-occurring condition, and up to 53% of autistic 4-year-olds having diagnoses of ≥ 4 co-occurring conditions (Soke et al., 2018). Common co-occurring NDCs include motor delay (MD), language delay (LD), global developmental delay (GDD), and attention-deficit/hyperactivity disorder (ADHD). While data regarding the high prevalence of individual co-occurring NDCs in autism are available (Maenner, 2021), little is understood about how having one or more NDCs may impact the timing of an autism diagnosis.

Objectives:

This study uses North Carolina Medicaid claims data to assess the impact of an NDC on the timing of an autism diagnosis.

Methods:

Using a cohort of children with Medicaid claims data from North Carolina in children who were born in 2014 with continuous enrollment (N=59496), we identified children who received an autism diagnosis (n=1540) by age 8. Of these children, we identified who had any of the four NDC diagnoses (n=1431), prior to the autism diagnosis. For all diagnoses, children had to have two distinct ICD codes on different service dates, with the first date used for diagnostic timing.

To test difference in timing of autism diagnosis, we age-sex-race matched each child with an NDC (case) to a child without the NDC (control) who had not yet received their autism diagnosis. We performed two-tailed paired *t*-test for mean difference of timing of autism diagnosis.

Results:

We found that children who received a diagnosis of MD, LD, and DD were more likely to receive their diagnosis of autism at an earlier age (p 's < 0.001). There was no significant difference in age at which children who were diagnosed with ADHD received a diagnosis of autism ($p=0.73$).

Results shown in Figure 1.

Conclusions:

Autistic children often receive a diagnosis of another NDC prior to their diagnosis of autism. These findings may hold relevance for considering a diagnosis of an NDC as a possible predictor of an autism diagnosis, which could potentially facilitate early identification and targeted interventions for autistic children. It is worth further understanding how early NDCs can facilitate making a timely autism diagnosis.

438.164 Comparative Longitudinal Actigraphy Analysis Shows Delayed Sleep Midpoint in Autistic Vs. Neurotypical Adults.

Y. S. Lograsso¹, J. A. Nielsen², T. P. Gabrielsen³, M. South⁴, K. M. Mossa⁴, R. A. Lundwall⁵, S. Tass¹ and L. Parker¹. (1)Brigham Young University, Provo, UT, (2)Counseling Psychology and Special Education, Brigham Young University, Provo, UT, (3)Psychology & Neuroscience, Emory Autism Center, Decatur, GA, (4)Clinical Psychology, Brigham Young University, Provo, UT, (5)Psychology & Neuroscience, Brigham Young University, Provo, UT

Background:

Individuals diagnosed with Autism Spectrum Disorder (AUT) and Social Anxiety Disorder (SA), and co-occurring mental health concerns often face challenges that impact their sleep patterns, which can be indicators of more serious concerns affecting daily functioning and quality of life. Actigraphy is a low-invasive method for assessing physical activity and sleep patterns that has potential benefits for understanding health behaviors on a wide scale over long periods. This study aims to explore sleep midpoint, the middle time between sleep onset and wake in autistic vis-à-vis socially anxious and non-anxious neurotypical adults. The midpoint between sleep onset and wake time (sleep midpoint) has been identified as a predictive marker associated with an increased risk of depression and other affective disorders in other populations. A better understanding of these risk factors can contribute to increased detection and intervention.

Objectives:

The primary aim of this research was to evaluate sleep midpoint across three comparison groups of adults: diagnosed with autism (AUT), social anxiety but not autism (SA), and a non-anxious neurotypical comparison group (NT). We hypothesized that both the AUT and SA groups would have a significantly delayed sleep midpoint compared to the neurotypical comparison group.

Methods:

A total of young adult participants (74% female), including 30 with AUT, 23 SA, and 26 NT with no significant difference in FSIQ. Data were collected longitudinally across an average 115.92 days ($R = 30-234$, $SD = 53.75$). The sleep midpoint was collected using GENEActiv actigraphy devices and comparison was analyzed using linear mixed-effects models using R.

Results:

Sleep midpoint means were 5:30 AM (AUT), 5:12 AM (SA), and 4:36 AM (NT). Individuals in the AUT group had a significantly later sleep midpoint compared to the NT group ($\beta = 0.919$, $p = 0.0232$). No significant difference was observed between the AUT and SA groups ($p = 0.5614$), or between the NT and SA groups ($p = 0.2666$).

Conclusions:

This study shows significant differences in sleep midpoint between individuals with AUT and those in the NT group, with AUT exhibiting a later sleep midpoint. These findings suggest that significantly different sleep midpoints may indicate heightened sleep concerns and associated risks for mental health issues. Additionally, the average sleep midpoint of the SA group falls between the other two groups, suggesting that the AUT group faces additional factors that affect sleep. The low-invasive nature of actigraphy presents an opportunity to use sleep midpoint as an early screening tool for identifying individuals at risk within the broader population.

438.165 Variability in Suicidal Thoughts and Behavior Among Autistic Adolescents and Adults: Subgroup Identification, Predictive Features, and Group Differences

S. Eldeeb, C. M. Conner, L. Antezana, K. B. Beck and C. A. Mazefsky, Department of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, PA

Background: Autistic people experience high rates of suicidal thoughts and behaviors (STB) and are three times more likely to die by suicide compared to non-autistic people. Despite these alarming rates, there is substantial variability, and we lack understanding of who is the most at risk. Identifying subgroups of autistic people with varying levels of STB would improve prevention efforts and target those at highest risk.

Objectives: The study sought to: 1) identify and characterize STB subgroups of autistic individuals using a machine learning clustering method, 2) identify specific assessment items that predict STB subgroups.

Methods: The sample included 831 autistic adolescents and adults who participated in an online study as part of the University of Pittsburgh Autism Center of Excellence (age 37 ± 12 ; range 14-86). We applied a random forests clustering technique to item-level data from the Autism Suicidality Inventory (ASI), Columbia-Suicide Severity Rating Scale (C-SSRS), and Suicidal Thoughts and Behaviors Questionnaire (STUQ). Feature importance analyses identified which items were most informative for subgroup membership. Demographic (e.g. age, gender, food/housing insecurity), health (e.g. physical health, quality of life), and mental health (e.g. historical psychiatric diagnoses, emotion dysregulation (ED), depression, anxiety, masking) variables were examined to identify subgroup differences.

Results: The machine learning clustering algorithm identified five significantly distinct groups of STB risk, which varied both by suicidal thought severity and past attempt history (Table 1). Groups (G1-G5) range from lowest risk (G1: no current suicidal thoughts, 6.2% lifetime attempts) to highest risk (G5: 97% current suicidal thoughts, 62.5% reporting past attempts); G2 and 3 differ on current and past STB, while G3 and G4 share similarities in past but differ in their current STB. G5 had the most female-identifying people (41% vs. 19% in G1), the highest mean age (35 years), and the highest prevalence of psychiatric diagnoses. G5 also reported the most food and housing insecurity, physical pain, and health challenges. Groups also separated on levels of ED, anxiety, depression, with G5 having the highest severity. Further, high masking, low self-compassion, and feelings of inadequacy characterized G5. Across clustering measures, the STUQ item on frequency of suicidal thoughts contributed the most to STB subgroup clustering, followed by 19 ASI items (Table 2). Key ASI items included concerns of STB disclosure, social challenges and rejection, perseverative self-critical thinking, and social and emotional masking.

Conclusions: This study used new (ASI, STUQ) and established (C-SSRS) measures of suicidality to identify five distinct groups of autistic individuals with varying STB risk. Results highlight new areas to consider, such as food and housing insecurity, physical pain, and self-compassion, in addition to known correlates of STB in autism (e.g. masking and ED). The items that contributed most to STB subgroups highlight key targets for prevention and intervention, including understanding barriers to STB disclosure, social supports surrounding being rejected/excluded, alternative ED strategies, and fostering self-compassion. Future work should explore near-term increases in STB based on factors identified as contributing to risk. Finally, the multifaceted nature of subgroup contributors highlights the complexity surrounding STB in autistic people.

438.166 Why Am I like This? Exploring the Research Priorities and Experiences of Autistic People with Eating Disorders: A Photovoice Study**K. Buchan**, *Clinical and Health Psychology, University of Edinburgh, Edinburgh, United Kingdom***Background:**

Research has shown that Autistic people—or people with heightened Autistic traits—have an increased risk of developing eating disorders (EDs; Micai et al., 2023; Inoue et al., 2021). Despite this, little research has captured the deeper, qualitative nuances underlying this co-occurrence, and those that have are exclusively focused on the experiences of Autistic women with Anorexia Nervosa (Nimbley et al., 2023; Brede et al., 2021; Kinnaird et al., 2019; Babb et al., 2020). Consequently, it is unclear whether prior investigations have accurately captured experiences across Autistic presentation, gender, and ED type.

Furthermore, a failure to explore the research priorities of Autistic people with EDs has resulted in the exclusion of lived experience when shaping the academic landscape (Keller et al., 2024). Consequently, this has limited the clinical utility of findings by failing to produce research which is meaningful to the community. Therefore, it is imperative that research adopts accessible methodologies which facilitate inclusion of more heterogeneous samples to accurately capture the experiences and priorities of the Autistic ED community (Duffy et al., 2024; Cobbaert & Rose, 2023). To this end, we employed Photovoice, a flexible, participatory method which can empower lived experience voices, incite community change (Wang & Burris, 1997), and reduce neurotypical bias in autism research (Do et al., 2021).

Objectives:

To explore the experiences of Autistic people with EDs and set research priorities that are informed by the Autistic ED community.

Methods:

14 Autistic participants (M = 31.07 years, SD = 8.26; Table 1) attended focus groups held online or in-person. Groups met weekly for a period of 5 weeks, producing and sharing images that facilitated group discussions to co-produce meaning. Participants produced six titled images (three for experiences and three for research priorities) and provided written narratives that gave context to each image. Data from the image content, narratives, and workshops were analysed iteratively, using an adapted version of Wang & Hannes' (2020) question matrices and inductive-reflexive thematic analysis (Braun & Clarke, 2021).

Results:

Themes detected within Autistic people's experiences of EDs included an overarching theme of *Autistic Identity*, which underpinned themes: *The Overwhelm Bucket*; *Diagnostic Intersectionality*; *Go without me: Social Consequences of EDs*; and *Services and Support*. Five priorities for research were set by participants, including: *the Impact of Early Experiences*; *the Function of EDs*; *Barriers and Facilitators to ED Recovery*; *Understanding and Accommodating for Complexity*; and *Changing the Research Culture*. These informed preliminary research questions for future research (Table 2).

Conclusions:

Autistic Identity is central to participant ED experiences, showing that EDs are not merely characterised by Autistic traits, but rather how those traits are perceived by Autistic people operating within a wider neuronormative culture. Therefore, autism-affirming research / practice must extend conceptualisations of EDs beyond Autistic traits alone and account for deeper, qualitative experiences, particularly within areas highlighted as priorities by the community.

**438.167** “I Did Not Think They Could Help Me”: Understanding Autistic People's Reasons for Not Seeking NHS Support When Experiencing Suicidal Thoughts/Behaviours

T. L. Procyshyn¹, **R. L. Moseley²**, **S. J. Marsden³**, **C. Allison⁴**, **T. Parsons⁵**, **S. A. Cassidy⁶**, **M. Pelton⁷**, **E. M. Weir⁸**, **T. A. Chikaura⁹**, **D. Mosse⁹**, **I. Hall¹⁰**, **L. Owens¹¹**, **D. Crichton³**, **J. Rodgers¹²** and **S. Baron-Cohen⁴**, (1)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, NA, United Kingdom, (2)Department of Psychology, Bournemouth University, Poole, United Kingdom, (3)United Kingdom, (4)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, Cambridgeshire, United Kingdom, (5)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, Cambridge, United Kingdom, (6)School of Psychology, University of Nottingham, Nottingham, Nottinghamshire, UNITED KINGDOM, (7)University of Cambridge, Cambridge, Cambridgeshire, United Kingdom, (8)Psychiatry, Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, Cambridgeshire, United Kingdom, (9)Department of Anthropology and Sociology, SOAS University of London, London, United Kingdom, (10)East London NHS Foundation Trust, London, London, United Kingdom, (11)EdmissionUK, London, London, United Kingdom, (12)Population Health Sciences Institute, Newcastle University, Newcastle, Newcastle upon Tyne, United Kingdom

Background: Autistic people experience mental health challenges at higher rates than the general population, with estimates that 1 in 3 experience suicidal thoughts and 1 in 4 attempt suicide. It is likely that many autistic people who struggle with their mental health do not seek professional support. However, little is known about this group.

Objectives: To gain insights into why autistic people who experience suicidal thoughts/behaviours do not seek support from the UK National Health Service (NHS).

Methods: Autistic people in the UK with experiences of suicidal thoughts/behaviours were invited to complete a co-designed online survey from January-July 2024. Respondents who said they did not contact the NHS when they last experienced suicidal thoughts/behaviours were asked to share the underlying reasons. Respondents were able to select multiple responses from a list of 20 reasons and to share their own reasons as a free-text response. Descriptive statistics were used to characterize the sample and understand the most frequently endorsed reasons for not seeking support. These reasons were then compared across age groups (age < 25, 25-40, 41+) and gender (cisgender males, cisgender females, trans/non-binary) using analysis of variance.

Results: Of 1357 respondents who answered questions about help-seeking, 1002 (74%) did not seek help from the NHS. Among those who said why, the three most commonly endorsed reasons for not seeking NHS support were “I tried to cope and manage my feelings by myself” (50%), “I did not think they could help me” (44%), and “The waiting list is too long – no point” (39%). Notably, only 21% of respondents endorsed “I did not think it was necessary” and 0% endorsed “I did not want to be stopped”. In the analysis by gender (**Fig. 1A**), cis women were more likely to endorse that the “thought of talking about it was too difficult”, while both cis women and trans/non-binary respondents were more likely to endorse “previous negative experience when suicidal”, “negative experience with other health issues”, and “I could not face a doctor appointment”. In the analysis by age (**Fig. 1B**), younger respondents were more likely to endorse “I did not think it was necessary”.

Conclusions: Understanding why autistic people may not seek support during a mental health crisis is crucial for improving access to care and developing more inclusive, tailored support systems. Of the large number of autistic people who chose to complete our survey, the majority did *not* seek NHS support when experiencing suicidal thoughts/behaviours. The most commonly endorsed reasons reflect lack of confidence in existing services and barriers to accessing support (i.e. wait times), with previous negative healthcare-related experiences emerging as particular barriers for cisgender women and trans/non-binary respondents in our sample. While this survey provides the most comprehensive information to date about this understudied group, the findings are subject to sampling bias and may not be reflective of the overall autistic population.

438.168 Predictors of Suicidal Thoughts Among Young Autistic Users of a Mental Health App

T. L. Procyshyn¹, M. Pelton², E. M. Weir³, T. A. Chikaura⁴, K. Comley⁵, S. Godson⁶, C. Allison⁶ and S. Baron-Cohen⁶, (1)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, NA, United Kingdom, (2)University of Cambridge, Cambridge, Cambridgeshire, United Kingdom, (3)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, Cambridgeshire, United Kingdom, (4)Psychiatry, Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, Cambridgeshire, United Kingdom, (5)Tellmi, London, NA, United Kingdom, (6)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, Cambridgeshire, United Kingdom

Background: Across all age groups, autistic people experience higher rates of suicidal thoughts and behaviours than the general population. While previous studies have identified various risk factors for suicidality among autistic adults, findings are more limited for autistic youth and typically rely on parent report or medical records, potentially overlooking important risk factors.

Objectives: To use self-reported data from young autistic users of a peer support mental health app in the UK to gain insights into factors associated with suicidal thoughts.

Methods: Autistic users of the Tellmi mental health app were invited to complete a 50-item survey co-designed with feedback from autistic people. In addition to reporting whether they experienced suicidal thoughts, respondents answered items related to (i) demographic characteristics, (ii) autism-related characteristics, (iii) adverse experiences/challenges, and (iv) co-occurring conditions. Descriptive statistics were used to describe the sample, and the chi-square test was used for comparisons between possible sub-groups. Binomial logistic regression was used to explore whether items from the above-mentioned four categories predicted suicidal thoughts.

Results: Complete data were available for 365 participants who believe they are autistic. The majority of participants were 11-16 years old (58%), cisgender female (54%), straight (72%), of white ethnicity (87%), and not eligible for free school meals (51%). A total of 122 participants had an autism diagnosis and 243 suspect they are autistic. As diagnosed and self-identifying participants did not differ in the frequency with which they experienced autism-related challenges (e.g., social interaction differences, communication differences, camouflaging/masking, repetitive behaviours, sensory differences, preference for sameness; all $p > 0.45$), they were analyzed as one group. The majority of participants (63%) reported that they experience suicidal thoughts, which is higher than the rate determined from a previous survey of non-autistic Tellmi users (51%). The binomial logistic regression results are presented in **Table 1**. Among demographic factors, gender non-conformity (i.e., identifying as trans, non-binary, gender questioning, etc.) and eligibility for school meals (as a proxy of socioeconomic status) were associated with a significantly higher odds ratio (OR) of suicidal thoughts. Among autism-related characteristics, requiring full-time care and higher reported levels of camouflaging were associated with suicidal thoughts. Among adverse experiences/challenges, experiencing hopelessness, family difficulties, physical abuse, and not wanting to attend school had a significantly higher OR of suicidal thoughts. Among co-occurring conditions, participants who experienced depression, bipolar disorder, and self-harm had a significantly higher OR of suicidal thoughts.

Conclusions: This study offers novel insights into factors associated with suicidal thoughts in young autistic users of a mental health app. Due to sampling bias, the findings may not be generalizable to all young autistic people. Despite these limitations, the findings suggest that established risk factors for suicidality extend to autistic youth (i.e., gender non-conformity, camouflaging, self-harm, depression, abuse, hopelessness), while identifying additional factors that may be unique to this group (i.e., family difficulties, higher care needs, not wanting to attend school). As suicidal thoughts typically precede suicidal behaviour, knowledge of risk factors could be applied to identify young people at high-risk and offer support.

438.169 A Transdiagnostic Exploration of Neurodevelopmental and Psychopathology Traits in Neurodiverse Children and Adolescents: Links to Adaptive Functioning and Quality of Life

T. Chau¹, J. J. Carmichael², M. A. Bellgrove³, B. Johnson⁴ and J. Tiego³, (1)Department of Paediatrics, Monash University, Clayton, VIC, Australia, (2)Monash-Epworth Rehabilitation Research Centre, Monash University, Richmond, VIC, Australia, (3)Turner Institute for Brain and Mental Health, Monash University, Clayton, VIC, Australia, (4)Monash University, Notting Hill, VIC, Australia

Background: Receiving co-occurring diagnoses across neurodevelopmental and psychiatric categories is commonplace for neurodivergent young people. When repeated patterns of co-occurring diagnoses arise, it raises concerns about the conceptual validity and utility of such categorical nosologies. Dimensional models of neurodevelopmental traits and psychopathology aim to address these concerns by characterising individuals along different spectra of transdiagnostic constructs.

Objectives: This study aimed to (a) develop a preliminary hierarchical model of autistic, ADHD, and psychopathological traits, and (b) explore the predictive utility of this model for adaptive functioning and quality of life outcomes, relative to the traditional DSM-5-TR categories.

Methods: The Extended BassAckwards procedure (Forbes, 2023) was applied to parent-report questionnaire responses of $N = 217$ neurotypical, autistic, ADHD, and AuDHD children and adolescents aged 6-18 years participating in the Monash Autism-ADHD Neurodevelopment and Genetics (MAGNET) Project based in Victoria, Australia. The questionnaires encompassed autistic and ADHD traits, anxiety, depression, and general emotional and behavioural wellbeing. The predictive validity of this transdiagnostic, dimensional model was compared against DSM-5-TR diagnoses with respect to the child's adaptive functioning (Vineland Adaptive Behaviour Scale) and quality of life (Child Health and Illness Profile).

Results: The model revealed a shared hierarchical relationship between autistic and ADHD traits with a common, higher-order 'Neurodevelopment' factor as well as a middle-order 'Withdrawal & Emotional Dysregulation' factor. Internalising and externalising phenomena were largely discrete from autistic and ADHD traits. The model was superior in predicting adaptive functioning and quality of life outcomes when compared to the DSM-5-TR diagnoses.

Conclusions: A dimensional understanding of autism and ADHD suggests potential aetiological overlap with aspects of emotional and behavioural regulation challenges. The personal and environmental contributors to these challenging experiences may represent a valuable treatment target for neurodivergent children, rather than solely focusing on their autistic and/or ADHD traits alone.

438.170 The Strengths and Difficulties Questionnaire As a Screening Instrument for Co-Occurring Mental Health Disorders in Autistic Children: An Explorative Study

M. B. Halvorsen¹, A. N. Kildahl², L. M. B. Slettvoll³, M. K. Eriksen⁴, M. I. Bjoernaa Haavrik⁵, A. Anke⁶ and S. B. Helverschow⁷, (1)Department of Pediatric Rehabilitation, University Hospital of North Norway, Tromsø, Norway, (2)Norwegian Advisory Unit for Mental Health in Intellectual Disabilities, Oslo University Hospital, Oslo, Norway, (3)Nordland Hospital Trust, Bodø, Nordland, Norway, (4)Finnmark Hospital Trust, Hammerfest, Finnmark, Norway, (5)Helgeland Hospital Trust, Mosjøen, Nordland, Norway, (6)Institute of Clinical Medicine, UiT The Arctic University of Norway, Tromsø, Troms, Norway, (7)NevSom, NevSom, Oslo University Hospital, Oslo, Norway

Background: The Strengths and Difficulties Questionnaire (SDQ) has been recommended as a mental health (MH) screening measure for children undergoing autism assessment to identify possible concurrent MH disorders. However, there is a notable lack of studies on the SDQ's ability to predict risk of disorder among children diagnosed with autism.

Objectives: Explore how the SDQ multi-informant algorithm agrees with the Diagnostic and Statistical Manual of Mental Disorders-Fifth Edition (DSM-5) based Kiddie-Schedule for Affective Disorders and Schizophrenia for School-Age Children (Kiddie-SADS) interview in identifying co-occurring MH disorders in autistic children.

Methods: The sample comprised 51 children and adolescents (age $M = 11.12$ years, $SD = 3.45$ years; full-scale IQ $M = 91.38$; $SD = 20.93$) who received an autism spectrum disorder diagnosis in the specialist health service. The majority (87%) were verbally fluent. The SDQ was completed by 51 parents, 16 adolescents and 39 teachers. In 45 cases both parent and teacher or self-report were available from the same families. Co-occurring MH diagnoses were based on the Kiddie-SADS interview conducted with parents, and the clinician conducting the interview was blind to the SDQ results. The main diagnostic groups (emotional, oppositional defiant disorder [ODD], attentional-deficit/hyperactivity disorder, and any disorders) were then compared to the SDQ scoring algorithm using two dichotomization levels: "possible" and "probable" levels. Sensitivity, specificity, positive predictive value, negative predictive value, and odds ratio were calculated.

Results: Sensitivity for the diagnostic categories was 0.30-0.73 ("probable" SDQ dichotomization level) and 0.68-0.84 ("possible" SDQ dichotomization level). Specificity was 0.80-0.90 ("probable" SDQ dichotomization level) and 0.38-0.73 ("possible" SDQ dichotomization level) (Table 1). Of the specific SDQ diagnostic algorithms, the emotional disorder algorithm showed an acceptable balance between sensitivity (0.74) and specificity (0.73) at the "possible" SDQ dichotomization level, followed by the oppositional defiant disorder (ODD) algorithm (sensitivity: 0.78; specificity: 0.69) (Table 1 and Figure 1). The SDQ any disorder algorithm performed adequate in terms of sensitivity (0.73) and specificity (0.88) at the "probable" dichotomization level.

Conclusions: In the clinic, sensitivity and specificity are important because these parameters indicate how many people with MH disorders the SDQ can correctly identify. In MH assessment of children using information from multiple informants is usually recommended. These results indicate that use of the SDQ multi-informant predictive algorithm shows acceptable sensitivity and specificity for the co-occurring diagnoses emotional disorder and ODD in mainly verbally fluent autistic children and adolescents. However, the sample was small, and more systematic attempts at validation are warranted, including examining the usefulness of the SDQ in combination with MH measures specifically developed for autistic children.

**438.171** Validity of the Psychopathology in Autism Checklist in Children with Autism Spectrum Disorder

M. B. Halvorsen¹, A. N. Kildahl², J. Thimm³ and S. B. Helverschow⁴, (1)Department of Pediatric Rehabilitation, University Hospital of North Norway, Tromsø, Norway, (2)Norwegian Advisory Unit for Mental Health in Intellectual Disabilities, Oslo University Hospital, Oslo, Norway, (3)Dep. of Psychology, UiT The Arctic University of Norway, Tromsø, Troms, Norway, (4)NevSom, NevSom, Oslo University Hospital, Oslo, Norway

Background: The Psychopathology in Autism Checklist (PAC) is a measure developed for older autistic adolescents and adults for identifying co-occurring mental health problems. Item development was informed by diagnostic criteria and expert judgement of what represents four major mental health disorders in autistic people (psychosis, depression, anxiety disorder, and obsessive-compulsive disorder [OCD]). The factor structure of the PAC has not yet been examined in a child sample.

Objectives: To evaluate the factor structure and validity of the PAC in a well-defined sample of autistic children. We hypothesized that: i) a four-factor solution would emerge consistent with the original four disorder-specific subscales, ii) a three-factor solution omitting items belonging to the psychotic subscale, would provide the best fit in this child sample compared to the originally proposed four-factor solution.

Methods: The sample comprised of 171 autistic children ($M = 8.16$ years, $SD = 4.73$; girls = 32%; full-scale IQ $M = 86.42$, $SD = 19.53$) referred for an autism spectrum disorder (ASD) assessment in the specialist health service. We conducted confirmatory factor analyses (CFA) comparing the proposed four-factor model against a three-factor model omitting the psychotic items. Correlations between the PAC subscales and the Strengths and Difficulties Questionnaire (SDQ), Vineland Adaptive Behavior Scales (VABS-II) and demographic variables were examined.

Results: The CFA revealed adequate fit indices for the three-factor solution (see Table 1). All factor loadings were greater than 0.50, except for two items belonging to the depression subscale. The CFA for the four-factor solution revealed less-than-optimal fit indices (Table 1). Overall, the PAC subscales OCD, depression, and anxiety showed meaningful overlap and differentiation with the SDQ subscales, VABS-II, autism symptoms, full-scale IQ, and demographic variables (see Table 2).

Conclusions: The current study contributed to the field of mental health assessment by examining the validity of a screening measure developed for autistic people. Satisfactory structural validity was found for the PAC when omitting the psychotic items, in a sample of autistic children referred for an autism assessment. The findings support the use of the PAC subscales OCD, depression, and anxiety among autistic children for identifying co-occurring mental health problems in need of further assessment.

Poster Session

439 - Communication and Language II

May 3rd, 2025, 12:30 PM - 1:30 PM - Hall 4A

439.175 Finding Common Ground: The Power of Linguistic Entrainment in Matched Neurotype Communication

M. Jameson¹ and **A. Bean²**, (1)Communication Sciences and Disorders, University of Memphis, Memphis, TN, (2)Speech and Hearing Science, The Ohio State University, Columbus, OH

Background: Recent evidence shows that matched-neurotype pairs communicate more effectively than mixed-neurotype pairs (Crompton et al., 2020; Oates et al., 2024). These dynamics occur, in part, because autistic individuals share a profile of pragmatic differences and a unique communication style that facilitates mutual understanding and connection, contributing to positive social experiences (Milton, 2012; Williams et al., 2021). One aspect of communication that has not yet been examined through the lens of double empathy is linguistic entrainment - the phenomenon in which communication partners gradually shift their speech and language to become more alike (Borrie & Liss, 2014; Garrod & Anderson, 1987). Greater convergence is strongly associated with increased rapport for neurotypical communicators (Borrie & Ivanova, 2021; Borrie & Liss, 2014; Gill, 2012). Because autistic people establish rapport differently than non-autistic people (Heasman & Gillespie, 2019; Rifai et al., 2022), we sought to analyze whether entrainment plays a role in the development of rapport among matched autistic pairs, and if so, whether it is correlated to the same extent as in matched non-autistic pairs.

Objectives: This study sought to investigate the extent of syntactic and semantic linguistic entrainment (i.e., increasing similarity over time) between communication partners with matched or mixed neurotypes; and secondly, to explore how these differences influence rapport development for communicators of different neurotypes.

Methods:

Thirty-three autistic adults and 37 non-autistic adults were systematically paired in either a matched-neurotype (i.e., matched non-autistic or matched autistic) or mixed-neurotype condition. Participants were blinded to their assigned condition. The pairs completed two structured communication tasks and a survey about the rapport they experienced in the interaction. The interactions were recorded, transcribed, and coded for syntactic and semantic convergence. Syntactic convergence was defined as change in MLU over the duration of the individual tasks and the full interaction. Semantic convergence was defined as the change in percentage of shared lexical items. Multiple team members conducted the transcriptions and coding for increased reliability.

Results: Initial analyses indicate that mixed-neurotype communication partners engaged in significantly less syntactic and semantic entrainment than matched-neurotype communication pairs. Moreover, syntactic entrainment contributed to rapport development for both non-autistic and autistic communicators in a similar manner, while semantic entrainment did not influence rapport for either group. Mixed-neurotype pairs reported significantly lower rapport than the two matched-neurotype pair conditions ($p=.023$), which did not differ significantly from one another.

Conclusions: Matched autistic and matched non-autistic communication partners are more likely than mixed-neurotype partners to adapt syntactic and semantic features of their language to one another. While matched non-autistic pairs used linguistic entrainment in communicative contexts that encouraged greater cooperation, matched autistic pairs tended to use it at least to some extent in all tasks. Both autistic and non-autistic communicators experienced boosts in interpersonal rapport associated with syntactic convergence. This innovative study underscores the importance of setting aside preconceived notions of autistic communication that are based on mixed-neurotype interactions. Furthermore, it contributes to the application of the double empathy theory to communication and introduces convergence as a unique pragmatic strength of autistic communicators.

439.176 Fine Motor Dexterity Associated with Vocal and Facial Affect Production in Autistic Youth

G. Lilly¹ and **C. Demopoulos²**, (1)UCSF Department of Psychiatry and Behavioral Sciences, University of California, San Francisco, San Francisco, CA, (2)Psychiatry & Behavioral Sciences, UCSF Center for ASD and NDDs, San Francisco, CA

Background: Previous research indicates deficits in gross motor coordination (e.g., arm movement, gait, and postural) are common in children with autism spectrum disorder (ASD; Fournier et al., 2010). These gross motor abilities have been associated with performance in other functional domains as well. Specifically, gross motor skills were found to significantly predict receptive and expressive language development (Bedford et al., 2016) and broad social skills, including adaptive social skills, social cognition, and social motivation (Wang et al., 2022). Further, impaired fine motor skills have been associated with poorer performance on tasks of articulation, receptive and expressive language and vocabulary, rapid naming, and parent report of functional and social communication skills (Simarro Gonzalez et al., 2024). However, associations between fine motor skills and specific aspects of social communication, such as expression of facial and vocal affect, have not been explored.

Objectives: This study examined associations between fine motor dexterity and vocal and facial affect production in children with ASD.

Methods: Participants included 58 autistic youth (33 males, 25 females), aged 8-17 ($M=12.27$, $SD=2.60$) who obtained a standard score of at least 80 on the Clinical Evaluation of Language Fundamentals-Fifth Edition (CELF-5) Core Language Index. This cut-off was applied to ensure participants were able to understand the narrative presented in one condition of the affect production task described below. Participants were administered a test of fine motor dexterity (grooved pegboard test) according to standardized clinical procedures and their performance was norm-referenced based on age (Knights & Norwood, 1980). Vocal and facial affect production were measured via a novel affect production task (Demopoulos et al., 2024). On this task, participants were prompted to produce a specific affective expression via either a monosyllabic or sentence-length utterance in response to an emotional narrative or without stated context. Audio and visual recordings captured their responses, and raters, blind to what expression the participant was prompted to produce were asked to identify the expressions. Facial and vocal ratings were performed separately. Accuracy was quantified by correspondence between the blinded rater's affective label and the emotion the participants were prompted to produce. Hierarchical linear regression analyses were performed in SPSS (version 29) to evaluate the relationship between dominant hand fine motor dexterity and vocal and facial affect production, after controlling for nonverbal intellectual abilities.

Results: After controlling for nonverbal intellectual abilities, dominant hand fine motor dexterity accounted for an additional significant proportion of the variance in vocal (R^2 Change=0.083, $F(1,50)=4.871$, $p=0.032$) and facial affect production abilities (R^2 Change=0.072, $F(1,54)=4.230$, $p=0.045$).

Conclusions: This study focused on the associations between fine motor skills and isolated social communication abilities, specifically vocal and facial affect production. Results indicated that better fine motor dexterity was associated with more effective facial and vocal affective communication in children with autism, after controlling for intellectual abilities. Facial expression and vocalization require coordination of many muscles within the face and vocal apparatus, respectively. These results may suggest that a common underlying difficulty in motor control may contribute to affect production difficulties that can be characteristic of ASD.

439.177 Gesture, Multimodal Communication, and Temporal Synchrony in Neurotypical and Autistic Children: A Microanalytic Exploration

A. Campisi^{1,2}, **E. Leonardi**³, **S. Aiello**³, **F. I. Famà**³, **M. Proietti**⁴, **C. Carrozza**³, **T. NEST Team**³, **G. Tartarisco**³, **Y. Ozturk**², **M. C. Passolunghi**⁵, **S. Pellizzoni**², **E. Bortolotti**², **M. V. Lombardo**³, **G. Pioggia**³, **O. Capirci**⁸, **M. Mastrogiuseppe**^{2,9} and **L. Ruta**³, (1)University of Trieste, Messina, Italy, (2)University of Trieste, Trieste, Italy, (3)Institute for Biomedical Research and Innovation (IRIB), National Research Council of Italy (CNR), Messina, Italy, (4)Institute of Cognitive Sciences and Technologies (ISTC), National Research Council of Italy (CNR), Rome, Italy, (5)Institute for Biomedical Research and Innovation (IRIB), National Research Council of Italy, Messina, Italy, (6)University of Trieste, Trieste, Trieste, Italy, (7)Laboratory for Autism and Neurodevelopmental Disorders, Italian Institute of Technology, Rovereto, Trento, Italy, (8)Institute of Cognitive Sciences and Technologies, National Research Council of Italy, Rome, Italy, (9)Institute for Biomedical Research and Innovation (IRIB), National Research Council of Italy (CNR), Messina, Sicily, Italy

Background:

In typical development, infants frequently use multimodal communication, such as gaze, gestures, and speech, integrating these to capture caregiver attention (Goldin-Meadow, 2007). Multimodality is a key aspect of early communication (Iverson, 2010) and correlates with later language and social skills (Parladé, 2009; Rowe & Goldin-Meadow, 2009). In addition, temporal synchrony in these combinations serves as a powerful social cue for effective communication (Iverson, 2010). Previous studies indicate that children with an elevated likelihood of autism show a reduced use of multimodal combinations, such as gaze, gesture, and speech, during interactions (Parladé, 2015; Heymann, 2018; Choi, 2019; Wetherby, 2022), while, to the author's knowledge, temporal synchrony in gesture-speech combinations in very young autistic children during naturalistic parent-child interactions has not yet been explored. Our study aims to address this important gap.

Objectives:

We conducted a detailed micro-analysis of gesture-speech and gesture-gaze integration and their temporal dynamics in neurotypical and autistic children during naturalistic parent-child play interactions.

Methods:

The study included 28 neurotypical (NT) children (16 males) and 30 children (18 males) with an autism spectrum condition (ASC). The two groups were matched by the chronological age of the NT group (mean: 20.3 months, SD 5.7) with the developmental performance age of the ASC group (mean: 21 months, SD 8.3). We analyzed videos of naturalistic parent-child play interactions using a novel moment-by-moment coding scheme.

Our focus was on total gesture production—including deictic, representative-iconic, and conventional-interactive gestures—and its coordination with gaze shifts between the activity area and the partner's face, as well as the coordination of gestures with speech production.

Both measures were calculated as the proportion of gesture-gaze and gesture-speech behaviors relative to the total number of gestures produced by each child. Furthermore, we examined the temporal synchrony between gesture strokes and speech by calculating the proportion of gesture strokes aligned with speech relative to the total number of gesture-speech integrations.

Results:

ASC children exhibited a significantly lower total number of gestures than NT children ($U=179$; $p=0.0001$), a lower proportion of gestures integrated with alternate gaze ($U=205.5$; $p=0.01$) and reduced combinations of gestures with speech ($U=168$; $p=0.0027$). In addition, ASC children showed a reduced temporal synchrony between the gesture stroke and the speech ($U=114$; $p=0.024$, two-tailed) (fig.1).

Conclusions:

This micro-analytic study of early communication during naturalistic parent-child play interactions reveals that very young children with a clinical diagnosis of ASC coordinate gestures with alternate gaze and speech less frequently than their neurotypical peers, confirming previous findings in children with an elevated likelihood of autism. Importantly, this is the first report of reduced temporal synchrony between gesture strokes and speech in autism at such a young age.

By using a neurodiversity perspective, our study offers new insights into the multimodal communication profile of neurodivergent ASC children, enhancing our understanding of communication differences in autism. These findings support early detection and individualized, strengths-based interventions within a developmental framework.

439.179 How Do Virtual Communication Settings Impact Pragmatic Language in Autistic Adults?

E. Hay¹, T. Potter¹, J. Hohenberg¹, L. Silverman² and E. Prud'hommeaux¹, (1)Boston College, Chestnut Hill, MA, (2)University of Rochester Medical Center, Rochester, NY

Background: Improving conversational use of spoken language is a common intervention goal for verbal individuals with autism, but there have been relatively few studies exploring discourse and dialog in autistic adults. Furthermore, we know little about how pragmatic language might be influenced by communication modality, which has grown increasingly important with the rise of the virtual workplace. To address these issues, we measure discourse features in autistic and neurotypical adults with low support needs as they engage in collaborative tasks with non-autistic peers. We explore these first in an in-person setting and later via a teleconferencing platform in order to better understand how communication modality impacts these discourse features.

Objectives: (1) To understand how communication modality (in person vs. teleconferencing) influences a speaker's overall degree of uncertainty, politeness, and informativeness. (2) To determine whether these discourse features are differentially impacted in autistic adults.

Methods: A subset of 10 adults (NT $n=5$, AUT $n=5$) from an earlier study ($n=25$) of in-person communication in autistic adults with low-support needs were invited to participate in a Zoom-based version of our earlier protocol. Each experimental participant (EP), autistic or neurotypical, engaged in a task requiring collaborative discussion with a designated conversational partner (CP). In this task, the EP and CP viewed maps of the same location with different roadblocks and labeled points, while the EP directed the CP to their location on the map. Each transcribed utterance was rated by two annotators on a 3-point scale for three discourse features: politeness, uncertainty, and informativeness. Cohen's kappa between the two annotators exceeded 0.8 for all three features. The average of the two RAs' ratings for each utterance was recorded as the final rating.

Results: In prior work with a larger group of EPs ($n=25$) in an in-person only setting, we noted a between-group difference in politeness, with utterances produced by autistic EPs rated as more polite ($p<0.001$). With this smaller subset, EPs did not show any significant between-group differences in politeness, uncertainty, or informativeness, whether in person or in the virtual modality. However, we did observe that autistic EPs were significantly less uncertain ($p<0.01$, $t=-3.608$) on average in the virtual modality (see Figure 1).

Conclusions: These results indicate that autistic adults with low support needs adjust their pragmatic language use when conversing via teleconferencing in ways that neurotypical individuals do not. There is prior work suggesting that autistic individuals may benefit from the reduction in sensory input streams afforded by virtual rather than in-person communication. The decrease in observed uncertainty when communicating on Zoom lend some support for these prior findings. We will continue to explore this phenomenon with additional as-yet unannotated data from a different collaborative task, as well as additional annotations of speech act labels.

439.180 Identifying Predictors of Language for Minimally Verbal Autistic Children Among Slow Responders to Initial Intervention
W. I. Shih¹, S. Y. Shire², Y. C. Chang³, J. Panganiban⁴ and C. Kasari⁵, (1)University of California - Los Angeles, Los Angeles, CA, (2)Special Education and Clinical Sciences, University of Oregon, Eugene, OR, (3)Special Education and Counseling, California State University, Los Angeles, Los Angeles, CA, (4)Semel Institute, University of California Los Angeles, Los Angeles, CA, (5)Education and Psychiatry, University of California Los Angeles, Los Angeles, CA

Background: Minimally verbal (MV) autistic children continue to be an understudied population. These children's social communication skills can be complex and variable and there is a need for more tailored interventions for this population. Intervention studies have examined predictors of intervention outcomes, but few studies explore predictors for MV autistic children who are slow to respond to initial interventions.

Objectives: This study explored whether independently assessed nonverbal social communication behaviors at early response (Week 6) to exit predict children's language at the end of study among MV autistic children who were slow responders to initial intervention strategies.

Methods: Ninety-seven MV autistic children (M=73.07 months old, SD=14.76; non-verbal mental age of 35.7 months), average of 3.4 distinct words enrolled in this study across 4 sites. On average, these children were primarily male (83.5%), from diverse ethnic/racial backgrounds (46% non-Caucasian) with average ADOS severity scores of 7.43 (moderate-severe).

This is a secondary data analysis based on a multisite Sequential Multiple-Assignment, Randomized Trial (n=194). For this study, only data from children (n=97) who were considered slow responders to initial intervention at Week 6-Early Response were included. Assessments were collected at the major time-points: baseline, Week 6 early response, and Week-18 exit.

The Naturalistic Language Sample (NLS) is a 21-minute standardized, video-recorded, naturalistic adult-child interaction where socially communicative utterances (SCU) and the number of distinct word roots (NDWR) are the primary outcomes.

The Early Social-Communication Scales were administered by blinded assessors to assess children's social communication skills. The type and frequency of spontaneous initiations of joint attention skills (IJA) and behavioral requests (IBR) were coded as well as responding to joint attention request (RJA) and behavioral requests (RBR).

Regression analyses were used to determine the association between changes in child behaviors from early response to exit with child's language (SCU) at exit while controlling for site differences, child's age and gender.

Results: After receiving 6 weeks of initial intervention, these children remained as marked or severe (92.7%) in terms of their social communication skills at Week 6-early response. From Week 6 to exit, these children made significant improvements in their SCU (p=0.0215) with an average increase of 1.88 SCU (SD=7.81). Children's IBR and RJA at Week 6 were positively associated with increased SCU at exit (p=0.015 and p=0.016), but not IJA and RBR. Further, changes in children's IJA from Week 6 to exit is positively associated with increased number of NDWR from early response to exit (p=0.01).

Conclusions: Among these slow responders in either arm of the intervention, their IBR and RJA at Week 6 is positively associated with increased SCU at exit and their improvement in IJA is associated with gains in NDWR from early response to exit. The findings suggest that for this group of MV children who are slower to respond to intervention can continue to make significant improvement in their social communication skills with several children increased as much as 17-18 novel words. This suggests an increasing ability to express themselves more meaningfully and with greater linguistic diversity.

439.181 Impact of High-Fidelity Jasper Implementation on the Developmental Skills of Young Children with Autism

Y. C. Chang¹, S. Y. Shire², W. I. Shih³ and C. Kasari⁴, (1)Special Education and Counseling, California State University, Los Angeles, Los Angeles, CA, (2)Special Education and Clinical Sciences, University of Oregon, Eugene, OR, (3)University of California - Los Angeles, Los Angeles, CA, (4)Education and Psychiatry, University of California Los Angeles, Los Angeles, CA

Background: Early intervention approaches for young children with autism can be implemented in community classrooms with fidelity (Panganiban et al., 2022; Shire et al., 2017). Overall fidelity of program implementation has been associated with children's skills (Shire et al., 2017), however, the specific components embedded within these packages that may be driving child outcomes remain unclear.

Objectives: The current study was a secondary data analysis combining two previously published school-based intervention studies (Chang et al., 2016; Shire et al., 2017). The goal of this study was to determine if a) high fidelity and b) to which components of the intervention model (JASPER), were associated with differential child outcomes, including joint engagement (JE) and initiations of joint attention (IJA).

Methods:

Participants. Children (n=197) with autism aged 2-5 years (M=38 months; SD= 9.35 months) were included. Eighty percent of the sample were male participants and had diverse backgrounds (49% Hispanic, 19% Black, 15% White, 10% Mixed, and 7% Asian). Children in both studies were randomized to JASPER immediate treatment (IT) or school as usual waitlist (WL) for 3 months.

Intervention. Educators received training and in-vivo coaching with the research team to learn the JASPER intervention. In the IT group, educators implemented JASPER 30 minutes a day with their students for 3 months, while WL educators continued with standard school curriculum.

Teacher-child play interactions (TCX). Teachers' accurate implementation of JASPER was coded at entry and exit. Seven strategy sets were coded: Supports for Engagement and Regulation, Environment, Balancing Imitation and Modeling, Play Routines, Expanding Play Routines, Joint Attention and Requesting Skills, and Language Strategies. These strategies were examined within three subscales of strategy sets: Foundational, Core, and Advanced. Implementation fidelity for each set of strategies was split into high (70%+) and low (<70%).

Results: Regression analyses indicated that for JASPER classroom educators with high implementation fidelity of Core strategies at exit (>70%), the students demonstrated more time in JE (p=0.030) and more IJA (p=0.019) from baseline to exit. Strategy fidelity of Foundational and Advanced strategies were not associated with greater JE and IJA at exit.

Within the JASPER intervention group, the increase in implementation fidelity of Advanced Strategies from baseline to exit, was associated with increases in children's IJA (p=0.028), but not the other two strategies (p=0.065 and p=0.427). There were no associations between increase in fidelity implementation with increase in JE.

Conclusions: Educators' JASPER implementation fidelity is linked to children's progress in JE and JA. There was no signal that foundational strategies alone will impact children's outcomes. Rather, it is necessary to deliver high quality Core strategies to make changes in JE, the documented mechanism of change in JASPER intervention (Gulsrud et al., 2016). Further, the more complex Advanced strategies are required to advance higher level IJA skills. Future studies should examine strategies to better support educators in the implementation of the strategies (i.e., fidelity) to maximize outcomes for children with autism.

439.182 Infant and Caregiver Gesture Use and Language Abilities in Infants at Elevated Familial Likelihood for Autism from India
M. Srikanth¹, R. Raju², N. Raman¹, A. Roy¹, A. V. Reddy¹, D. Swaminathan³ and S. S. Meera⁴, (1)National Institute of Mental Health and Neurosciences (NIMHANS), Bangalore, India, (2)National Institute of Mental Health and Neuro Sciences (NIMHANS), Bangalore, Bangalore, Karnataka, India, (3)National Institute of Mental Health and Neurosciences (NIMHANS), Bangalore, India, Bangalore, India, (4)National Institute of Mental Health and Neurosciences (NIMHANS), Bangalore, Karnataka, India

Background: Gestures are key developmental milestones that support communication and language in infants. Infant siblings of autistic children, at elevated familial likelihood for autism or related neurodevelopmental disorders (EL-A), tend to use fewer gestures than typical likelihood (TL) infants, potentially affecting their later language development.^{1,2} However, gesture use may vary across cultures and is yet to be systematically studied in non-Western contexts like India. Although research indicates EL-A infants receive differential caregiver verbal input compared to TL infants,³ gesture input remains understudied.

Objectives: To investigate (a) early gesture use in EL-A and TL infants, (b) caregiver gesture use with EL-A and TL infants, and (c) association of (i) infant and (ii) caregiver gestures use, with concurrent infant language abilities

Methods: Six-minute caregiver-infant free-play videos were collected from 33 EL-A ($M_{age}=11.65\pm2.04$ months, 13F) and 15 TL ($M_{age}=12.75\pm2.12$ months, 9F) dyads. Directed gestures from caregivers and infants were coded by three trained reliable coders using EUDICO Linguistic Annotator (ELAN v.6.8) software, following a coding schema developed for gestures (GC) and gesture-speech combinations (GSC) (see Figure 1). Annotation frequencies were compiled, and total gestures types (GT) was computed. Non-parametric Quade's ANCOVA controlling for infant age was used to investigate gesture use between the groups and partial Spearman's correlations adjusted for age was used to assess association between gesture use and language.

Results: Table-1 depicts descriptive data for infant development. EL-A infants used significantly fewer deictic gestures ($F=4.41, p=.042$),² gesture types ($F=21.21, p<.001$) and gesture initiations ($F=25.74, p<.001$)⁴ compared to TL infants. Conversely, EL-A caregivers provided more GSC ($F=5.13, p=.028$), and initiated more gestures ($F=6.69, p=.013$) than TL caregivers (Table 1). While EL-A caregivers showed significant preference for reinforcing gestures ($F=17.33, p<.001$), TL caregivers used significantly more disambiguate gestures ($F=10.54, p=.002$), possibly reflecting their efforts to engage/maintain their infants' attention⁴ or following practices learned through interventions for their older autistic child.

In the overall sample, following positive moderate associations were observed between infant gestures and language abilities: GT with both receptive ($p=0.37, p=.01$) and expressive language ($p=0.37, p=.009$) on VABS and MCDI early gesture ($p=0.38, p=.009$); initiation with VABS receptive language ($p=0.4, p=.005$) and MCDI early gesture ($p=0.41, p=.004$) (Figure 2). These findings reinforce a link between infant gesture use and language abilities.¹ However, deictic gestures ($p=0.31, p=.033$), GC ($p=0.3, p=.045$), and gesture responses ($p=0.42, p=.004$); were negatively associated with MCDI expressive vocabulary. This direction of findings was unexpected and needs to be explored further at later ages with stabilized verbal repertoire (i.e., >24months).

Surprisingly, caregiver GC was negatively associated with VABS receptive language ($r=0.32, p=.03$) and gesture initiation was negatively associated with MCDI expressive vocabulary ($r=0.41, p=.005$) and early gestures ($r=0.29, p=.048$). These findings suggest caregivers may compensate by using more gestures with infants who have difficulty in understanding them and initiating more with less expressive infants.

Conclusions: This is one of the first studies exploring infant and caregiver gestures use in EL-A dyads in a non-Western context. Observed findings highlight the importance of monitoring infant gesture use and including this as a target for early intervention programs. Larger longitudinal studies are required to further investigate present findings.

439.183 Lexical Processing in Autistic Children: Associations with Word Learning, Vocabulary, and Cognition

H. Barton¹, S. Xu¹ and S. T. Kover², (1)University of Washington, Seattle, WA, (2)Speech and Hearing Sciences, University of Washington, Seattle, WA

Background:

Looking-while-listening (LWL) measures real-time lexical processing by presenting two images on a screen and quantifying the extent to which a child directs their eye-gaze to the visual stimulus that matches an auditory one (Fernald et al., 2008; Venker & Kover, 2015). In autistic children, Venker et al. (2013) found relationships between LWL performance, vocabulary, and nonverbal cognition, but only examined familiar words. Haebig et al. (2017) found associations between LWL performance for recently taught novel words and vocabulary size in autistic children, but not between nonverbal cognition and word learning. Recently, Ronfard et al. (2022) demonstrated associations among LWL familiar word processing, novel word learning, vocabulary, and cognition in neurotypical toddlers. The current study extends this research with an LWL task that taps both familiar and novel words in older autistic children.

Objectives:

We address whether individual differences in LWL performance for familiar words are associated with LWL performance for novel words, vocabulary size, and nonverbal cognition among autistic children.

Methods:

Participants were autistic 3- to 11-year-olds ($N=29$) who completed an LWL task (Fernald et al., 2008). Auditory stimuli included both short (1-syllable) and long (2-syllable) words, with familiar and novel words interspersed. Trial order, target side, and label-object pairings were counterbalanced. Visual stimuli were color images of unfamiliar objects (Law & Edwards, 2015) and familiar objects of similar size and complexity.

Accuracy for each trial was calculated as the proportion of time spent looking at the target (as opposed to the distracter). The test window was defined as 267ms-3500ms after target word onset. Trials were excluded when less than 50% of gaze in the test window was to the images; participants were excluded when contributing fewer than 3 trials of a given task segment. To yield familiar and novel word accuracy, performance was collapsed across word length because accuracy did not differ between short and long words ($p>.34$).

Receptive and expressive vocabulary were characterized with Peabody Picture Vocabulary Test (PPVT-4) and Expressive Vocabulary Test (EVT-2) growth scale values. Nonverbal cognition was assessed using the Leiter International Performance Scale (Leiter-3). See Table 1.

Results:

Accuracy for familiar and novel words statistically exceeded chance (i.e., .5; $M_{\text{Familiar}}=.70$, $SD=.14$; $M_{\text{Novel}}=.61$, $SD=.14$). Familiar word accuracy significantly exceeded novel word accuracy, $t(27)=3.32$, $p<.01$. See Figure 1. Using Pearson's correlations, familiar word accuracy was positively correlated with novel word accuracy, receptive and expressive vocabulary size, and nonverbal cognition ($p<.01$). Partial correlations controlling for age yielded the same conclusions.

Conclusions:

Similar to Ronfard et al.'s (2022) findings for neurotypical toddlers, familiar word processing was associated with novel word processing, vocabulary size, and cognition among autistic children, pointing to LWL familiar word accuracy as reflective of a broader set of developmental skills, as well as the utility of LWL for assessing novel word learning in this population. Next steps include examining response time and lexical characteristics, such as phonological neighborhood density, as they relate to lexical processing for familiar and novel words for autistic children.

439.184 Investigating Gesture-Speech Integration Impairments in Autism: An fNIRS Study

B. M. Farran¹, S. J. Sheinkopf² and L. M. Morett¹, (1)Speech, Language and Hearing Sciences, University of Missouri, Columbia, MO, (2)Thompson Center for Autism & Neurodevelopment, University of Missouri, Columbia, MO

Background:

Gesture-speech integration is a fundamental aspect of human communication, and disruptions in this multimodal process are frequently observed in individuals with Autism Spectrum Disorder (ASD). Prior research has identified atypical neural responses to multimodal stimuli in ASD, particularly in inferior frontal gyrus (IFG) and posterior superior temporal sulcus (pSTS), two key brain regions subserving language and social communication. However, the neural mechanisms underlying these disruptions in speech processing, specifically during gesture-speech integration, remain poorly understood. This study addresses this gap by examining neural activation in children with ASD during tasks involving unimodal gesture and speech processing and congruent and incongruent gesture-speech pairings.

Objectives:

The objective of this study was to identify the neural correlates of gesture-speech integration in children with ASD using functional near-infrared spectroscopy (fNIRS). Specifically, we aimed to identify differences in hemodynamic responses of IFG and pSTS across four experimental conditions: 1. Congruent gesture-speech pairings; 2. incongruent gesture-speech pairings; 3. gesture only stimuli; 4. speech only stimuli. We hypothesized that children with ASD would exhibit reduced activation in IFG and pSTS, particularly for incongruent gesture-speech pairings, and that these neural disruptions would correlate with social communication deficits.

Methods:

7 (1/6 F/M) children with ASD and 11 (9/2 F/M) typically developing (TD) children, aged 5 to 10 years, all with average range IQ scores, and we anticipate collecting data from 8 additional ASD and 4 additional TD children. Groups are matched for age and sex (mean age = 8.5 years; 8/10 females/males). Using fNIRS, we measured oxyhemoglobin (HbO) and deoxyhemoglobin (HbR) concentration changes in IFG and pSTS bilaterally the four experimental conditions. An interleaved design was used, with each trial consisting of a fixation period (4–6 seconds), followed by stimulus presentation (3–4 seconds), a 500-ms blank screen, and a 10-second response window. Responses were extracted by averaging the signal from the stimulus presentation onset through the response phase (i.e., to the offset of the response window). Data were processed with motion artifact removal, Fast Fourier Transform, and band-pass filtering techniques. Group differences in functional activity in the IFG and pSTS were assessed using a generalized linear model (GLM).

Results:

Only correct trials were included in the analysis. Children with ASD exhibited reduced activation in left IFG and pSTS during all pairings, with particularly pronounced reductions during incongruent gesture-speech pairings, compared to TD. No significant differences in activation were observed in the right hemisphere between groups.

Conclusions:

This study provides new evidence of reduced neural activity during gesture-speech integration in children with ASD in IFG and pSTS, both of which play a key role in multimodal processing. These findings reinforce the importance of multimodal processing in gesture-speech integration and point to neural processes underlying this aspect of communication impairments in ASD.

439.185 Language Differences in Regressive and Non-Regressive Autism: The Role of Speech and Language Therapy, Cognitive Skills, and Autism Characteristics

K. Saleem¹, H. Roeyers² and S. Boterberg², (1)Faculty of Clinical, Educational and Developmental Psychology, Ghent University, Ghent, East Flanders, Belgium, (2)Department of Experimental-Clinical and Health Psychology, Ghent University, Ghent, Belgium

Background: Developmental regression in autism, marked by the loss of previously acquired abilities, often occurs between 6 and 30 months, and affects 30% of autistic children. In contrast, those without regression may show early developmental delays, including atypical language and social skills. These differences in onset patterns are linked to variability in developmental domains including cognitive abilities, motor skills, and language proficiency. Early recognition and intervention of language difficulties in autism are crucial for long-term outcomes. Speech and language therapy (SLT) is considered a fundamental intervention, but its differential impact in autistic children with and without regression has not yet been thoroughly examined.

Objectives: This study aimed to 1) Examine how the interaction between autism onset (regression vs. non-regression) and SLT participation affects language outcomes, and 2) Determine if cognitive abilities, motor skills, and autism characteristics predict language development in autistic children with and without regression.

Methods: The study included 117 autistic children aged 2 to 10 years (boys=95, girls=22), classified into regressive (n=21) and non-regressive groups (n=96) based on retrospective parent reporting during developmental history sessions. Children were further subdivided based on their history of SLT participation—those who received therapy before diagnosis (n=42) and those without any prior intervention (n=75). Measures included language outcomes, which were assessed in three domains: total language, receptive language, and expressive language. Cognitive abilities were measured using the DAYC-2, and autism characteristics were assessed with the Childhood Autism Rating Scale (CARS).

Results: MANOVA revealed a significant interaction between autism onset type and SLT participation, affecting total, receptive, and expressive language abilities (Wilks' $\Lambda = .83$, $F(3, 113) = 7.84$, $p < .001$). Post-hoc two-way ANOVAs showed the interaction effect between onset type and SLT was significant for receptive ($F(1, 113) = 10.221$, $p = .002$, $\eta^2 = .083$) and expressive language scores ($F(1, 113) = 22.596$, $p < .001$, $\eta^2 = .167$). These findings suggest that attending SLT significantly positively affected language development for autistic children with regression (See Figure 1).

Additionally, cognitive ability emerged as a significant positive predictor of language development ($t = 2.115$, $p = .037$), while autism characteristics were a strong negative predictor ($t = -6.403$, $p < .001$). Gross motor ($t = -.741$, $p = .460$) and fine motor skills ($t = -.552$, $p = .582$) were not significant predictors. For the non-regression group, autism characteristics remained a significant negative predictor ($t = -6.264$, $p < .001$), but no significant predictors were identified for the regression group.

Conclusions: The study highlights the importance of personalized interventions based on autism onset patterns, emphasizing that SLT may be more effective when tailored to the child's specific developmental Understanding the interaction between SLT, cognitive abilities, and autism characteristics can help clinicians design more effective therapies for improving communication skills. Further research is essential to expand these findings and to explore how these variables influence long-term language outcomes.

439.186 Language Style Matching and Conversational Success in Autistic and Non-Autistic Adolescents

A. Knox¹, M. Lyons¹, S. Schillinger¹, A. L. Lee¹, L. J. Fulop¹, S. Cho², M. Liberman², J. Uzokwe³, L. D. Yankowitz⁴, C. J. Zampella¹, L. S. Cubit⁵, J. Pandey¹, R. T. Schultz⁶ and J. Parish-Morris¹, (1)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (2)Linguistic Data Consortium, University of Pennsylvania, Philadelphia, PA, (3)Children Hospital of Philadelphia, Philadelphia, PA, (4)Laboratories of Cognitive Neuroscience, Boston Children's Hospital/Harvard Medical School, Boston, MA, (5)Clinical and Social Sciences in Psychology, Center for Autism Research, Rochester, NY, (6)The Center for Autism Research/CHOP, Philadelphia, PA

Background: Successful conversations are characterized by mutual engagement and coordination across multiple verbal and non-verbal domains. One type of linguistic coordination is language style matching (LSM), which captures the degree to which two people emulate each other's speaking style during a conversation, marked by the degree at which participants produce similar rates of function words (Gonzales et.al., 2010). Prior research in neurotypical populations suggests that greater LSM is associated with better conversational outcomes (greater perceived conversational quality; Ireland et.al., 2010), but little is known about the relationship between LSM and conversational outcomes in autistic adolescents or teens with other neurodevelopmental/psychiatric conditions.

Objectives: Examine the relationship between LSM and conversation quality to determine if greater LSM correlates with better conversational outcomes in autistic teens (AUT), neurotypical teens (NT), and teens with other neurodevelopmental/psychiatric conditions like ADHD or anxiety (PSY).

Methods: One hundred and thirty-seven adolescents (AUT N=36, 14 female; NT N=23, 8 female; PSY N=78, 40 female) aged 12-18 years participated in a 5-minute, "get-to-know-you" conversation with novel young adult interlocutors (study staff). Both participants and interlocutors respectively completed a 15-question Conversation Rating Scale (CRS; Ratto et.al., 2011) immediately after finishing the conversation. Questions on the CRS were rated on a 7-point Likert scale, with the sum of all questions calculated to produce a total score (higher scores indicate greater conversational success and satisfaction). Conversations were orthographically transcribed and a pairwise comparison LSM metric for each dyadic conversation was computed using LIWC-22 (Pennebaker, 2022). Participant and confederate CRS scores were then separately correlated with their respective conversational LSM.

Results: Across the entire sample, there was a significant positive correlation between extent of language style matching between conversation partners and staff ratings of conversation quality (Fig. 1a). This effect held within the PSY and AUT groups separately (Fig. 1b, 1c). There was no significant correlation between CRS scores and LSM in NT dyads (Fig. 1d). Correlations between LSM and conversation quality as rated by teen participants followed a different pattern, with no statistically significant correlations overall nor within each subgroup separately.

Conclusions: Greater language style matching during naturalistic conversations between teens with autism or other neurodevelopmental/psychiatric conditions and adult interlocutors leads to perceptions of greater conversational success – but only from the adult perspective. These results, while preliminary, suggest that adolescents may not perceive a conversation as successful even when they and their conversation partner are engaging in a high degree of language style matching. Future research is warranted to clarify the extent to which language style matching predicts conversational success in other relevant contexts (e.g., between same-aged peers of different neurotypes) and if there may be other measures that predict adolescent conversation ratings.

**439.187 Leveraging Retrieval-Augmented Large Language Models for Enhanced Communication of Autism Therapy Guidelines**

D. Wattegama¹, B. Black^{2,3}, E. Ranum^{4,5} and C. R. Shyu^{3,6,7}, (1)Institute for Data Science and Informatics, University of Missouri - Columbia, Columbia, MO, (2)Pediatrics-Developmental Behavioral, University Of Missouri, Columbia, MO, (3)Thompson Center for Autism & Neurodevelopment, University of Missouri, Columbia, MO, (4)Thompson Center for Autism & Neurodevelopment, Columbia, MO, (5)Resident Child Health, University of Missouri, Columbia, MO, (6)Institute for Data Science and Informatics, University of Missouri - Columbia, Columbia, MO, (7)Electrical Engineering and Computer Science, University of Missouri, Columbia, MO

Background:

The complexity of autism spectrum disorders (ASD) and the frequent requests for guidance that clinicians receive make it challenging for clinicians to provide personalized advice for each child within limited time constraints. Clinicians often turn to autism-specific toolkits as resources to answer common questions. However, conveying this information to caregivers does not always result in tailored instructions that meet each child's unique needs, or clear actionable advice for caregivers, as the information tends to be generalized.

Objectives:

Adopting a Large Language Model (LLM)-centered approach can enable clinicians to quickly generate and share personalized, conversational responses with caregivers, aligning with the specific needs of each child and caregiver with minimal time and effort. By combining an LLM-centric approach with Retrieval-Augmented Generation (RAG), we introduce a framework that uses embedding finetuning and prompt chaining to improve both answer accuracy and clarity, including generating clear examples for better caregiver understanding. Initial testing with a selected set of questions showed that clinician evaluators preferred our RAG-enhanced model over a general LLM (ChatGPT).

Methods:

To ensure factual accuracy and reduce hallucinations, we compiled a comprehensive autism-related resource collection, guided by clinicians, including research papers, Autism Speaks toolkits, and journal articles. This collection supports reliable responses to autism treatment inquiries. To further enhance document retrieval accuracy, we customized the out-of-shelf embeddings by fine-tuning on a synthetic dataset curated from autism-specific documents, increasing the relevance and quality of retrieved content.

Our framework consists of two main components. First, the offline component organizes and stores essential documents in a fast, flexible embedding database. The second component operates online, retrieving relevant documents in response to user queries and using prompt chaining to generate detailed answers. We employed a three-stage prompt chaining approach with ChatGPT (gpt-4-0613) to generate responses for autism treatment queries. The generative stage creates responses based only on the retrieved documents. In the validation stage, we verify each response step against the documents to avoid reliance on LLMs internal knowledge. Finally, the elaboration stage enhances the response with easy-to-understand examples, making the guidelines more accessible and actionable for caregivers.

Results:

During initial testing, we compared the RAG model to standalone ChatGPT using five main evaluation categories: "Factuality," "Completeness," "Safety," "Creativity," and "Similarity." Two pediatric specialists rated responses on a scale from 1 to 10 for five questions, assessing 11 criteria. Shown in Figure 1, Regarding the aspect of factuality ([A], [B]), the RAG model's performance is marginally better according to evaluations by clinicians, and the explanations provided by the RAG model were deemed by clinicians to be most closely aligned with the actual responses given by physicians ([K]). According to the Creativity ([I]) aspect, the RAG model outperforms ChatGPT by an average of 40% in mean ratings.

Conclusions:

Clinicians preferred the RAG model 70% of the time, underscoring its potential to simplify the creation and timely delivery of autism guidelines. Future work will involve refinement through broader clinician feedback and enhancing model using retrieval optimization.

439.188 Development of Receptive Vocabulary and Verbal Fluency Skills from School-Age to Adolescence in Autistics and Non-Autistics

M. Côté¹, J. H. L. Wong¹, N. Amantayev², M. Reingold¹ and A. Nadig³, (1)McGill University, Montreal, QC, Canada, (2)Communication Sciences and Disorders, McGill University, Montreal, QC, Canada, (3)School of Communication Sciences and Disorders, McGill University, Montreal, QC, Canada

Background: Language skills are established predictors of positive long-term outcomes in autism.^{1,2} Most studies focus on monolingual speakers in the early years.³ Yet, vocabulary skills develop into adulthood and are important for functioning in multiple domains.^{4,5} We focus on the development of receptive vocabulary, expressive vocabulary (via a semantic verbal fluency task) and non-verbal IQ (NVIQ). Prior work has found autistic youth to have receptive vocabulary scores at the lower end of the normal range.⁶ In autism, higher NVIQ has been found to be associated with greater receptive vocabulary growth.^{7,8} Researchers have also found performance on verbal fluency tasks, where people are asked to produce items in a given category (e.g. animals), to increase with age.⁹

Objectives: We address a gap in our understanding of adolescent language development through an inclusive and intersectional lens,¹⁰ by following French speakers (the majority of whom are multilingual), who are autistic or non-autistic, from school-age to adolescence. We compare developmental trajectories of their receptive vocabulary and verbal fluency. We also investigate the role NVIQ plays in receptive vocabulary development.

Methods: We followed twenty-six participants (12 autistic, 14 non-autistic) from school-age (T1; 5 to 10 years old) to adolescence (T2; 12 to 19 years old), with approximately 8 years between visits (M = 100 months, SD = 9.24 months). Participants were tested in Montreal, Canada in French, as this was the shared language of the sample. Receptive vocabulary was measured using raw scores from the *Échelle de vocabulaire en images Peabody* (ÉVIP)¹¹. Semantic verbal fluency was analyzed using the number of correct words produced.¹² NVIQ was measured using raw scores on the Leiter International Performance Scale-Revised.¹³

Results: Data from T1 and T2 are plotted in Figure 1. We ran linear mixed effects models with timepoint, diagnostic group, and number of months between T1 and T2 (as there was significant variability) as fixed effects, and participant ID as the random intercept (i.e., grouping factor).

Receptive vocabulary: there was a significant effect of timepoint (higher at T2) and number of months between visits (decreasing with greater separation between visits). There was a significant interaction between timepoint and group: the autistic group experienced more gains in receptive vocabulary. **Verbal Fluency:** the only significant effect was of timepoint (higher at T2). **NVIQ and receptive vocabulary growth:** we examined the relationship between T1 NVIQ and receptive vocabulary growth (Figure 2). We observed a non-significant trend for an inverse relationship ($\rho = -.24$; higher NVIQ, less growth).

Conclusions: We found similar patterns of receptive and expressive vocabulary growth in autistics and non-autistics. A subset of autistic participants were the lowest performers at both timepoints, while other low performers experienced significant growth and caught up by adolescence. In contrast to prior findings, lower NVIQ did not predict if participants remained low in receptive vocabulary; in fact, we found a trend in the opposite direction. This is likely due to the majority of our sample having high NVIQ, and those with lower NVIQ showing a “catch up” trajectory.

439.189 Mandarin-Speaking Autistic Preschoolers' Production, Comprehension and Prosodic Modification of Grammatical Aspect Marker LE

L. Yu¹, Y. Yi², A. Yi², Y. Liang² and S. Wang⁴, (1)Center for Autism Research, School of Education, Guangzhou University, Guangzhou, Guangdong, China, (2)Guangzhou University, Guangzhou, Guangdong, China, (3)Department of Pediatrics, The Third Affiliated Hospital of Guangzhou Medical University (Women's and Children's Hospital of Guangzhou Medical University), Guangzhou, China, (4)South China Normal University, Guangzhou, China

Background: The knowledge and use of grammatical aspect/tense markers are key indicators of language development in young children. Autistic children often struggle with producing these markers in both Western and Eastern languages, such as English and Chinese. However, both English- and Chinese-speaking autistic preschoolers have been found to have relatively intact comprehension of grammatical aspect markers, suggesting aspectual comprehension to be a strength and independent from aspectual production challenges. However, few studies have examined both production and comprehension in young autistic children simultaneously. Furthermore, as a syllable-timed language, Chinese prosody can better reflect grammatical knowledge of aspect markers through prosodic features, such as the shortening of perfective marker "le," which may provide additional insight into aspectual comprehension.

Objectives: 1) To compare autistic children with typically developing (TD) children and children with developmental language disorder (DLD) in order to determine whether atypical patterns of production and comprehension of aspect markers are specific to autistic language; to explore the prosodic characteristics of the aspect marker "le" in these three groups and gain insight into their understanding of this morphosyntactic cue.

Methods: The study included 20 autistic children aged 3 to 7, 25 typically developing children, and 12 children with DLD. The groups were matched on chronological age and receptive vocabulary. A verbal elicitation task was used to assess the production of the perfective marker "le." In addition to production accuracy, the duration of syllables/words in three-word sentences (verb + hao/wan + le) was measured to capture prosodic modulation. A picture-sentence matching task was then used to assess comprehension of "le." Lastly, an asymmetry index was calculated to evaluate the balance between production and comprehension abilities.

Results: No significant differences in the production accuracy of "le" were found across the autistic, TD, and DLD groups. However, durational analysis revealed atypical prosodic patterns in the autistic group. While the TD group showed no significant variation in syllable duration, with a trend toward "le" shortening, the DLD group demonstrated a quadratic trend, with shortening of both the verb and "le." In contrast, the autistic group exhibited a linear increase in syllable duration from the verb to "le," indicating atypical lengthening of "le."

Conclusions: Chinese preschoolers with autism display a distinct pattern of atypical lengthening of the grammatical marker "le" compared to their TD and DLD peers, suggesting challenges with the rhythmic modulation and syntactic knowledge involving aspect markers. Comprehension data suggests that autistic children struggle more with understanding "le" than their neurotypical peers, contrasting existing research. These findings depict a multifaceted profile of aspect marker knowledge of autistic preschooler, and add linguistic diversity to the literature.

439.190 Natural Speech Markers of Autism Spectrum Disorder in Children

T. Torres Barbero¹, B. Soria¹, A. García², A. Rattazzi³, E. Vaucheret⁴ and M. L. González Gadea¹, (1)CNC-UdeSA, Buenos Aires, Buenos Aires, Argentina, (2)Universidad de Santiago de Chile, Santiago de Chile, Santiago, Chile, (3)PANAACEA, Buenos Aires, ARGENTINA, (4)Hospital Italiano de Buenos Aires, Buenos Aires, Buenos Aires, Argentina

Background: Autism spectrum disorder (ASD) is a neurodevelopmental condition characterized by persistent communication deficits, restricted interests (RI) and stereotyped behavior. Though very useful, standard tests used for ASD diagnosis are time-consuming, costly to perform, and dependent on highly specialized examiners who are unevenly available across world regions. Such shortcomings can be tackled via automated speech and language analysis (ASLA) tools, which offer affordable, accurate, automated metrics of potential relevance for diagnosing and phenotyping persons with ASD.

Objectives: The present pilot study aims to detect ASLA markers of ASD in children with a such a diagnosis (N=35) relative to typically developing children (N=37). Specifically, we compared the differences in these features between the group of children with ASD and the group of typically developing children.

Methods: For this purpose, semi-structured interviews were conducted on RI and topics of general interest (e.g., *how to prepare a cake or a backpack for a camping*). Afterwards, software CHAT was used to transform the audio to text, and to automatically extract speech metrics (fluency, disfluencies and morphosyntactics). For the acoustic metrics, an automated pipeline was used to preprocess the audio and then Praat to extract the required metrics. By the features of the sample, non-parametric statistical analysis (Mann U Whitney) was used to perform the analysis, comparing both groups in each task separately. The statistic significance level were set at $p = <0.05$.

Results: Relative to typically developing children, those with ASD presented greater fluency level (higher number of words, utterances and speaking time). However, a higher number of disfluencies (repetitions, corrections and stuttering) and a lower degree of lexical richness (type-token ratio) were also observed in the ASD group compared to the typical developing group, particularly during interviews about RI. Also, it was observed that children with ASD used more third person verbs and pronouns than typically developing children.

Conclusions: The results obtained show that, in describing their RIs, children with ASD produce more but verbose but less diverse, fluent, and self-centered discourse than neurotypical children. Such findings suggest that ASLA could be enhance the characterization and understanding of cognitive outcomes in children with ASD, representing an accurate, cost-effective diagnostic-support tool to complement traditional assessments.

439.191 Navigating AAC Applications: A Review of High-Tech Communication Apps for Autistic Children and Youth

L. Denusik¹, J. Coan-Brill¹, J. Kay^{1,2}, J. Oram¹ and A. Binns^{1,3}, (1)Western University, London, ON, Canada, (2)TVCC, London, ON, Canada, (3)University of Toronto, Toronto, ON, Canada

Background: Augmentative and alternative communication (AAC) refers to any communication modality other than speech used to convey messages (American Speech-Language-Hearing Association, n.d.). High-tech aided AAC uses computerized aids (e.g., tablets) that generate speech and supports communicative development and participation for autistic individuals (Beukelman & Light, 2020; Ganz, 2008). In recent years, the number of AAC applications (apps) available to download on a tablet or phone has grown significantly. However, limited research has examined how these apps differ from each other. To facilitate effective clinical decision-making, clinicians, families, and clients must have adequate resources to determine which AAC apps fit their needs. Selecting the best AAC app is a highly complex task unique to each client (Webb et al., 2023); thus, exploring and comparing their features is critical. Consequently, this systematic health app review aimed to explore and compare the AAC apps currently available on Android and Apple devices with the overarching goal of supporting communication for autistic children and youth.

Objectives: This review has two primary objectives: (1) What AAC apps are currently available for autistic children and youth? (2) How do the existing AAC apps vary according to accessibility (i.e., cost of the app, devices supported), individualization (i.e., adding new words, customizing voice), and usability (i.e., layout, easy to navigate)?

Methods: Our protocol was preregistered with the Open Science Framework (<https://osf.io/tsq8p>). Relevant apps were identified by searching key terms (e.g., “AAC & Autism”, “communication apps”) on the Apple App Store and Google Play Store. Two members of our team screened apps to identify those meeting our inclusion criteria: (a) standalone app available on Apple/Android phone/tablet; (b) available in Canada/US/UK; (c) available in English; (d) can be used by autistic individuals (i.e., not intended for a clinician/parent); (e) fit our definition of high-tech AAC (e.g., text-to-speech, symbol-based). Data extraction was completed in duplicate through information collected from the app store entries and exploration of each app.

Results: Searches captured 1277 apps across both app stores (including duplicates). Following the screening, 182 apps met the inclusion criteria, 63% of which were available to download at no cost. However, most apps were available only on Apple devices. The apps included text-to-speech and symbol-based systems, as well as alternative response methods (e.g., eye-tracking). Many apps had vocabulary to support communication in various contexts (e.g., school, home); however, some had vocabulary specific to a hospital or other healthcare setting. Findings regarding the accessibility, individuality, and usability features of each app will also be included in our presentation.

Conclusions: The findings of this review will provide clinicians, families, and clients with the necessary information to make informed decisions regarding which AAC apps are most suitable for their needs. Although we identified many apps that are free to download, most require an Apple device, which can be costly, significantly limiting their accessibility. Despite the abundance of apps identified, there is a need for additional good-quality AAC apps that are financially accessible across multiple devices.

439.192 Objective Measurement of Vocal Features in Early Development Among Toddlers with Later ASD

A. Viggiano¹, J. M. Moffitt^{1,2}, M. Alessandri³ and D. S. Messinger¹, (1)Department of Psychology, University of Miami, Coral Gables, FL, (2)Claremont Autism Center, Claremont McKenna College, Claremont, CA, (3)Department of Psychology, University of Miami Center for Autism and Related Disabilities, Coral Gables, FL

Background: Toddlers with autism spectrum disorder (ASD) display atypical speech characteristics such as increased variability in fundamental frequency (F0). Objective measurement of these speech features early in development may help detect toddlers that go on to develop ASD from toddlers with no later ASD.

Objectives: Leverage audio recordings of individual toddlers during both low and high stress social interactions to determine if F0 distinguishes toddlers at 15 months with an eventual ASD diagnosis at 36 months from toddlers with no later ASD diagnosis during episode types of the Strange Situation Procedure (SSP).

Methods: 92 toddlers (51 boys) completed the SSP at 15 months and were later evaluated for ASD at 36 months (15 later diagnosed with ASD). Objectively measured vocalizations and cries from toddlers were identified during audio-video recordings of the SSP. Classification of child versus adult speech from Automatic Linguistic unit Count Estimator (ALICE) showed an overall agreement with an expert coder of 80% (Kappa= 0.79). Child cries were detected by software combining a support vector machine classifier using deep spectrum and acoustic features (filtering audio above 350 Hz), labeling if crying was detected in each one second window. Human expert coders labeled 400 clips as cry/ non-cry vocalizations with 76.3% overall agreement (Kappa= 0.45). PRAAT was utilized to obtain the mean and standard deviation of F0 of ALICE-identified child vocalizations (analyzed with a range of 90 to 600 Hz) and cries. Values were averaged within each SSP episode type to obtain the overall mean F0 (the mean of the mean) and overall mean SD of F0 (the mean of the SD) of each individual toddler's vocalizations and cries for each episode type. **Results:** No mean differences were found between toddlers with and without later ASD (Table 1). F tests indicated there was greater variability between toddlers with later ASD in mean F0 for vocalizations in the separation episode type ($p<.01$) and for cries in the low stress interaction episode type ($p=0.02$) than between toddlers without later ASD. Greater variability was also found between toddlers with later ASD in the mean SD of their F0 for vocalizations in the reunion episode type ($p=.04$) and for cries in the low stress interaction episode type ($p=.05$). Conversely, there was lower variability between toddlers with later ASD in the mean SD of F0 for vocalizations in the stranger introduction episode type ($p=0.04$).

Conclusions: Toddlers with later ASD exhibited more within group variability for the mean pitch and mean SD of the pitch of vocalizations and cries in some high- and low-stress episodes than toddlers without later ASD, suggesting that greater variability in vocal signaling may characterize groups of toddlers headed toward an ASD outcome. In the high-stress stranger introduction episode, however, toddlers with later ASD showed lower within group variability in the mean SD of F0 than toddlers without later ASD. These results suggest that the characterization of the emerging ASD phenotype by variability of objectively measured vocal features may be context-specific.

439.193 Orthographic Learning in Hyperlexic Children

J. Crutcher¹, J. S. Magnuson^{1,2,3} and I. M. Eigsti¹, (1)Psychological Sciences, University of Connecticut, Storrs, CT, (2)BCBL: Basque Center on Cognition, Brain, and Language, Donostia-San Sebastián, Spain, (3)Ikerbasque: Basque Foundation for Science, Bilbao, Spain

Background: Hyperlexia (HPL), characterized by precocious reading (decoding) skills that outstrip reading comprehension, occurs in approximately 5-10% of autistic children (Ostrolenk et al., 2017). It is often conceptualized as one form of restrictive and repetitive behaviors and interests (RRBIs). The mechanisms underlying reading acquisition in HPL are unknown and could reflect the extended time spent engaged in reading-related activities, or could reflect reliance on particular attentional, perceptual, or learning mechanisms.

Objectives: This study compared the learning of novel alphabetic and phonological systems in children with HPL versus neurotypical developmental histories.

Methods: Participants were four HPL children ages 5-10 and 44 neurotypical controls. The HPL participants met DSM-5 criteria for autism, had reading scores 1.5 SD > than language comprehension or nonverbal IQ scores, and displayed precocious (prior to 4 years) acquisition of reading without explicit instruction and an early interest in reading (Table 1). Participants completed a novel **orthographic learning task**, in which they were presented with eight concrete nouns (e.g., “horse”), matched with a pronounceable nonword label (e.g., “mig”) that was “spelled” with a novel orthographic character (e.g., see in image below). The lexicon included items that were potential competitors in phonology or meaning. There were 8 learning trials during which participants were exposed to pairings of symbols, spoken labels, and pictures, with feedback about the correct mappings, followed by 32 trials testing their ability to choose the correct picture when given the orthographic symbol and spoken label (OrthToPic trials), and 32 trials testing their ability to choose the correct orthographic symbol when given the spoken label and picture (PicToOrth).

Results: Given the small HPL sample, inferential statistical tests were not conducted. The HPL group's scores on standardized assessments of phonological decoding skills ranged from High Average to Very Superior ($M = 129$). On the orthography task, across groups, participants attained 70-80% accuracy within the first 8 trials and had overall greater accuracy in the OrthToPic condition (HPL = 83.6%, NT = 80.7%), while accuracy was much lower in PicToOrth condition (HPL = 63.3%, NT = 62.8%). We examined learning over the course of trials by measuring accuracy between groups for each quartile (8 trials per quartile). Looking at the fourth quarter of each condition cleared showed the HPL group with faster and more accurate learning in OrthToPic condition (HPL = 89.3%, NT = 77.5%) and PicToOrth condition (HPL = 70.2%, NT = 63.1%; See Figure. 1).

Conclusions: When learning of a novel lexicon and orthographic system, the overall accuracy appeared to be similar. However, HPL children displayed enhanced learning and performance accuracy appeared greater in the final quarter of trials across both experimental conditions. This finding is consistent with the hypothesis that HPL does not simply reflect from extended “time on task,” but may instead suggest the presence of special perceptual or learning mechanisms. These findings are exploratory and tentative, given the small size of the HPL group.

439.194 Characterizing Fast Responders Among Minimally Verbal Autistic Children Receiving Social Communication Intervention

J. Panganiban¹, W. I. Shih² and C. Kasari³, (1)Semel Institute, University of California Los Angeles, Los Angeles, CA, (2)University of California - Los Angeles, Los Angeles, CA, (3)Education and Psychiatry, University of California Los Angeles, Los Angeles, CA

Background: Early intervention can be a helpful resource for autistic children experiencing challenges or delays in core areas of development. However, autism encompasses a wide range of developmental abilities, and autistic individuals in need of early intervention may benefit from an adaptive approach that can address their dynamic needs (Kasari et al., 2014; Almirall et al., 2016). This is especially true for minimally verbal (MV) autistic children, whose social communication skills can be complex and variable. Adaptive interventions give service providers the ability to adjust strategies and approaches to match the needs of an individual. A critical component of an adaptive intervention approach is the ability to assess response to the intervention in order to make a decision on the best course of action. Previous work in identifying response to intervention has identified key predictors such as IQ, age, and expressive language ability. However, it may be helpful to examine core developmental skills as important variables driving decisions in adaptive intervention approaches.

Objectives: The current study aims to explore how core developmental skills of MV autistic children are related to fast response to early intervention. Specifically, we are looking at baseline developmental skills that predict fast response to an adaptive intervention approach and characterizing the skills that are changing among MV children identified as fast responders.

Methods: This is a secondary data analysis of 194 MV autistic children ($M=72.42$ months old, $SD=15.14$ months) that were recruited to receive an adaptive intervention. The children were assessed for their development in social communication, play, expressive language, and cognition prior to receiving the adaptive intervention, and again after six weeks of intervention. At the six week mark, children were also assessed for their response to the intervention using a Clinical Global Impression Scale (CGI), which identified children as fast or slow responders to the intervention.

Results: Logistic regressions were used to determine the association between core developmental skills and early response to initial intervention while controlling for site differences, age and gender. Child initiated joint attention ($Z=2.439$, $p=0.015$) and response to joint attention ($Z=2.28$, $p=0.023$) predicted fast response to intervention. Higher play mastery level and more diversity at baseline also significantly predicted fast response ($Z=3.46$, $p<0.001$; $Z=3.405$, $p<0.001$). Among children identified as fast responders, requesting skills and responding to joint attention were identified as important variables. Children with improved requesting skills ($Z=2.565$, $p=0.0103$) and response to joint attention ($Z=0.979$, $p=0.007$) had increased odds of being identified as fast responders to the intervention.

Conclusions: Identifying important core developmental skills among MV autistic children can play a critical role in the decision making process of adaptive interventions. Especially helpful for MV children is the ability to identify meaningful skills and change related to early intervention. Our analyses identified the importance of core developmental skills like joint attention and play as meaningful predictors of fast responders. Furthermore, the skills that made the most change among these fast responders were requesting skills and response to joint attention.

439.195 Patterns of Codeswitching Among Multilingual Chinese Immigrant Caregivers of Autistic Children in the US

Y. Xu¹, L. Shen², F. Chen², S. Vanegas³, S. Magana⁴ and X. Kapetanidakis⁵, (1)Department of Health Sciences Education, University of Illinois College of Medicine, Rockford, IL, (2)University of Illinois at Chicago, Chicago, IL, (3)Texas Center for Disability Studies, University of Texas at Austin, Austin, TX, (4)Steve Hicks School of Social Work, The University of Texas at Austin, Austin, TX, (5)Adelphi University, Garden City, NY

Background: Around the world, bilingual and multilingual speakers outnumber monolinguals (Kohnert & Medina, 2009). Recent census data in the U.S. finds that one in five Americans speak a language other than English at home. Codeswitching is a common practice among multilingual speakers where the speaker alternates between two or more languages within a single conversation, sentence, or situation. Research on typically developing multilingual children has shown that adult caregivers or teachers' codeswitching has a positive impact on children's cognitive flexibility (Sun et al., 2019), and when children codeswitch, it helps them fill lexical gaps (Kuzyk et al., 2019) and serves as a marker of linguistic competence (Yow et al., 2017). Furthermore, bilingual children reading "codeswitching" children's books are more likely to enjoy a novel word retention boost (Read et al., 2020). Research is emerging on the topic of codeswitching among autistic children or their adult caregivers. In Yu's single case study, a bilingual autistic child strategically and systematically uses codeswitching as a pragmatic communication resource (Yu, 2016). More research is needed to better understand how multilingual caregivers practice codeswitching across different activities.

Objectives: To fill this gap, we collected video clips of mother-child interactions from multilingual Chinese immigrant families with autistic children (2-5 years) in naturalistic settings.

Methods: Eleven Chinese mothers and young children under the age of five with autism were recruited as part of a pilot parent psychoeducational intervention study. Each mother-child dyad was asked to select three daily activities (5 minutes per activity) from the following: play with small toys (e.g., cars, figurines, puzzles), play with larger objects (e.g., large ball), play with people, reading a book, caregiving (e.g., changing diaper, washing hands), and house chores. The frequency of codeswitching was coded from videos using ELAN. We also documented the type of activity in which codeswitching happened and the caregiver and child's conversation.

Results: Children were, on average, 3.7 years old ($SD=1.32$) and had a mean Social Communication Questionnaire score of 20.9 ($SD=5.85$). Preliminary analysis shows that caregivers, on average, codeswitched 27 times during 15 minutes of interaction. Codeswitching happened most often during play activities as compared to the other five activities. Codeswitching from Chinese to English served as a tool to a) reinforce rules (e.g., "No," "Sit down," "Wait"); b) teach and label (e.g., "triangle" "purple"); and c) show encouragement ("You got this!" "Good job"). Codeswitching from English to Chinese served broader linguistic functions.

Conclusions: This study explores how multilingual Chinese immigrant mothers code-switch during daily activities. We found that codeswitching happens more often during play activities as opposed to other activities. This may be due to the more action-oriented nature of play. Playing with their children is also a relatively "new" concept to many Chinese parents since children are expected to play with each other rather than with their parents. Therefore, parents may be filling the linguistic gap with English they could use during play (e.g., high five, you got this). Further studies should explore children's reactions and outcomes in the context of caregivers' codeswitching.

439.197 Preliminary Validation of a Naturalistic Play-Based, Caregiver-Mediated Communication Measure for Young Autistic Children

J. R. Steinbrenner¹, S. W. Nowell², A. Wallisch³, D. Irvin⁴, B. Salley⁵, L. Woolf⁶, J. Buzhardt⁷ and B. A. Boyd¹, (1)Health Sciences, University of North Carolina at Chapel Hill, Chapel Hill, NC, (2)Health Sciences, Division of Speech and Hearing Sciences, UNC Chapel Hill, Chapel Hill, NC, (3)Juniper Gardens Children's Project, Juniper Gardens Children's Project, University of Kansas, Kansas City, KS, (4)Juniper Gardens Children's Project, University of Kansas, Kansas City, KS, (5)Pediatrics, University of Kansas Medical Center, Kansas City, KS, (6)Health Sciences, Division of Speech and Hearing Sciences, The University of North Carolina at Chapel Hill, Chapel Hill, NC, (7)School of Education, University of North Carolina at Chapel Hill, Chapel Hill, NC

Background: Although communication is often a primary goal of early intervention to support young autistic children, there are few communication measures that are designed to be sensitive to change to assess child communication outcomes. The Early Communication Indicator (ECI) is a norm-referenced, progress-monitoring tool to measure change in communication/early language skills (gestures, vocalizations, single words, multiple words) in young children in the context of naturalistic play interactions with a familiar adult (Buzhardt et al., 2022; Greenwood et al. 2013; 2020). Our team adapted the tool to create the ECI-Autism (or ECI-A), which also includes social-communication skills that are common intervention goals (joint attention and directed communication) and is validating the measure with a large group of autistic children up to 60 months in age.

Objectives: The objectives of this measure validation study are (1) to examine preliminary descriptive data from the ECI-A, and (2) to examine preliminary psychometric data on reliability and validity.

Methods: To date, the study team has recruited about 352 autistic children (12-60 months) and their caregivers to participate in the study. The ECI-A has been collected and coded for 262 of the recruited participants. The participants are racially/ethnically diverse (~54% are from historically marginalized populations in the US) and socio-economically diverse (~32% have household incomes <40K US dollars). At Time 1, participants completed the ECI-A, a 10-minute play-based assessment that includes free play with a house or barn play set and four activities designed to elicit joint attention. The ECI-A video-recordings were then scored by trained coders, which resulted in counts of gestures, vocalizations, single words, and multiple words, and a weighted communication rate, as well as proportion of initiation of joint attention (IJA, 0-1 score) and mean ratings for direct communication (0-3 score). The child and/or caregiver participants also completed autism screeners, direct assessments (e.g., Mullen, ADOS, BOSCC), and caregiver-report measures (e.g., ABAS, PICS). A subset of the sample completed the ECI-A at additional time points (1-2 week test/retest, 6 weeks, 6 months, 12 months).

The final analysis will include (a) descriptive data for the primary ECI-A measures (mean, SD, and range), (b) analyses of reliability (inter-rater and test-retest reliability using ICCs), and (c) analyses of validity (concurrent and divergent validity with other measures using Pearson's correlations, sensitivity to change with growth trajectories). Data collection will conclude in December 2024, but we present several preliminary findings below based on available data.

Results: The ECI-A captures a range of communication skills in young, autistic children and has strong inter-rater reliability (see Table 1 in attached image). Additionally, the ECI-A has medium and large correlations with the PICS and BOSCC, respectively (see Table 2). A preliminary analysis of cross-sectional growth trajectories of IJA suggests that the measure does not have floor or ceiling effects (see Figure 1).

Conclusions: The ECI-A is a promising tool for progress monitoring in research and practice, and is relatively easy to administer and code. There is emerging evidence of the ECI-A's reliability and validity based on preliminary analyses.

439.198 Receptive Vocabulary, Joint Attention, and Emergent Literacy Skills in Autistic Children

D. Davidson¹ and B. Sawyer², (1)Psychology, Loyola University Chicago, Chicago, IL, (2)Loyola University Chicago, Chicago, IL

Background:

While previous research has addressed emergent literacy skills' relation to domain-specific joint attention literacy activities (e.g., Wicks et al., 2020), less attention has been paid to how emergent literacy relates to domain-general joint attention and receptive vocabulary in autistic children. Emergent literacy is a developmental stage in which skills, knowledge, and attitudes that are the precursors of reading begin to develop (Whitehurst & Lonigan, 1998). Autistic children have a pattern of struggling with specific emergent literacy skills while showing strengths in others (Westerveld & Roberts, 2017). Potential challenges may be due to more limited engagement in literacy, language and joint attention activities.

Objectives:

The primary objective of this study is to observe how receptive vocabulary skills and joint attention skills relate to emergent literacy skill outcomes in autistic children. While autistic children have shown patterns of being less engaged in domain-specific joint attention activities such as shared book reading (Wicks et al., 2020), they may show different patterns of joint attention in domain-general activities. Domain-general joint attention may relate to receptive vocabulary and emergent literacy outcomes.

Methods:

17 autistic and 20 non-autistic children participated (see Table 1 for demographics). All autistic children had a clinical diagnosis established by a pediatrician or licensed clinical psychologist. Following consent procedures, children were assessed in their receptive vocabulary skills using the PPVT-4 (Dunn & Dunn, 2007) and emergent literacy skill measures. Parents were administered a parent-report questionnaire to assess their child's domain-general joint attention skills.

Results:

While autistic and non-autistic children's PPVT-4 scores did not significantly differ, they were trending in that direction ($p = .06$). Receptive vocabulary was found to be statistically significantly correlated to all six emergent literacy skills tested (letter knowledge, phonological awareness, print concept, name writing, oral narrative quality, and oral narrative comprehension) for autistic children. In contrast, receptive vocabulary was only significantly related to the emergent literacy skills of phonological awareness and print concept for non-autistic children. Joint attention was found to be significantly related to meaning-related emergent literacy skills (oral narrative quality and oral narrative comprehension) in autistic children but was not significantly related to any emergent literacy skills in non-autistic children. Receptive vocabulary and joint attention were also found to be related in autistic but not non-autistic children.

Conclusions:

Receptive vocabulary skills play a significant role in autistic children's emergent literacy skills regardless of whether those skills are a strength or a weakness. Domain-general joint attention also plays a role in autistic children's meaning-related emergent literacy skills. Receptive vocabulary and joint attention are also related skills that both affect literacy outcomes. Further research should explore how to encourage receptive vocabulary and joint attention skills in autistic children in order to bolster emergent literacy outcomes. Clinicians and teachers may benefit autistic clients and students by explicitly training vocabulary rather than relying on implicit vocabulary acquisition. This explicit teaching may aid in emergent literacy skills and literacy abilities later in development.

439.200 Speech-like Vocalizing and Expressive Language in Very Young Infants at Elevated Likelihood of Autism: Does Parent Input at 6 Months of Age Predict Infant Behavior at 12 Months?

S. Schillinger¹, M. Lyons¹, A. L. Lee¹, L. J. Fulop¹, S. Govindaraj², S. Smalley³, K. Shapiro³, H. Hazlett⁴, R. T. Schultz⁵, N. Marrus⁶, S. R. Dager⁷, A. M. Estes⁸, L. Zwaigenbaum⁹, J. Pandey¹, T. St. John¹⁰, J. Piven⁴, J. R. Pruett¹¹, M. Swanson¹² and J. Parish-Morris¹, (1)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (2)The University of Texas at Dallas, Dallas, TX, (3)Department of Pediatrics, University of Minnesota, Minneapolis, MN, (4)University of North Carolina, Chapel Hill, NC, (5)The Center for Autism Research/CHOP, Philadelphia, PA, (6)Washington University in St. Louis, St. Louis, MO, (7)Radiology, University of Washington, Seattle, WA, (8)Speech and Hearing Sciences, UW Autism Center, Seattle, WA, (9)University of Alberta, Edmonton, AB, Canada, (10)University of Washington, Seattle, WA, (11)Washington University School of Medicine, St. Louis, MO, (12)University of Minnesota, Minneapolis, MN

Background: Infant vocalizations are quantifiable behavioral markers that are easily obtained long before a reliable autism diagnosis can be made. In infants at elevated likelihood for autism, speech-like vocalizations at 12 months are associated with diagnosis at age 2 (Plate et al., 2022). Parent speech can influence child language outcomes. In typically developing samples, parent vocabulary diversity, syntactic complexity, and number of words all influence children's language outcomes (Anderson et al., 2021). In autism, Swanson and colleagues (2019) studied a sample including infants at low- and elevated-likelihood of autism by virtue of having an autistic older sibling. They found that more adult words and conversational turns at 9 and 15 months was associated with better language at 24 months. In another low- and elevated-likelihood sample, Northrup and Iverson (2015) found that more overlapping speech and reduced vocal coordination between mother and infant at 9 months predicted greater language delay at 3 years. These findings underscore the importance of parental language input for language development in children at elevated likelihood for autism, but this relationship has rarely been explored in infants younger than 9 months.

Objectives: Investigate whether parental language input at 6 months is associated with (1) infants' natural language output (number of speech-like vocalizations) and (2) standardized language outcomes (Bayley receptive and expressive scaled scores) at age 1.

Methods: Of 88 total participants collected thus far, participants in this preliminary analysis included 11 infants (5 female, 6 male), 10 of whom had standardized language scores at age 1. All infants were at elevated likelihood for autism by virtue of having an autistic older sibling, and completed 12-minute parent-child at-home freeplay sessions at 6 and/or 12 months of age. To quantify natural language, a team of reliable coders segmented and annotated freeplay recordings, labeling infant vocalizations and transcribing all adult speech. Lexical diversity was calculated using the 'quanteda' package in R (Benoit et al., 2024).

Results: Preliminary results revealed a significant positive association between parent vocalization rates at 6 months and their infants' expressive language scaled scores at 12 months ($\beta=0.035$, $SE=0.011$, $p=0.013$) (Figure), but not receptive language scores ($\beta=0.012$, $SE=0.015$, $p=0.45$). In this small sample, there was no strong association between parent speech (number of speech vocalizations or lexical diversity) at 6 months and infant speech-like vocalizations at 12 months. Parent lexical diversity was not associated with infant language scores at 12 months.

Conclusions: In this preliminary study of parental input and infant language outcomes in the first year of life, we found a positive relationship between parent talk at 6 months and infants' expressive language at 12 months. By April 2025, we anticipate doubling our coded sample, which will provide sufficient power to assess the relationship between parent input and children's natural language output 6 months later. Future research with larger samples is important to understand nuances in the relationship between parent and infant language in samples at elevated likelihood of autism, which may predict long-term communicative outcomes.

**439.201** Syntactic Complexity and Lexical Diversity in Non-Autistic Children and Autistic Children with and without Language Difficulty

T. Liu¹, M. Kalina Heinrich¹, J. D. E. Gabrieli², H. Tager-Flusberg³ and J. Zuk¹, (1)Speech, Language, and Hearing Sciences, Boston University, Boston, MA, (2)Brain and Cognitive Sciences, MIT, Cambridge, MA, (3)Psychological and Brain Sciences, Boston University, Boston, MA

Background: Language profiles in autism are heterogeneous (Kjelgaard & Tager-Flusberg, 2001), and individual language profiles can be defined based on differences in structural (rather than pragmatic) language abilities (Tager-Flusberg, 2006). Narrative assessment is a common language sampling tool used to assess language difficulty. Meta-analyses examining narrative structures in autistic and non-autistic children suggest autistic children tend to produce narratives with less complex syntax and lower lexical diversity (Baixauli et al., 2016). However, these studies often compare autistic to non-autistic children while overlooking the role of children's overall language skills. Furthermore, findings are inconsistent across individual studies. In one study including non-autistic children and autistic children both with and without language difficulty, autistic children with language difficulty produced less syntactically complex narratives, while lexical diversity did not differ among groups (Peristeri et al., 2017). Other studies found no difference in syntactic complexity among autistic and non-autistic children's narratives (e.g., Diehl et al., 2006). To reconcile inconsistent findings, additional work accounting for whether autistic children have co-occurring language difficulty is needed.

Objectives: To assess differences in the narrative microstructure (i.e., utterance-level measures of narrative production) of non-autistic children and autistic children with and without language difficulty.

Methods: Twenty-six non-autistic children, twenty autistic children without language difficulty (A-noLD), and ten autistic children with co-occurring language difficulty (A-LD) aged 6-17 years old ($M=10.4$, $SD=2.7$) completed the ADOS-2 "Telling a Story from a Book" task. Language samples from the task were transcribed in accordance with Systematic Analysis of Language Transcripts (SALT) conventions. Mean length utterance (MLU) in morphemes, a measure of syntactic complexity, and number of different words (NDW), a measure of lexical diversity, were extracted based on the SALT transcripts. Non-autistic and A-noLD groups were matched on overall language skills (measured by CELF Core Language Scores).

Results: One-way ANOVAs revealed a significant effect of diagnostic group on children's narratives' MLU [$F(2,53)=4.26$, $p=.019$, $\eta^2=0.14$] and NDW [$F(2,53)=6.90$, $p=.002$, $\eta^2=0.21$]. Post-hoc analyses revealed that non-autistic children's MLU was significantly greater than A-LD children's MLU [$p=.014$] (and not A-noLD children's), while NDW differed between non-autistic children and both A-LD [$p=.002$] and A-noLD children [$p=.006$]. NDW did not significantly differ between A-LD and A-noLD groups [$p=.66$] (see Figure).

Conclusions: Findings suggest that autistic children without language difficulty produce utterances with syntactic complexity that are comparable to their non-autistic peers. Whereas much of the existing literature suggests that autistic children produce less syntactically complex utterances than non-autistic children, the present findings indicate that this difference may be attributed to overall language skills. While syntactic complexity may look similar among non-autistic and autistic children without language difficulty, autistic children, regardless of language difficulty, produced utterances with lower lexical diversity than non-autistic children. Future directions include examining narrative macrostructure and comparing narrative task performance to other language sampling contexts, like conversations. By highlighting the unique language patterns and varying profiles of strengths within autism, findings emphasize the critical need for comprehensive and individualized language assessment and intervention approaches for autistic children.

439.202 The Influence of Body-Object Interaction Rating on Semantic Processing in Autistic and Non-Autistic Adults

E. H. Vu¹, S. West², N. E. Fears¹, C. Cox² and E. Haebig³, (1)School of Kinesiology, Louisiana State University, Baton Rouge, LA, (2)Louisiana State University, Baton Rouge, LA, (3)Communication Sciences and Disorders, Louisiana State University, Baton Rouge, LA

Background:

Word features influence when we learn words and how we process the words when we read them. The ease with which one can interact with the word's referent (Body-Object Interaction Rating; BOI) has been shown to influence word processing (Pexman et al., 2019). Motor skills and language are highly interrelated in early development. Autistic individuals often have clinically significant motor difficulties, making it more difficult for them to interact with objects. This may alter their association with their object-body interactions and words for objects. We aimed to examine embodied language processing in autistic and non-autistic individuals using the BOI rating.

Objectives:

We aimed to extend the previous literature by: 1) examining the effect of BOI on word processing in autistic adults, and 2) examining differences in the effect of BOI on word processing between autistic and non-autistic adults.

Methods:

We assessed word processing in 152 adults using the online Prolific platform, with 76 autistic adults who reported receiving a formal autism diagnosis and 76 non-autistic adults who did not identify as autistic or have a history of being diagnosed as autistic. The participants completed a semantic decision task in which participants were presented with 600 printed words individually and were asked to classify whether the word was a concrete or abstract word. Of the 600 words, 300 were abstract nouns and 300 were concrete nouns that were matched on age of acquisition, frequency, and contextual diversity. The 300 concrete nouns consisted of 100 low, medium, and high BOI words following the Pexman et al. (2019) BOI ratings (from a scale of 1 to 7, $M_{\text{BOI-Low}} = 2.86$, $M_{\text{BOI-Medium}} = 4.19$, $M_{\text{BOI-High}} = 5.44$). Accuracy and reaction times were recorded for each word classification. Only trials for concrete words were used for these analyses.

Results:

Accuracy. We regressed proportion correct onto Group and BOI level (Adjusted $R^2 = .397$, $F_{5,450} = 60.92$, $p < .001$). We found a significant effect of Group with autistic participants having a higher proportion correct compared to non-autistic participants ($b = -0.023$, $SE = 0.010$, $t = -2.369$, $p = .018$, Figure 1). There were also significant effects of BOI level with the proportion correct being higher for medium and high BOI words than low BOI words ($b = -0.56$, $SE = 0.003$, $t = -16.19$, $p < 0.001$, Figure 1). Additionally proportion correct was higher for high BOI words than medium BOI words ($b = -0.03$, $SE = 0.006$, $t = -5.723$, $p < 0.001$, Figure 1). There were no significant interactions.

Reaction Time. We regressed reaction time onto Group and BOI level (Adjusted $R^2 = .176$, $F_{5,450} = 20.39$, $p < .001$, Figure 2). We found a significant effect of BOI levels with faster reaction time for high and medium BOI words than low ($b = 52.319$, $SE = 5.813$, $t = 9.0$, $p < .001$, Figure 2), with the fastest reaction time for high BOI words ($b = 41.28$, $SE = 10.07$, $t = 4.1$, $p < 0.001$, Figure 2)

Conclusions:

The current study found that autistic individuals are affected by the BOI level of concrete words to a similar extent to non-autistic individuals, with proportion correct increasing and reaction time decreasing as BOI level increased. Additionally, autistic individuals classified concrete words more accurately than non-autistic adults, indexing a relative strength in semantic classification.

439.203 The Relationship between Fundamental Frequency Variability and Fine Motor Skills in Autistic Children with and without Childhood Apraxia of Speech

S. Shen¹, **K. V. Chenausky²**, **F. Su³**, **J. R. Green⁴** and **H. Tager-Flusberg⁵**, (1)Department of Speech, Language, and Hearing Sciences, Boston University, Boston, China, (2)Communication Sciences and Disorders, MGH Institute of Health Professions, Boston, MA, (3)Linguistics, Boston University, Boston, MA, (4)Speech and Feeding Disorders Lab, MGH Institute of Health Professions, Boston, MA, (5)Psychological and Brain Sciences, Boston University, Boston, MA

Background:

Childhood apraxia of speech (CAS), a developmental speech motor disorder, affects spoken language development in autism spectrum disorder (ASD, Chenausky et al., 2019). A decrease in fundamental frequency (F0) variability may help identify ASD with comorbid CAS at an early age, as it reflects developmental changes in phonatory control (Kent et al., 2021). Fine motor skill impairment is another common comorbidity in ASD, which may predict concurrent speech motor control. However, no study has investigated the relationship between speech and fine motor development in ASD with heterogeneous speech profiles.

Objectives:

1. Evaluate whether F0 variability differs between ASD with and without CAS.
2. Investigate the relationship between F0 variability and fine motor skills in ASD with and without CAS.

Methods:

The sample included 46 participants who received a community diagnosis of ASD, independently confirmed by the Social Communication Questionnaire (Rutter et al., 2003). Participants produced at least three attempts of a target vowel during a syllable imitation task.

The syllable imitation task involved six syllables ([bi], [ba], [bu], [bæ], [bʌ], [pʌ]), each consisting of a stop consonant and a vowel. A researcher who was a native American English speaker produced these syllables in the same order and asked participants to repeat immediately after the demonstration. Participants were given four attempts for each syllable. Participants' speech during this task was coded to determine whether they were assigned to the ASD with or without CAS group (Chenausky et al., 2019). If participants did not produce enough attempts to determine a CAS diagnosis, they were assigned to the insufficient speech group. F0 variability, measured as the ratio of the F0 standard deviation to F0 mean, was characterized from this task following the default setting in Praat.

Fine motor skills were measured using the raw score of the fine motor domain of the Vineland Adaptive Behavior Scales, Third Edition (Sparrow et al., 2016).

Spearman correlation and the Wilcoxon rank-sum test were performed to investigate the influences of age and sex on F0 variability because the F0 variability data did not fit a normal distribution. We then performed linear regression analyses to address both objectives.

Results:

F0 variability was not influenced by age or sex. ASD without CAS showed significantly higher F0 variability than ASD with CAS. A wide range of F0 variability was observed in ASD with CAS group. Lower F0 variability was associated with higher fine motor skills in both ASD with and without CAS groups.

Conclusions:

Fine motor skills predicted the concurrent development of phonatory stability in ASD, highlighting the significance of motor control in mastering fine-tuned gestures in fine motor and speech domains. At the group level, more stable phonatory control was observed in ASD with CAS than ASD without CAS, suggesting that phonatory control may be a relative strength in speech production for ASD with CAS. Future study should take a longitudinal approach to investigate the role of motor control in the development of fine motor and speech skills in ASD who later exhibit heterogeneous spoken language outcomes.

439.204 "Taking the Temperature" of Natural Conversations in Autism Plus ADHD: A Transdiagnostic Sentiment Analysis

S. Cho¹, U. Vurgun², R. Fusaroli³, M. R. Pelella⁴, A. Knox⁵, A. Hauptmann⁶, M. L. Covello³, M. Madya⁴, M. Lyons¹, A. L. Lee⁴, L. J. Fulop⁴, A. S. Russell⁶, G. Hicks⁴, J. Fiumara⁴, J. Pandey⁴, B. Tunc⁴, E. Sariyanidi⁴, M. Liberman⁴, R. T. Schultz⁵ and J. Parish-Morris⁴, (1)Linguistic Data Consortium, University of Pennsylvania, Philadelphia, PA, (2)Penn Institute for Biomedical Informatics, University of Pennsylvania, Philadelphia, PA, (3)Aarhus University, Aarhus, Denmark, (4)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (5)The Center for Autism Research/CHOP, Philadelphia, PA, (6)University of North Carolina at Chapel Hill- Carolina Institute for Developmental Disabilities, Chapel Hill, NC

Background:

Autism and ADHD are two of the most common neurodevelopmental conditions of childhood, and they often co-occur (i.e., 37-85% of autistic children have co-occurring ADHD; Rong et al., 2021). Research suggests that autistic children with co-occurring ADHD experience increased autism symptoms and higher risk of developing anxiety and mood disorders (White et al., 2009). Unfortunately, children with autism+ADHD are often diagnosed later than children with autism alone (Wodka et al., 2021), reducing the likelihood that they receive timely interventions and supports. Autistic children and their ADHD peers both experience challenges when it comes to making and keeping friends (Black et al., 2024; Rokeach & Wiener, 2020), which may be due – in part – to atypical conversational interactions (Kouvava et al., 2022). However, little is known about conversational behavior in children with autism+ADHD vs. either diagnosis alone.

Objectives:

Assess language produced during a spontaneous “get-to-know-you” conversation in teens with autism+ADHD vs. autistic teens without ADHD vs. teens with ADHD without autism vs. neurotypical teens.

Methods:

Teens with autism+ADHD ($n=11$; 5 boys; age= 14.4 ± 1.8 y; IQ= 114.2 ± 20.1), autistic teens without ADHD ($n=12$; 6 boys; age= 15 ± 1.7 y; IQ= 115.4 ± 16.2), teens with ADHD only ($n=30$; 19 boys; age= 13.6 ± 1.8 y; IQ= 116.9 ± 16.1) and their neurotypical peers (NT; $n=22$; 15 boys; age= 13.9 ± 1.8 y; IQ= 111.9 ± 12.3) participated in a get-to-know-you conversation with a novel young adult confederate. Groups were matched on IQ ($p=0.76$), sex ratio ($p=0.53$), and age ($p=0.16$). Teens and undergraduate student confederates sat in separate rooms with high-quality video and audio interfaces; speech was recorded into separate channels and transcribed by trained human annotators. Lexical features were extracted from the transcripts using SEANCE (Crossley et al., 2017). Several principal component (PC) analyses reduced the feature space ($n=270$) into 20 major dimensions (e.g., arousal, positive/negative emotions, valence) that were given by the program. ANCOVA tested group differences with each lexical dimension (the first PC) as a dependent variable and group as an independent variable, covarying for other conditions (e.g., anxiety) and age. When a significant group effect was found, estimated marginal means were compared. P-values were adjusted using the false discovery rate (fdr).

Results:

Teens with autism+ADHD produced more words with strong emotions (i.e., higher valence; $F(3,68)=3.87$, $p=0.013$; Fig.1A) and more negative words ($F(3,68)=0.003$, $p=0.003$; Fig.1B) compared to teens with ADHD (valence: $p=0.016$, negative: $p=0.002$) and neurotypical teens (valence: $p=0.014$, negative: $p=0.012$). Autistic teens without ADHD did not differ from the other groups in these dimensions. Also, a significant group difference was found in other affect-related words ($F(3,68)=2.87$, $p=0.043$), where teens with autism+ADHD vs. NT: ($p=0.047$).

Conclusions:

Autistic teens with ADHD (autism+ADHD) use more words with strong emotional valence and more negative words than teens with ADHD only or neurotypical peers. Our results suggest that computational linguistic features extracted using a fully automated pipeline can reliably characterize conversational behavior in autistic teens with ADHD compared to other groups, which could inform personalized interventions that support social conversational success.

439.205 To “B” or Not to “B”: Exploring Letter Statistical Learning in the Language Network of Autistic Children

K. Trice¹, A. Ciriello¹, B. E. Siles² and Z. Qi², (1)Department of Psychology, Northeastern University, Boston, MA, (2)Department of Communication Sciences and Disorders, Northeastern University, Boston, MA

Background: Autistic (ASD) children exhibit highly variable language and reading skills^{1,2}. The latest autism research has found an association between spoken-language skills and atypical statistical learning (SL, the detection and extraction of patterns from environmental input) in the linguistic domain^{3,4,5}. Moreover, the tight connection between syllable auditory SL and letter visual SL found in typically-developing (TD) children does not exist in autistic children, indicating a lack of support from phonological processes for letter SL in ASD. Indeed, reading difficulties in autism have been attributed to verbal communication and phonological difficulties^{6,7,8}. Thus, in the current fMRI study, we ask whether letters and their embedded patterns are processed by the language network in autistic school-aged children. The answers to this question will provide mechanistic insights for reading difficulties in autism.

Objectives: Here, we seek to explicitly examine how autistic children process letter sequences via studying the neural activation of the language-related brain regions during letter SL in both ASD and TD groups.

Methods: Using a visual letter SL task, we examined brain activation in seven language regions (defined by a language localizer task; Regions: left posterior superior temporal gyrus (LpSTG), left anterior STG (LaSTG), right pSTG (RpSTG), right aSTG (RaSTG), left temporal parietal junction (LTPJ), left inferior frontal gyrus (LIFG), left middle frontal gyrus (LMFG)) while children were passively viewing structured letter (embedded statistical patterns) vs random letter sequences (Fig.1) in 14 autistic and 22 TD children. (Exploratory: target of 25 and 25 by INSAR. ASD: 3 girls, $M_{age}=7.85$ years, $SD_{age}=1.03$. TD: 12 girls, $M_{age}=8.78$ years, $SD_{age}=2.04$. Gender/age differences marginal but controlled for). To maximize learning, structured and random letter sequences were presented in separate runs and intermixed with random image and structured image sequences (Fig.1⁹).

Results: In TD, the LpSTG, LMFG, and LIFG regions showed sensitivity to letters, regardless of sequence type (LpSTG: $t(43)=2.43$, $p<0.001$; LMFG: $t(43)=3.30$, $p<0.001$; LIFG: $t(43)=4.94$, $p<0.001$), but not ASD ($ps>0.10$, Fig.2). No sensitivity to images, regardless of sequence type, in either group were seen in these regions ($ps>0.10$). Furthermore, TD demonstrated sensitivity to structured over random letter sequences in the LIFG and LaSTG (LIFG: $b=0.25$, $SE=0.11$, $p=0.03$; LaSTG: $b=0.14$, $SE=0.07$, $p=0.03$), but not ASD ($ps>0.10$). This wasn't a case of lateralization effects – none of the right hemisphere regions defined by the language localizer or additional right-hemisphere homologues showed sensitivity to letters or letter sequences (structured over random).

Conclusions: Unlike their TD peers, letter SL in autistic school-aged children did not engage language-related regions of the brain. In fact, letters in either random or structured sequences did not activate language-related regions or their right-hemisphere homologues. These findings suggest that autistic children may not treat letters in their phonological forms during SL which might partially explain learning difficulty for patterns embedded within letters that might lead to downstream reading difficulties in autism.

439.206 Uh Uhm – Filler Speech in Autistic and Non-Autistic Children

M. Reedy, T. Q. Boucher, A. Minniss and G. Iarocci, Psychology, Simon Fraser University, Burnaby, BC, Canada

Background:

Previous literature has investigated the differential use of filler speech (i.e., ‘uh’, ‘uhm’) as an example of social communication in autistic and non-autistic individuals. Research has suggested non-autistic children’s speech includes a greater ratio of ‘uhm’ use than autistic children. The lack of ‘um’ use has been suggested as a potential marker of pragmatic language difficulties in autism since filler speech often communicates delays in speech for utterance planning (Clark & Fox Tree, 2002; McGregor & Hadden, 2020). However, how do we quantify the ratio of ‘uhm’ to ‘uh’ use and the impact of social competence skills on autistic children?

Objectives:

To investigate if filler speech production differs in autistic and non-autistic children when it comes to ‘uh’ and ‘uhm’ use and extend previous literature by investigating the association between filler speech and social competence skills in autistic children. Our research had three hypotheses: 1) autistic and non-autistic children would not differ in their use of ‘uh’ filler words, 2) non-autistic children would use a greater ratio of ‘uhm’ filler words than autistic children, 3) greater ‘uhm’ use in autistic children would be positively correlated with social competence and negatively correlated with autistic traits.

Methods:

Twenty-eight autistic ($M_{age} = 9.51$, $SD = 2.06$; 20 male) and twenty-four non-autistic children ($M_{age} = 8.83$, $SD = 1.66$; 12 male) completed a semi-structured interview about their interests adapted from Winter-Messiers (2007). Interviews were transcribed verbatim using an abridged Jefferson (1984) model and reviewed by three researchers for accuracy. Caregivers completed the Autism-Spectrum Quotient (AQ; Baron-Cohen et al., 2001) to assess autistic traits, Social Responsiveness Scale, 2nd edition (SRS-2; Constantino & Gruber, 2012) to assess social challenges associated with autism, and the Multidimensional Social Competence Scale (MSCS; Yager & Iarocci, 2013) to assess social competence. Participants also completed the Weschler Abbreviated Scale of Intelligence, 2nd edition (WASI-II; Wechsler, 2011) to assess intellectual ability.

Results:

Data was analyzed using non-parametric Kruskal-Wallis tests. Autistic and non-autistic children did not differ in their use of ‘uh’ words ($H(1) = 1.235$, $p = .266$). Non-autistic children were more likely to use ‘uhm’ filler words ($H(1) = 18.774$, $p < .001$). In autistic children, ‘uhm’ filler word use was not associated with increased social competence ($r(26) = .146$, $p = .624$) and was not significantly correlated with autistic trait severity ($r(26) = .107$, $p = .588$).

Conclusions:

The results supported hypothesis 1 and 2, that specific filler word use (i.e., “uhm”) was higher in non-autistic than autistic children. Additionally, non-autistic and autistic children did not significantly differ in their use of ‘uh’ filler words as found previously in the literature, suggesting autistic children have difficulty with the pragmatic use of ‘uhm’ as an announcement of utterance planning. Interestingly, we did not find the expected relationship between ‘uhm’ use and increased social competency or decreased autistic trait severity. To adequately investigate the relationship of these variables in the future, studies may include several measures of social competency and autistic trait severity and include a larger sample size.

439.207 Use of Group Affiliation Language By Cisgender and Gender-Expansive Autistic Adults: A Mixed Methods Analysis

C. Connors¹, B. F. Worth², K. L. Coburn³ and R. B. Grossman⁴, (1)Emerson College, Boston, MA, (2)Communication Sciences and Disorders, Emerson College, Boston, MA, (3)Department of Psychology, University of Alabama, TUSCALOOSA, AL, (4)CSD, Emerson College, Boston, MA

Background: Autistic people are significantly more likely to reject cisgender identities than allistic people (Dewinter et al., 2017; Hillier et al., 2019; Moore et al., 2022). As a result of belonging to two marginalized communities (autistic and gender-expansive), many autistic individuals express concern about rejection from both communities (Hillier et al., 2019; Kanfischer et al., 2017; Strang et al., 2018). Autistic people have been found to express this concern and lower attachment to either group by using more qualified affiliation language (e.g., “I suppose” or “kinda”) than strong affiliation language (e.g., “belong” or “proud”) when talking about their communities (Nguyen et al., 2015). However, there has not yet been a rigorous investigation of affiliation language use in gender-expansive autistic people.

Objectives: To analyze affiliative language and themes of belonging used by gender-expansive and cisgender autistic adults to talk about community.

Methods: Autistic adults ($N=46$) recorded themselves talking about identity and community belonging. We used mixed methods to analyze affiliative language in these narratives. Quantitative methods include between- and within-group comparisons of strong vs. qualified affiliation language used by gender-expansive and cisgender participants. Qualitative methods include reflexive analysis of themes related to the impact of intersectionality on belonging and identity narratives.

Results: We present preliminary quantitative results based on 17 gender-expansive and ten cis-gender narratives. A 2 (group: Cisgender, Gender-Expansive) by 2 (Affiliation Language: Strong, Qualified) Repeated Measures ANOVA showed a significant effect for affiliation language ($F(1, 25) = 88.18$, $p < .001$), with both groups using more qualified than strong affiliation terms. There was no main effect for gender group ($F(1, 25) = .64$, $p = .43$), but we did identify a trend toward an interaction between gender group and affiliation language ($F(1, 25) 3.61$, $p = .069$, $\eta^2 = .13$, medium effect size). Both groups used significantly more qualified than strong affiliation words, but there was a trend for that difference being more pronounced in gender-expansive than cisgender autistic individuals. We expect more power for this analysis once the transcription of all 46 participants is complete. We are also exploring the linguistic context of affiliation word use, such as the word community appearing in strong (“we have a great community”) vs. qualified (“I might be a part of the autism community”) contexts, as well as the themes of belonging and identity via reflexive thematic analysis.

Conclusions: Findings suggest a relationship between affiliation language and gender identity of autistic adults. Both gender groups use more qualified than strong affiliation words, but gender-expansive autistic individuals have a tendency for that difference to be even greater compared to cis-gender autistic adults. This finding indicates that people who identify with two marginalized groups express a proportionally more qualified, less strong, sense of belonging to either of their communities compared with cisgender autistic individuals who identify with only one marginalized community. Thematic analysis will shed light on the experiential origins of these differences in belonging.

439.208 Vocalization Volubility in Children at Risk of Autism: Cross-Sectional and Longitudinal Comparisons Among Children with Neurogenetic Syndromes and Siblings of Autistic Children

B. Yin¹, L. R. Hamrick², A. Seidl¹ and B. L. Kelleher³, (1)Communication Sciences and Disorders, University of Delaware, Newark, DE, (2)Psychology, University of South Carolina, Columbia, SC, (3)Psychological Sciences, Purdue University, West Lafayette, IN

Background: Children with certain neurogenetic syndromes and siblings of autistic children are more likely to be diagnosed with autism. These children experience delays in language development compared to their peers (Buiting et al., 2016; Finestack et al., 2009; Robert et al., 2007). It is important that we understand how vocal development delays manifest among these populations especially during infancy and early childhood as such understanding can potentially inform improvement of assessment of language development among autistic children and implementation of relevant interventions.

Objectives: Examining whether children within these populations show different developmental profiles of early vocal development by looking at vocalization volubility.

Methods: We explored differences in vocal development trajectories of siblings of autistic children, children with Angelman, Down, and Fragile X Syndrome, and children in the low-risk-of-autism control group from the age of 4 months to 5 years. We conducted both cross-sectional and longitudinal analyses of daylong recordings collected from 224 children, focusing on the Language ENvironment analysis (LENA; Wang et al., 2020) system's automatically extracted summary vocalization volubility variables of conversational turn (CT) and child vocalization (CV). Participants' caregivers were instructed to record a typical day in their homes. The resulting recordings were 9 ~16 hours long and were representative of each participant's home language environment.

Results: Two of the multiple linear regression models in the cross-sectional analyses were: 1) CT Rate / 2) CV Rate ~ child age* group. The overall regression was statistically significant for both models, adjusted $R^2 = 0.15$, $F(9,214) = 5.5$, $p < .001$ and adjusted $R^2 = 0.24$, $F(9,214) = 8.9$, $p < .001$ respectively. For both DVs, there was no significant age-group interaction for the Autism Sibling group compared to the Low Risk group, while for all 3 neurogenetic groups there was. For the CT Rate model: Angelman: $b = -.027$, $t(214) = -4.6$, $p < .001$, 95% CI[-.039, -.016], Down: $b = -.018$, $t(214) = -3.2$, $p < .01$, 95% CI[-.030, -.0072], Fragile X: $b = -.018$, $t(214) = -2.8$, $p < .01$, 95% CI[-.032, -.0053]; For the CV Rate model: Angelman: $b = -.11$, $t(214) = -5.4$, $p < .001$, 95% CI[-.14, -.067], Down: $b = -.075$, $t(214) = -4.0$, $p < .001$, 95% CI[-.11, -.039], Fragile X: $b = -.0449$, $t(214) = -2.0$, $p < .05$, 95% CI[-0.089, -0.0013]. Two of the linear mixed effects regressions (LMMs) in the longitudinal analyses were: CT_Rate/CV_Rate ~ group + child_age + child_age * group + (1 | child_id) + (1 | group). Down and Fragile X groups did not significantly differ in CT or CV Rate across age, while there was a significant age-group interaction Angelman vs. Down/Fragile X for CV Rate, $b = -.022$, $t(203) = -2.3$, $p < .05$, 95% CI[-.039, -.0038] and $b = -.032$, $t(174) = -3.0$, $p < .01$, 95% CI[-.054, -.011] respectively.

Conclusions: Compared to the children at low risk of autism, there were significant differences in vocalization volubility in children with neurogenetic syndromes who were at higher risk for autism.

439.209 What Is the Impact of Second Language Exposure and Intellectual Disability Status on Executive Function and Functional Communication Outcomes in Children with and without Autism Spectrum Disorder?

S. M. Hutchison¹, N. DiazPinzon², T. Oberlander³ and G. Iarocci⁴, (1)Pediatrics, University of British Columbia, Vancouver, BC, Canada, (2)2329 West Mall, Vancouver BC, Canada, V6T 1Z4, University of British Columbia, Vancouver, BC, Canada, (3)University of British Columbia, Vancouver, BC, Canada, (4)Psychology, Simon Fraser University, Burnaby, BC, Canada

Background: Over the past 10 years, research has suggested no negative effect on second language exposure in children with autism spectrum disorder (ASD), yet, parents and professionals may be concerned about using a second language with a child with ASD as it may negatively impact their communication and cognitive skills, especially if the child also has an intellectual disability

Objectives: Our goal in the current study was to extend previous research in two ways: 1) to compare a large sample ($n = 396$) of children with ASD to typically developing (TD) peers who are not significantly different on socioeconomic status using parent ratings of EF and FC to see if we could replicate our preliminary results found with a smaller sample ($n = 174$) (Iarocci et al., 2017) and 2) to compare children with ASD (with and without second language exposure) who do or do not have an intellectual disability. This second aim is a unique feature of this study as children with ASD who also have an intellectual disability are typically excluded from research, including our previous research (Iarocci et al., 2017), as it was thought this condition should be considered separately.

Methods: In this study, 396 youth (5- 16 years) with and without ASD and with and without second language exposure participated in the study. Parents reported on language exposure and rated executive function (EF) and functional communication (FC) skills using a standardized questionnaire. IQ was directly measured using the WASI-II and children were classified as having an intellectual disability if they had a full-scale score of less than 70.

Results: Results showed that children with ASD and second language exposure had significantly better EF skills and were significantly less likely to have executive dysfunction in the clinical range than children with ASD with no second language exposure. Second language exposure also did not have a negative impact on EF skills in children with ASD even when an intellectual disability was present. For FC skills, we failed to find significant differences between children with ASD and second language exposure compared to children with ASD and no second language exposure. Intellectual disability was associated with having poorer FC skills; however, this pattern of results was the same regardless of whether the children were exposed to a second language or not.

Conclusions: Despite growing evidence that second language exposure does not have a negative impact on children with ASD, misconceptions persist. The current study suggests there is no evidence that functional communication and executive function are more impaired in children with ASD who have been exposed to more than one language, and our preliminary data suggest this is the case even when an intellectual disability is present. Additional research with a larger sample of children with ASD and an intellectual disability is needed to provide conclusive evidence.

439.210 Word Learning in Autism and Fetal Alcohol Spectrum Disorders: Social and Nonsocial Contexts for Learning

P. Ram and S. T. Kover, Speech and Hearing Sciences, University of Washington, Seattle, WA

Background: While social understanding is thought to play a pivotal role in vocabulary development, learning may readily occur for some children in non-social contexts when the expectations and processing demands of social interaction are removed. This may be especially pertinent to autistic children who have known social challenges. Children with fetal alcohol spectrum disorders (FASD) share many co-occurring challenges with autistic children, including in the areas of cognition, language, and social communication. There is a paucity of literature that compares word learning across social and non-social contexts in autistic children or that extends to other groups of children with disabilities that might have shared or distinct learning strengths, such as FASD.

Objectives:

The present study examined the performance of autistic children and children with FASD in word learning tasks, in a social versus a less-socially-mediated context. We assessed recognition and production of novel words in both contexts, and compared word learning across the two groups.

Methods:

Participants were 23 autistic children and 24 children with FASD (3-11 years old) who completed norm-referenced measures of receptive vocabulary and expressive vocabulary, as well as nonverbal cognition (Table 1). The groups did not differ on nonverbal IQ, $p = .279$, Cohen's $d = .27$.

Participants completed two novel word learning tasks that differed in the extent to which they provided a social context for linking labels and referents. To reduce bias due to order effects, task order (social, non-social) was counterbalanced across participants. The social context involved live, interactive exposure to novel objects presented by an examiner, who labeled each object 8 times in a child-directed manner while seated adjacent to the child; in contrast, the non-social context involved novel objects being presented on a wall-mounted screen and labeled 8 times using a child-directed recording.

Stimuli were 16 distinct novel words, with half assigned to the social context and the other half assigned to the non-social context. Word learning was measured in the same way immediately following exposure in each context via recognition (pointing) and production (labelling) probes.

Results:

For recognition, there was a significant main effect of context ($p = .016$), with a large effect size ($\eta^2 = 0.12$), indicating that performance was better in the non-social context (Figure 1). Neither the group effect ($p = .123$), nor the context by group interaction ($p = .737$) was significant.

For production, autistic participants produced a higher proportion of words correctly ($p = .014$, $\eta^2 = .133$). Neither the effect of context ($p = .331$), nor the interaction between context and group ($p = .248$) were significant.

Conclusions:

Across groups, recognition performance was statistically better in the less-socially-mediated context. Moreover, production performance was higher in the autistic group across contexts. These findings hold potential to inform future intervention studies on word learning for both autism and FASD, in exploring whether reduced social demands can facilitate better learning of words. Despite the focus on social prerequisites in many language intervention approaches, it may be warranted to focus on relative strengths for autistic children and children with FASD (e.g., nonsocial contexts), shifting away from deficit-based perspectives.

439.211 'Uh Huh': Backchanneling By Autistic and Neurotypical Teens and Their Caregivers in a Collaborative Task

N. Verastegui¹, G. Corrigan¹, C. Boo², R. Fusaroli³, E. Weed³ and L. R. Naigles¹, (1)Psychological Sciences, University of Connecticut, Storrs, CT, (2)Psychological Sciences, New York University, Storrs, CT, (3)Aarhus University, Aarhus, Denmark

Background: Backchannels (i.e., *mhm, okay*) signal and promote engagement, attention, and agreement between interlocutors.[1] Backchannels are socially important because they influence perceived communicative success, establish mutual understanding, and influence subjective judgements between conversational partners.[1] At least for neurotypical (NT) dyads, backchannel use varies by context and is more frequently used in affiliative than in task-oriented conversations.[2] Autism is associated with challenges in social interactions throughout development,[3] so autistic individuals might backchannel differently. In one study involving autistic and NT adults in same-neurotype dyads (ASD-ASD, NT-NT) while engaging in a collaborative task, autistic adults produced fewer backchannels per minute and fewer backchannel types compared to NT adults.[1] However, these interlocutors did not know each other, whereas autistic individuals with familiar conversation partners might produce more backchanneling.

Objectives: To deploy an ecologically valid approach investigating similarities and differences in how autistic and neurotypical teens and their caregivers use backchannels while talking in a family setting.

Methods: Participants included 15 autistic and 15 NT adolescents (Table 1) from an ongoing longitudinal study that had matched them on their expressive language at 18-30 months of age.[4] As teens, they completed a collaborative video game (the Aliens game[5]) where caregiver-teen dyads discussed whether each of 40 aliens was good or bad and had a gem or didn't. Participant and caregiver speech was recorded and transcribed by trained research assistants in Datavyu.[6] Transcripts of both teen and caregiver speech were analyzed in CLAN[7] to identify number of utterances. Backchannels were identified from the transcripts and confirmed by reviewing the videos. To account for differences in verbosity, analyses were conducted on the proportion of backchannel tokens to utterances, and the number of backchannel tokens per minute.

Results: Teens and their caregivers produced a roughly comparable number of backchannel tokens across diagnostic groups during the approximately 20-minute interaction. NT teens and their caregivers tended to produce more backchannels per minute compared to autistic teens and their caregivers, (2 vs. 1 per minute, respectively $ps < .10$, Table 1). Out of the five backchannel types identified (*yeah, okay, uh huh/mhm, right, alright*), autistic teens produced significantly fewer than NT teens ($p < .01$, Table 1; primarily *yeah* and *okay*). Moreover, within the ASD group, teens who produced more backchannel types had caregivers who produced more backchannel types (Figure 1).

Conclusions: These findings provide replication, extension, and potential context to previous reports of less backchanneling in autistic adults. In particular, fewer backchannel types were observed in these autistic teens while conversing with their familiar caregivers during a collaborative task. Moreover, caregiver and teen backchannel types were correlated in the ASD group, raising intriguing questions about proximal (during this interaction) and distal (across the teen's lifetime) influences, as well as bi-directionality. Future analyses will consider backchanneling in conversations between these dyads when the teens were preschoolers.

439.212 Speech-Language Pathologists' Perceptions of Gestalt Language Processing/Natural Language Acquisition

C. E. Venker¹ and J. Johnson², (1)Communicative Sciences and Disorders, Michigan State University, East Lansing, MI, (2)Michigan State University, East Lansing, MI

Background: Among speech-language pathologists (SLPs) who work with autistic children, there has been a recent rise in the popularity of gestalt language processing/natural language acquisition (GLP/NLA). GLP is “a style of language acquisition that begins with larger chunks of language, as opposed to the traditional style of language acquisition...that begins with single words” (Blanc et al., 2023, p. 2). The NLA protocol is “a description of the six stages of gestalt language development...and a documentation of the natural supports that allow students to progress through the stages...” (Blanc et al., 2023, p. 3). Despite its popularity, there are growing concerns that GLP/NLA incorporates some concepts and recommendations that are theoretically and empirically unsupported (Evans, 2022; Hutchins, Knox and Fletcher, 2024; Venker and Lorang, 2024). **Objectives:** Given the popularity of (and controversy surrounding) GLP/NLA, the objective of this study was to better understand SLPs’ perceptions of GLP/NLA.

Methods: We conducted face-to-face, semi-structured interviews with 12 SLPs. SLPs were asked to describe GLP/NLA and discuss whether and how they use it in their practice. On average, interviews lasted 13 minutes ($SD = 11$). We analyzed the data using reflexive thematic analysis (Braun and Clarke, 2006). We developed codes using an inductive, data-driven approach and then organized the codes into themes.

Results: We identified four primary themes.

1) Differing impressions. SLPs’ impressions of GLP/NLA varied widely, leading us to categorize them as Embracers, Skeptics, and Neutral SLPs. One Embracer (SLP 342) said, “I love [GLP/NLA]...I think it’s really monumental...” Another Embracer (SLP 341) said, “I think it’s really opened my eyes to how a lot of our learners communicate and just a way for them to process language.” One Skeptic (SLP 340) said, “I feel like it’s a lot of, like, much ado about nothing, I guess.”

2) Clinical starting point. Embracers’ positive impressions of GLP/NLA were frequently associated with a starting point of discontent, wherein they felt frustrated by a lack of progress and uncertain what to do next. Skeptics and Neutral SLPs did not mention feeling stuck.

3) Experiences implementing GLP/NLA. Embracers described positive experiences implementing GLP/NLA (e.g., increased rapport). Embracers also described negative experiences (e.g., difficulty interpreting gestalts, discomfort using ungrammatical language).

4) Professional and outside influences. SLPs commonly mentioned the popularity of GLP/NLA. One Neutral SLP (SLP 347) described GLP/NLA as a “buzzword” and said that she felt “kind of embarrassed” she did not know more about it. One Embracer (SLP 342) said that her clients’ parents are seeing GLP/NLA content on social media and taking courses on it. Another Embracer (SLP 345) said parent advocacy led her to prioritize GLP/NLA in professional development.

Conclusions: Some SLPs expressed enthusiasm about GLP/NLA, and some expressed skepticism. It was notable that positive experiences implementing GLP/NLA usually related to the use of general, responsive strategies (e.g., child-led therapy), whereas negative experiences related to strategies unique to GLP/NLA (e.g., identifying stages). An important next step is determining what specific strategies SLPs use when they report that they are implementing “GLP/NLA.”

439.213 Affect Production and Psychosocial Functioning in Children with Autism Spectrum Disorder (ASD)

R. Narasimhan¹ and **C. Demopoulos²**, (1)Psychiatry and Behavioral Sciences, University of California San Francisco, San Francisco, CA, (2)Psychiatry & Behavioral Sciences, UCSF Center for ASD and NDDs, San Francisco, CA

Background: Autism spectrum disorder (ASD) can be associated with difficulties in expressing emotions through facial and vocal affect; however, little research has been dedicated to understanding the impact of these difficulties on social/emotional and adaptive functioning.

Objectives: This study examined the relationship between facial and vocal affect production and parent-reported internalizing, externalizing, and adaptive behaviors in children with ASD. This study is the first to evaluate how the ability to intentionally communicate a desired affective state is related to social and emotional outcomes in children with autism.

Methods: Participants were 88 children (ASD = 55; TDC = 33) aged 8 to 17 years who scored at least 80 on the Clinical Evaluation of Language Fundamentals-5th Edition (CELF-5) Receptive Language Index (RLI). This cutoff was applied to ensure that participants had sufficient receptive language abilities to meet task demands. Parents of participants completed the Behavior Assessment Scale for Children-3rd Edition (BASC-3) to derive scores on the Social Skills, Functional Communication, and Withdrawal scales and the Internalizing and Externalizing Composite scores. Participants were administered a novel affect production task which required them to produce facial and vocal expression of specified emotions happy, sad, angry, or afraid) in response to a prompt. Responses were audio/video recorded and classified as happy, sad, angry, afraid, or neutral by raters blinded to the emotion prompted. Affect production abilities were quantified by agreement between the prompted emotion and the emotion selected by the rater. Group differences in affect production and psychosocial functioning were assessed using Mann-Whitney U tests. Bivariate nonparametric correlation analyses examined associations between overall facial and vocal affect production accuracy and BASC-3 domains. **Results:** Significant group differences were found in BASC-3 Externalizing Composite ($U = 3882.500$, $p < .001$), Internalizing Composite ($U = 3675.500$, $p < .001$), Social Skills scale ($U = 1089.500$, $p < .001$), Withdrawal scale ($U = 4131.500$, $p < .001$), and Functional Communication scale ($U = 639.000$, $p < .001$). No significant differences were found in vocal affect production ($U = 731.500$, $p = .626$); however, the TDC group was more effective in conveying affective states via facial expression ($U = 707.500$, $p = .014$). Facial affect production was significantly correlated with parent reported anxiety ($Rho = .364$, $p = .006$), depression ($Rho = .276$, $p = .042$), overall internalizing symptoms ($Rho = .301$, $p = .026$), and social skills ($Rho = .396$, $p = .003$). Vocal affect production was significantly correlated with functional communication ($Rho = .357$, $p = .010$) and withdrawal ($Rho = -.388$, $p = .005$).

Conclusions: These findings suggest that affect production abilities impact social emotional functioning and/or parental perceptions thereof in autistic youth. Notably, autistic youth who were able to effectively communicate facial affect were more likely to have their emotional distress recognized by parents, highlighting the role of visible emotional cues in parent-report measures. This emphasizes the need for comprehensive risk assessment, particularly in a population with elevated internalizing symptoms and suicide risk.

439.215 An Expansive Approach to Assessment of Novel Word Acquisition in Autistic Children

H. Barton¹ and **S. T. Kover²**, (1)University of Washington, Seattle, WA, (2)Speech and Hearing Sciences, University of Washington, Seattle, WA

Background:

Language assessment seeks to quantify skills and knowledge that individuals possess, often for the purpose of identifying areas that would benefit most from intervention. Yet, children's verbal participation and compliance influence scoring outcomes, which can disproportionately challenge autistic children (Fipp-Rosenfield et al., 2024). Use of nonverbal response modalities (e.g., eye-gaze) enhances autistic children's participation in research, as well as researchers' and clinicians' understanding of their receptive vocabulary knowledge (Brady et al., 2014). However, individual children vary on what response modalities optimize receptive performance (e.g., eye-gaze, pointing; Skwerer et al., 2016). We extend previous research by implementing an expansive coding scheme that captures participants' responses (e.g., eye-gaze, point) regardless of the modality cued by the examiner. This approach may allow more flexibility in assessment protocols, reduce data loss, and encourage strengths-based framing of autistic children's language knowledge.

Objectives:

We present an expansive coding scheme for the assessment of receptive word knowledge, report rates of data missingness, and compare variation from cued response modalities for autistic and neurotypical (NT) children.

Methods:

Exploratory analyses were conducted on an existing dataset of 25 autistic children (2-11 years old, $M=7.1$, $SD=1.7$) and 32 NT children (2-7 years old, $M=4.5$, $SD=1.2$) who completed a remotely administered storybook-listening word-learning task. To score word learning assessments, coders were trained to make a judgment of the child's selection of a target object from an array of two, based on any observable behavior. Coders noted the child's selection (correct, incorrect) and the behavior that they (the coder) utilized as the basis of their judgment (e.g. eye-gaze, point, or cannot judge). Reliability for accuracy was high ($\kappa = 0.82$); reliability for behavior judgment is in progress. Responses were further classified as cued (e.g., gaze, when asked to look) or non-cued (e.g., point, when asked to look) modalities.

Results:

Regarding missingness, across 769 trials where children were cued to look at the target, only 126 trials were not scorable (e.g., examiner error, child stated 'I don't know'; 14% of autistic group trials, 18% of NT trials; no significant difference). Regarding response modalities, group and use of cued response modality were significantly associated (Fisher's exact test): autistic participants used more non-cued responses (e.g., pointing, when cued to look) than NT participants. This was the case both across all trials that elicited a scorable response ($p<.001$) and considering only trials with correct responses ($p<.001$); thus, modality distribution does not appear to be a function of accuracy.

Conclusions:

Autistic children may use additional response modalities beyond what is cued to indicate their receptive word knowledge. Additional analyses will examine this expansive scoring scheme for tasks that cue pointing rather than looking. Findings also suggest that this expansive scoring scheme allows for minimal data missingness across groups, which we will compare to traditional schemes. This work sheds light on scoring approaches that estimate autistic children's vocabulary knowledge with less reliance on behavioral compliance with specific response modalities.

439.216 Investigating Caregiver Linguistic Input Provided to Infants at Elevated Familial Likelihood for Autism in Families from India

S. Volme¹, D. Vernekar², S. Shyam Sundar³, M. Srikar³, R. Raju⁴, D. Swaminathan¹, R. Johnson⁵ and S. S. Meera⁶, (1)National Institute of Mental Health and Neurosciences (NIMHANS), Bangalore, India, Bangalore, India, (2)National Institute of Mental Health and Neurosciences (NIMHANS), Bengaluru, India, (3)National Institute of Mental Health and Neurosciences (NIMHANS), Bangalore, India, (4)National Institute of Mental Health and Neuro Sciences (NIMHANS), Bangalore, Bangalore, Karnataka, India, (5)National Institute of Mental Health and Neuro Sciences (NIMHANS), Bangalore, India, (6)National Institute of Mental Health and Neurosciences (NIMHANS), Bangalore, Karnataka, India

Background: Infant siblings of autistic children (EL-A) are three to four times more likely to exhibit language delay¹ and social communication difficulties compared to infants at typical likelihood (TL), i.e., having an older neurotypical sibling. Caregiver linguistic input (CLI) is among the key factors influencing language development in infants.² Comparative studies of EL-A and TL infants indicate differences in quantity and quality of CLI such as word counts, mean length of utterance, conversational turns and directiveness.² However, findings related to these differences (a) have not been consistent, (b) have been reported only in broad aspects of CLI (e.g., word token and directiveness) and not comprehensive aspects (e.g., nouns, verbs or attention directives) despite literature and clinical knowledge highlighting their importance in infants language development,² and (c) have been documented predominantly in western contexts although CLI can vary with culture and ethnicity.³ This preliminary study in India aims to investigate these gaps by examining a sample of EL-A and TL infants.

Objectives: To evaluate (a) differences in the quantity and quality of CLI (b) association between CLI and concurrent language abilities, in infants between 9-15 months of age.

Methods: Home-recorded caregiver-infant free play videos were obtained from 33 EL-A; [M= 10.97 (3.04)], and 15 TL; [(M= 12.42 (4.23)], infants (Table 1a). Videos were coded for quantity and quality of CLI using a study-specific modification of an existing system³, including 18 parameters focused on pragmatic language functions essential for fostering infants' social engagement (Figure 1). ATLAS.ti (v23.2.1), was used to annotate video transcriptions. A subsample (20%) was annotated by another coder for inter-rater reliability.

Quade's ANCOVA controlling for age was used to assess group differences and Spearman partial correlation to assess association between CLI and infant language abilities.

Results: Objective 1: Significant group differences were observed in three CLI parameters: attention directives (EL-A>TL) ($F= 10.09$ $p=.003$), prohibitions (EL-A<TL) ($F= 19.23$ $p<.001$) and exclamations (EL-A<TL) ($F= 18.98$ $p<.001$). Although not coded, increased object engagement over social engagement, fewer initiations⁴ and reduced social reciprocity⁵ in infants could be potential reasons.

Objective 2: Significant positive correlations were found between total words, verbs, and utterances and infants' receptive and expressive vocabulary and language abilities as measured on MCDI and VABS respectively. Word type was associated with words spoken on MCDI. Further, a negative correlation was obtained between type-token ratio and language abilities on VABS (Table 1b). These findings align with existing literature² indicating repetitive labelling of objects, actions, and events support infants' language abilities. However, no significant correlations were found between qualitative CLI parameters and infant language abilities, requiring further investigation.

Conclusions: Despite the small sample size, this annotation-intensive study revealed subtle variations in caregiver linguistic input (CLI), which may not be detected when focusing solely on broader aspects of CLI. Future research with larger samples and longitudinal design considering other infant and caregiver factors (e.g., caregivers education) may offer deeper insights into CLI and its impact on infants' language abilities and subsequently help inform interventions.

439.217 Parental Perspectives on Choosing a Monolingual or Bi/Multilingual Environment for Their Autistic Children Growing up in a Bilingual Environment in India

S. S. Meera¹, R. Johnson², A. Girimaji³, S. Shyam Sundar³ and I. Gangopadhyay⁴, (1)National Institute of Mental Health and Neurosciences (NIMHANS), Bangalore, Karnataka, India, (2)National Institute of Mental Health and Neuro Sciences (NIMHANS), Bangalore, India, (3)National Institute of Mental Health and Neurosciences (NIMHANS), Bangalore, India, (4)Indiana University-Bloomington, Room 2015, IN

Background: Recent studies have indicated that bilingualism does not negatively impact language development in autistic children, and may even serve as a protective factor against some cognitive and communication difficulties associated with autism.¹ Yet from studies in other parts of the world² and our own clinical experience³, parents of autistic children have expressed concerns that bilingualism may confuse their child and that it may cause additional language delays. This assumption may be especially harmful for children in bilingual environments like India, where exposure to multiple languages is an integral part of life.⁴ However, in a country as linguistically diverse as India, the roots of these beliefs and opinions on bi/multilingual exposure for autistic children are unknown.

Objectives: The study asked parents of autistic children growing up in bi/multilingual environments (a) their preferred choice of language environment (monolingual or bi/multilingual) for their child and, (b) their reasons for preferring a monolingual environment or a bi/multilingual environment. The study also evaluated whether there were differences in socio-economic status, parental education, communication mode, child receptive and expressive language abilities, and autistic symptom severity among parents that preferred a monolingual environment versus those who preferred a bi/multilingual environment.

Methods: A survey questionnaire was administered to 102 parents of 2-6 year-old autistic children exposed to two or more languages. Parents were recruited from a tertiary care hospital for mental health and neurosciences in Bengaluru city, India. Although the survey was administered to the parents in English, Kannada, and/or Hindi, their children were exposed to a variety of other languages (e.g., Bengali, Tamil, Telugu). Language abilities and autism severity were evaluated using the Receptive and Expressive Emergent Language Scale (REEL-3) and Childhood Autism Rating Scale (CARS-2), respectively.

Results: See Table 1 for sociodemographic data and analysis results. Mean age of children was 52.11 months (SD=11.77); female n=25 (24.5%). The survey was completed by 70 mothers ($M_{Age}=33.92$ years, $SD=5.08$) and 32 fathers ($M_{Age}=37.5$ years, $SD=5.52$). Nineteen (18.62%) parents preferred/wished they chose a monolingual environment and 83 (81.37%) preferred to continue to raise their child in a bi/multilingual environment. Top reasons that parents preferred a monolingual environment included: learning two languages would be hard for the child and fear that the child will be confused by two languages. Key reasons that parents preferred a bi/multilingual environment included: to help communicate with people in school, with family members, with people in the neighbourhood, and because parents were living in a bilingual/multilingual city and country. See Table 2 for more details. Controlling for age, children of parents who preferred a monolingual environment had lower expressive language scores ($M=24.47$, $SD=12.28$) than parents who preferred a bilingual environment ($M=33.44$, $SD=13.27$). There were no statistically significant differences in socio-economic status, parental education, mode of communication (parent report), receptive language abilities, or autism severity.

Conclusions: In this study, one of the first from India, most parents preferred bi/multilingual environments for their autistic children, unlike previously reported.^{1,2} Future analyses will explore how child- internal and external factors influence parents' decisions.

Poster Session**440 - Diagnostic, Behavioral & Intellectual Assessment II**

May 3rd, 2025, 12:30 PM - 1:30 PM - Hall 4A

440.218 Improving the Screening to Treatment Pathway for Autism with Telehealth

C. J. Smith¹, S. Boyd², T. Taber³, G. E. Mitchell⁴, L. Yin⁵, I. Quebles⁶, M. J. Morrier⁷, R. A. Sturmer⁸, B. J. Howard⁹ and R. Oberleitner¹⁰, (1)Southwest Autism Research & Resource Center, Phoenix, AZ, (2)Southwest Autism Research and Resource Center, Phoenix, AZ, (3)Research, SARRC, Phoenix, AZ, (4)Curriculum & Instruction, University of Idaho, Moscow, ID, (5)Children's Hospital Los Angeles, University Center for Excellence in Developmental Disabilities, Los Angeles, CA, (6)CHLA, LA, CA, (7)Department of Psychiatry & Behavioral Sciences, Morrier Consulting LLC, Decatur, GA, (8)Pediatrics, Center for Promotion of Child Development through Primary Care, Baltimore, MD, (9)Total Child Health, Baltimore, MD, (10)Behavior Imaging (Telehealth Research), Boise, ID

Background: Barriers to the screening-to-treatment pathway include variability in pediatrician screening and referral procedures, availability of skilled professionals to conduct evaluations, and challenges securing an autism treatment program. Telehealth options for screening and evaluation present a promising solution; however, they have not yet achieved widespread acceptance. In 2015, the Naturalistic Observation Diagnostic Assessment (NODA) was developed and validated. NODA aligned with an in-person evaluation in 88% of cases (Smith et al., 2017) Usability among clinicians was favorable (Nazneen et al., 2015). While NODA provides valuable behavioral examples, practical application in diagnostic services requires a comprehensive developmental history to enhance clinician confidence in diagnosing ASD. Thus, a live interview component was added to allow raters to gather evidence in real time. NODA-E (video review plus interview) was recently validated against the in-person assessment (Morrier et al., 2024). NODA-E paired with a telehealth system for screening and referring children, CHADIS, it is possible to overcome some of the barriers in this pathway.

Objectives: The current study aims to evaluate the time-saving advantages of this streamlined screening-to-treatment pathway.

Methods: Pediatricians in Arizona, California, and Idaho used CHADIS to screen 140 families electronically referred participants to a local study site. All procedures received approval from the Western Copernicus Group IRB. After consent, in Arizona only, families were randomized into either the Telehealth group or the Community group (Table 1). California and Idaho families completed only the telehealth procedure. To avoid bias associated with study participation, families in the Telehealth group were given the next available appointment with a diagnosing psychologist and completed three procedures: 1) recording four videos of the child at home to capture social communication and play behaviors (Smith et al., 2015); 2) completing an ABAS assessment through CHADIS; and 3) participating in a developmental history interview with a psychologist using the NODA-E platform. A diagnostic report was securely shared with parents through the NODA system. The Community group received a list of local providers to schedule evaluations independently. Both groups were contacted by study staff and sent reminders through CHADIS to regularly track progress, with milestones recorded via brief questionnaires. Significant attrition was observed in both groups. Nonparametric statistics were used to compare groups due to violations of normality.

Results: Participant attrition was indicated by significant differences in sample size in the Telehealth and Community groups for each dependent variable (Cochran's Q = 114.75, df = 3, p < .001; and 75.83, df = 3, p < .001). To preserve sample size, separate group comparisons were conducted, and alpha was corrected for multiple comparisons. Group comparisons revealed significant differences for the days between screening and evaluation, report, and treatment (p < .001), indicating that the telehealth procedure significantly reduced the screening-to-treatment pathway (Table 2).

Conclusions: Significant differences were found in the time between screening and scheduling evaluations, receiving reports, and enrolling in autism treatment between the Telehealth and Community groups. However, high attrition rates suggest challenges for families in both groups, indicating a need for larger studies to identify barriers in the screening-to-treatment pathway for children with autism.

**440.219 Influence of Co-Occurring ADHD on the Ability of a Digital Phenotyping App to Detect Behavioral Signs of Autism**

V. Aikat¹, K. L. Carpenter², P. R. K. Babu³, J. M. Di Martino⁴, S. Espinosa⁵, N. O. Davis⁶, L. Franz⁷, M. Spanos⁸, G. Sapiro⁹ and G. Dawson¹⁰, (1)Department of Computer Science, Duke University, Durham, NC, (2)Department of Psychiatry and Behavioral Sciences, Duke University Medical Center, Durham, NC, (3)Duke University, Durham, NC, (4)Department of Electrical and Computer Engineering, Duke University, Durham, NC, (5)Department of Psychiatry and Behavioral Sciences, Duke University Medical Center, Durham, NC, (6)Princeton University, Princeton, NJ, (7)Department of Psychiatry and Behavioral Sciences, Duke University, Durham, NC

Background:

While signs of autism can be observed during infancy, the time between onset of first signs and diagnosis can be lengthy, delaying services and intervention. Thus, there is a need for accurate, scalable methods for autism screening. Furthermore, autism frequently occurs alongside other conditions, such as attention-deficit/hyperactivity disorder (ADHD). Thus, validation of autism screening tools in children with co-occurring conditions is essential. We have previously shown that SenseToKnow, a digital phenotyping app which is designed to detect signs of autism, can be used to accurately detect autism in primary care settings and remotely at home. The app requires only a smartphone or tablet, using video of the child's behavioral responses collected from the device's front-facing camera. The video is analyzed using computer vision to automatically compute clinically relevant features such as social attention, facial expressions, and motor responses. In this work, we describe the use of the SenseToKnow app in preschool- and school-aged children who are diagnosed with autism alone, ADHD alone, or co-occurring autism and ADHD, compared to neurotypical children.

Objectives:

To compare the computer vision-based behavioral features derived from the SenseToKnow app across four groups of children: (1) autism, (2) ADHD, (3) co-occurring autism and ADHD, and (4) neurotypical.

Methods:

SenseToKnow, which is comprised of a series of strategically designed brief movies, was administered on an iPad in a clinical setting. The sample consisted of 181 participants, 40-100 months in age, as follows: 41 neurotypical, 51 autistic, 48 ADHD, and 41 autism and ADHD. Participants' behavioral responses were recorded using the tablet's front facing camera and analyzed with computer vision to quantify response to name, gaze, head movement metrics, facial movements, attention (facing forward), and blink rate.

Results:

Analysis of covariance (ANCOVA) with age as a covariate revealed significant group differences ($p < .05$) between autistic and non-autistic participants (Table 1). In contrast, we found no significant differences ($p > .05$) in any feature between those with autism alone and those with co-occurring autism and ADHD. Significant differences ($p < .05$) were found between neurotypical and ADHD participants for all features in response to nonsocial movies, as well as gaze silhouette score, a measure of gaze focus. Linear modeling of each feature comparing autistic (excluding co-occurring ADHD), ADHD, and neurotypical participants with age as a covariate indicated that autism status had a significantly stronger impact on feature outcome than ADHD status across all features, except for response to name delay, when compared to the neurotypical group (Figure 1).

Conclusions:

The SenseToKnow app can effectively distinguish neurotypical children from those with autism, ADHD, and co-occurring autism and ADHD. Additionally, the presence of autism has a significantly greater impact than the presence of ADHD on the majority of app-extracted features. These findings, together with prior work, further encourage the use of SenseToKnow to detect autism signs in children.

**440.220 Initial Use and Diagnostic Accuracy of the Tele-ASD-PEDS-Preschool (TAP-P)**

L. Corona¹, L. Wagner², A. Munoz Lavanderos³, M. Honaker⁴, T. E. Foster¹, C. Stone¹, A. Swanson⁵, A. Vehorn¹, A. S. Weitlauf⁶ and Z. Warren¹, (1)Vanderbilt University Medical Center - Treatment and Research Institute for Autism Spectrum Disorder, Nashville, TN, (2)Waisman Center, University of Wisconsin-Madison, Madison, WI, (3)University of Oregon, Eugene, OR, (4)Vanderbilt University, Nashville, TN, (5)Vanderbilt University Medical Center, Nashville, TN, (6)Vanderbilt Kennedy Center, Nashville, TN

Background: The wait for autism evaluation increases substantially with age, with wait times of a year or more common as children reach preschool. Even when appointments become available, families from traditionally underserved groups struggle to access care. Telemedicine has presented an alternate pathway for diagnostic assessment of toddlers with concerns for possible autism, yet addressing care disparities requires designing identification tools and processes specifically for and with individuals most at-risk for health inequities. This work evaluates the use of a novel telemedicine-based autism assessment tool for the preschool age range: the TELE-ASD-PEDS-Preschool (TAP-P), a play-based instrument with administration activities and scoring procedures based on the child's language level (i.e., TAP-P Verbal, TAP-P Non-verbal).

Objectives: To evaluate use of the TAP-P, assessing diagnostic concordance with in-person evaluation and understanding family and clinician perceptions.

Methods: Participants were children (28% female, 72% male, 42% identifying as from a racial or ethnic minority background) aged 36-71 months ($m = 47.8$ months, $SD = 9.90$) referred for autism-focused evaluation by primary care providers, early intervention teams, or by family self-referral. Participants completed in-home tele-assessment visits with a licensed psychological provider, including administration of the TAP-P, clinical interview, and developmental assessment using the Developmental Profile 4 (DP-4). Clinicians documented diagnostic impressions immediately following tele-assessment. All participants completed in-person assessment with a different psychological provider unaware of tele-assessment impressions. In-person assessment included developmental (Mullen Scales of Early Learning) or cognitive (Differential Ability Scales, Second Edition) assessment, adaptive behavior assessment (Vineland Scales of Adaptive Behavior, Third Edition), and administration of the Autism Diagnostic Observation Schedule (ADOS-2). Following in-person assessment, clinicians documented their diagnostic impressions and shared diagnostic feedback with families. Caregivers completed brief questionnaires following tele- and in-person assessment to share their feedback. **Results:** In total, 116 participants completed both tele- and in-person assessment ($n=2$ completed only tele-assessment). When asked to make a binary decision about the presence or absence of autism, tele-assessment and in-person clinicians agreed for 82% of cases (TAP-P Verbal: 76%; TAP-P Non-verbal: 89%). When given the option to select "unsure," tele-assessment clinicians reported uncertainty for 28% of participants in the TAP-P NV group and 52% of the TAP-P V group. Overall, tele-assessment clinicians reported stronger diagnostic certainty for children assessed using the TAP-P NV ($m = 3.11$, $SD = 1.07$) than the TAP-P V ($m = 2.61$, $SD = 0.86$), $t(113) = 2.78$, $p < .05$. Families reported broad satisfaction with tele-assessment procedures, with 87% indicating "very true" when asked whether they would recommend this kind of tele-evaluation to others.

Conclusions: This work represents an extension of prior research suggesting that clinicians can confidently and accurately identify autism over telehealth in preschool-aged children, particularly for children with limited verbal ability. These findings also identify important considerations and future directions for tele-assessment of verbal, phenotypically complex children, including adaptations designed to increase clinician certainty while preserving caregiver satisfaction and meaningful utilization of the TAP-P as one tool within existing systems to effectively identify concerns in preschool children facing disparities in access to diagnostic care.

440.221 Identifying Early Motor Patterns of Autism through Free Play: Validation of a Smart Toy for Preschoolers

A. Narzisi¹, F. A. Sandoval Villarreal², F. Pizzino³, M. Fabbri-Destro⁴, A. Milone⁵, V. Viglione³, G. Masi³ and S. Chessa³, (1)Department of Child Psychiatry and Psychopharmacology, Antonio Narzisi, Pisa (Calambrone), Pisa, Italy, (2)University of Pisa, Pisa, Italy, (3)irccs stella maris, PISA, Italy, (4)Istituto di Neuroscienze, Consiglio Nazionale delle Ricerche (CNR), Parma, Italy, (5)IRCCS Stella Maris Foundation, Pisa (Calambrone), Italy

Background:

One way to identify early signs of Autism Spectrum Disorder (ASD) is by observing children's motor behaviors during object manipulation in play. To enhance this process, this study introduces a novel Internet of Things (IoT) enabled smart toy, designed to serve as a screening tool. The toy can be used during free play, providing objective data on children's motor behaviors in natural environments. This approach aims to improve the early screening process, offering specialists valuable insights into motor patterns that may indicate the presence of ASD.

Objectives:

The study's primary objective is to assess the effectiveness of the smart toy in identifying early motor signs of ASD and to support specialists in the screening process. Specifically, the toy captures data on children's object manipulation behaviors during free play to analyze movement patterns that may distinguish ASD from Typical Development (TD). Additionally, the study aims to validate the use of neural network models for classifying these movement patterns based on key motor variables.

Methods:

This study involved 100 preschoolers (50 ASD; 50 TD). The ASD group included children with varying degrees of autism severity and developmental levels. Each child interacted with the smart toy, 3 minutes, which was equipped with sensors that tracked movement. The data were analyzed based on four primary motion variables: **Acceleration** (changes in toy speed), **Pitch** (rotation on the transverse axis), **Roll** (rotation on the longitudinal axis), and **Yaw** (rotation on the vertical axis). Two neural network models—Time Delay Neural Network (TDNN) and Recurrent Neural Network (RNN)—were applied to classify the movements. Overfitting detection was based on validation accuracy, and models were optimized using grid search techniques. TDNN optimization focused on filter numbers and kernel size, while RNN was optimized by adjusting the number of units in the recurrent layer.

Results:

Distinct movement patterns were observed between ASD and TD children. For ASD children, **Acceleration** showed oscillations tending towards zero, while **Pitch**, **Roll**, and **Yaw** demonstrated instability, with large yaw peaks exceeding $\pm 150^\circ$. These children exhibited continuous toy movement, with low acceleration and leftward longitudinal rotations, combined with significant vertical oscillations to the right and left. In contrast, TD children displayed more controlled movement patterns: **Acceleration** oscillated around zero with peaks near 50, while **Pitch** and **Roll** remained stable and low. **Yaw** exhibited only minor fluctuations. TD children applied more movement at the beginning and end of play sessions, with a vertical tilt to the right, while the toy remained stable in the middle of the session.

Conclusions:

The smart toy demonstrates strong potential as a non-invasive tool for early ASD screening by providing objective, naturalistic observations of motor behaviors during free play. The distinct movement patterns identified in ASD children, characterized by continuous movement and unstable yaw values, contrast with the more stable behaviors of TD children. The neural network models (TDNN and RNN) were effective in classifying these behaviors, offering a valuable data-driven approach to support screening. Future research will focus on refining the models and validating this technology in larger, more diverse populations to enhance early ASD detection.

440.222 Investigating Factors Linked to Research-Confirmed Diagnosis of Autism Spectrum Disorder in Children Referred for Diagnosis in a Research Study: Results from the Autism Biomarkers Consortium for Clinical Trials (ABC-CT)

S. P. Silber¹, C. M. Keifer², L. A. Wang³, A. Naples⁴, K. Chawarska⁵, G. Dawson⁶, R. A. Bernier⁷, S. Jeste⁸, S. Faja⁹, J. Dziura¹⁰, S. J. Webb¹, C. Sugar¹¹, F. Shic¹² and J. McPartland¹³, (1)Child Study Center, Yale School of Medicine, New Haven, CT, (2)Yale Child Study Center, Yale School of Medicine, New Haven, CT, (3)Center for Autism Research, Yale Child Study Center, Yale School of Medicine, Philadelphia, PA, (4)Yale Child Study Center, Yale University School of Medicine, New Haven, CT, (5)Child Study Center, Yale University School of Medicine, New Haven, CT, (6)Department of Psychiatry and Behavioral Sciences, Duke University, Durham, NC, (7)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (8)Children's Hospital Los Angeles, Los Angeles, CA, (9)Boston Children's Hospital, Harvard, Boston, MA, (10)Yale University, New Haven, CT, (11)University of California, Los Angeles, Los Angeles, CA, (12)Center for Child Health, Behavior and Development, Seattle Children's Research Institute, Seattle, WA, (13)Yale Child Study Center, Yale Child Study Center, New Haven, CT

Background: The prevalence of autism spectrum disorder (ASD) has increased, with the CDC reporting 1 in 36 children diagnosed (Maenner, 2023). Despite improved diagnostic reliability, concerns about over- and under-diagnosis remain (Berg, 2018). Increased awareness may lead to false positives, which could be reduced through gold-standard assessments (Duvall, 2022). Duvall et al. (2024) found that 47% of children with community-based ASD diagnoses didn't meet rigorous research diagnostic criteria. This study aims to replicate these findings using the Autism Biomarkers Consortium for Clinical Trials (ABC-CT) dataset.

Objectives: This study investigates the characteristics associated with research-confirmed diagnosis of ASD in children referred to participate in the ABC-CT. We compared groups of ASD+ (children recruited in the ASD path of the study who met research diagnostic criteria) and ASD- (children who did not meet research diagnostic criteria). Research diagnosis of ASD was defined as meeting criteria on the Autism Diagnostic Observation Schedule-2 (ADOS-2), the Autism Diagnostic Interview – Revised (ADI-R), and expert clinical judgement using the Diagnostic and Statistical Manual-5 (DSM-5). Per Duvall et al. (2024), we predicted that the ASD- group would have higher levels of internalizing and externalizing symptoms (Child & Adolescent Symptom Inventory-5 (CASI-5)), and higher Full Scale Intelligence Quotient (FSIQ) scores than children in the ASD+ group.

Methods: Analyses were conducted on a sample of 317 youth recruited in the ASD path of the ABC-CT. The ASD+ group included 280 children (65 female; $M_{age} = 8.43$, $SD_{age} = 1.66$; $M_{IQ} = 96.6$, $SD_{IQ} = 18.1$) and 37 children were in the ASD- group (11 female; $M_{age} = 8.47$, $SD_{age} = 1.41$; $M_{IQ} = 103$, $SD_{IQ} = 15.6$). Independent sample t-tests compared FSIQ, verbal IQ, non-verbal IQ, age, and internalizing and externalizing symptoms (CASI-5 subdomain t-scores) in the ASD+ and ASD- groups. Sex distribution was compared between groups using chi-square tests.

Results: Overall, children in the ASD- group had higher verbal IQ than children in the ASD+ group ($t(305) = 2.23$, $p = 0.02$, $d = 0.48$). The ASD- group had marginally higher FSIQ than children in the ASD+ group ($t(304) = 1.69$, $p = 0.09$, $d = 0.36$). Non-verbal IQ, CASI-5 t-scores, age, and sex did not differ significantly between groups (all p 's > 0.1).

Conclusions: Consistent with our hypotheses, the ASD- group demonstrated higher verbal IQ scores than those in the ASD+ group, indicating that youth with stronger verbal abilities may be more at risk for misdiagnosis of ASD. This study employs the ADI-R which is based on DSM-4 criteria, requiring communication difficulties. Thus, children with stronger communication skills who would have met DSM-5 criteria may have been excluded. Alternatively, clinicians may have less experience with the differential diagnosis of ASD in highly verbal children contributing to over-diagnosis. In contrast to our hypotheses, groups did not differ in their level of internalizing or externalizing symptoms or by demographic characteristics. Limitations include the use of a convenience sample not designed to evaluate accuracy of community diagnoses, small sample size, and missing data in the ASD- group. Future investigations would benefit from using multiple data sources to compare psychiatric symptoms across groups.

440.223 Investigating the Role of Neurodevelopmental Factors on Adaptive Function in Autism Spectrum Disorder

K. Niroomand¹, M. M. Vandewouw², D. A. Baribeau³, B. Trost⁴, J. P. Lerch⁵, E. Anagnostou⁶ and A. Kushki¹, (1)Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (2)Bloorview Research Institute, Autism Research Centre, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (3)University of Toronto, Toronto, ON, Canada, (4)sickkids, Toronto, ON, Canada, (5)Wellcome Centre for Integrative Neuroimaging, University of Oxford, Oxford, ON, United Kingdom, (6)Bloorview Research Institute, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada

Background: Neurodevelopmental conditions, including autism, are heterogeneous and overlapping disorders that affect more than one million children in Canada. A key determinant of outcomes in these conditions is adaptive functioning, or the ability to independently perform the skills needed to function in daily life (e.g., avoiding danger, managing money, toileting, food handling). Adaptive functioning profoundly impacts long-term outcomes such as academic achievement, employment, independent living, and healthcare use. Adaptive functioning difficulties remain a major barrier to activity participation and achieving positive outcomes. To improve this, there is a critical need to understand the factors that contribute to adaptive functioning to enable the development of timely and targeted supports.

Objectives: This study seeks to examine the association between cognitive, phenotypic, demographic, and genetic factors and adaptive functioning in individuals with autism, using data from the Province of Ontario Neurodevelopmental Disorders (POND) network. The goal is to identify predictors of adaptive function that could guide future personalized approaches to support.

Methods: Data were analyzed from 376 participants, aged 6–21 years, who had a diagnosis of autism (mean age [SD] = 11.04 [3.32] years, 303 males, 73 females). Adaptive functioning was measured using the General Adaptive Composite (GAC) score from the Adaptive Behavior Assessment System-II (ABAS-II). Cognitive abilities were assessed using the full-scale IQ (FSIQ) from the Wechsler scales. Phenotypic measures included social communication skills (Social Communication Questionnaire, SCQ), ADHD symptoms (Strengths and Weaknesses of ADHD Symptoms and Normal Behavior Scale, SWAN), OCD symptoms (Toronto Obsessive-Compulsive Scale, TOCS), and mental health symptoms (Child Behavior Checklist, CBCL). Sociodemographic variables, such as sex and age, were also included. Polygenic scores (PGSs) for 19 different phenotypes—including ADHD, anxiety, autism, and others—were calculated using the SBayesR method, adjusting for genetic ancestry via population principal components. A gradient boosting machine learning model was employed to predict the GAC score from (1) phenotypic, cognitive, and demographic data, and (2) phenotypic, cognitive, demographic, and polygenic scores.

Results: The phenotypic, cognitive, and demographic model achieved a R^2 score of 0.51, a root mean square error (RMSE) of 11.20, and a mean absolute error (MAE) of 8.34. The top three predictive features were FSIQ, SCQ total scores, and SWAN inattentive traits. When PGS features were included, prediction accuracy was maintained ($R^2=0.51$, RMSE=11.19, MAE= 8.24). The same three features remained the most influential, suggesting that PGS scores did not contribute significantly to predicting adaptive functioning with the current sample size.

Conclusions: This proof-of-concept study demonstrates the potential of machine learning to predict adaptive functioning in autism. The results highlight the role of IQ, social communication differences, and inattentive traits in adaptive functioning.

440.225 Item-Level Analyses of M-CHAT-R and ADOS-2: Concordance and Discrepancies between Caregiver and Clinician Observations

A. Constantine¹, S. M. Larsen², K. P. Nowell³, S. M. Kanne² and H. R. Brown², (1)Weill Cornell Medicine, White Plains, NY, (2)Center for Autism and the Developing Brain, Weill Cornell Medicine, White Plains, NY, (3)Health Psychology, Thompson Center for Autism & Neurodevelopmental Disorders, Columbia, MO

Background:

Autism spectrum disorder (ASD) is a childhood neurodevelopmental disorder often diagnosed in toddlers. Early caregiver screening for ASD is often the first step in initiating a diagnostic evaluation. However, caregivers and clinicians may differ on their perception of specific ASD symptoms and studies are mixed on caregiver and clinician agreement (Macari et al., 2018; Sacrey et al., 2018). The symptom domain may matter; caregivers are more likely to identify social deficits compared with repetitive behavior (Goodwin et al., 2019).

Objectives:

To our knowledge, limited research has compared ratings on similar symptoms across commonly used measures for autism screening and diagnosis: the Modified Checklist for Autism in Toddlers-Revised (M-CHAT-R; Robins et al., 2009) and the Autism Diagnostic Observation Schedule, Second Edition (ADOS-2; Lord et al., 2012). The present study compares item-level scores on these measures to identify differences in caregiver and clinician observation of autistic symptoms.

Methods:

Data collection is ongoing. Participants included 51 children aged 12-30 months ($M = 23.20$ months, $SD = 5.22$) who underwent diagnostic evaluation for autism (33 boys, 17 girls, 1 missing). Prior to the diagnostic assessment, caregivers completed the M-CHAT-R. Clinicians administered the ADOS-2 during the evaluation. Similar items across measures were chosen by 2-3 examiners familiar with both the M-CHAT-R and ADOS-2 by examining language used in each tool, focusing on key phrases such as "unusual movements," and "response to name" to highlight overlap. Independent chi-square analyses were conducted to explore the relationships between similar items on the M-CHAT-R and ADOS-2 item-level scores (converted to binary to align with the M-CHAT-R).

Results:

Across all analyses, parents and clinicians generally agreed when a skill was considered typical. However, discrepancies emerged in the identification of atypical skills. For pretend play, a statistically significant number of discrepancies were found when parents did not report this skill as atypical on the M-CHAT-R, while clinicians identified it as atypical during the ADOS-2 ($\chi^2(1) = 5.68$, $p = .017$). A similar pattern was observed for pointing, with a statistically significant number of discrepancies for requesting ($\chi^2(1) = 5.63$, $p = .018$) and for social pointing ($\chi^2(1) = 8.59$, $p = .003$). For ratings regarding showing, (i.e., holding up objects to orient towards others), clinicians identified significantly more cases as atypical compared to parents ($\chi^2(1) = 9.89$, $p = .002$). Several other comparisons (e.g., Complex Mannerisms, Response to Name, Eye Contact) did not reveal any significant discrepancies ($p > 0.05$).

Conclusions:

Preliminary findings suggest that parents may report fewer autistic symptoms on the M-CHAT-R than clinicians observe on the ADOS-2. Caregivers may be under-reporting certain symptoms, leading to fewer referrals and raising concerns about potential under-diagnosis in the broader population. Conversely, caregivers are considering a broader sample of behavior than the single ADOS-2 session. Results underscore the importance of combining caregiver and clinician impressions, as well as clinically interpreting specific parent reporting, in making a diagnosis. Future studies should explore the impact of caregiver psycho-education on autistic symptoms before screening to enhance the accuracy of assessing each child's developmental profile.

440.226 Kinematic Predictors of Handwriting Speed: A Comparative Study of Children and Adolescents with and without ASD

C. Orefice¹, R. Cardillo^{2,3} and I. C. Mammarella², (1)Department of Developmental and Social Psychology, University of Padova - DPSS, Padova, Italy, (2)Department of Developmental and Social Psychology, University of Padova, Padova, Italy, (3)Department of Women's and Children's Health, University of Padua, Padova, Italy

Background: Handwriting, the mechanical process of producing written letters (Medwell & Wary, 2010), is reported as impaired in children and adolescents with Autism Spectrum Disorder (ASD), particularly concerning legibility and speed (Finnegan & Accardo, 2018). Digital handwriting assessment provides new opportunities to investigate its features, beyond traditional metrics.

Objectives: This study aims to enhance the understanding of handwriting features in individuals with ASD without intellectual disability, compared to non-diagnosed (ND) peers, specifically exploring kinematic predictors that could influence handwriting speed.

Methods: A total of 174 participants (ASD=58 [45M]; ND=116 [85M]), aged 8-16 years, were included. The groups were matched by age, FSIQ, and biological sex distribution. Participants completed a tablet-based handwriting task, requiring them to write a given sentence under two conditions: maximum accuracy and maximum speed. Total completion time (CT), and kinematic measures (distance covered, pressure on the surface, writing/total time ratio, and inclination angle of the pen tip) were recorded. Regression models were run.

Results: The association between CT, as the dependent variable, and handwriting kinematics was analyzed for both the accurate and fast conditions. In the first model, considering the accurate condition, the predictors accounted for 35% of the variance, $F(11,162)=9.46$, $p<.001$. A significant main effect for pen tip inclination angle [$\beta=-0.26$, $t=-2.16$, $p=.032$] emerged. Moreover, the interaction between group and distance covered [$\beta=0.40$, $t=3.25$, $p=.001$] indicated an association between lower CT and greater dimensions of the handwritten product for the ASD group. The interactive effect between group and surface pressure [$\beta=-0.93$, $t=-3.49$, $p<.001$], indicated that higher pressure was associated to higher CT, limited to the ASD group. In the second model, considering the fast condition, predictors accounted for 37% of the variance, $F[11,162]=10.13$, $p<.001$. A significant main effect of group [$\beta=1.31$, $t=2.22$, $p=.028$] emerged. An interaction between group and distance covered [$\beta=0.50$, $t=4.40$, $p<.001$] was observed, with the ASD group linking lower CT to larger handwritten dimensions. Lastly, an interaction effect between group and writing/total time ratio [$\beta=-0.97$, $t=-2.91$, $p=.004$] indicated that, limited to the ND group, lower CT was associated with a greater proportion of time spent writing. Such association has not been observed for the ASD group, resulting in a substantial independence between CT and writing/total time ratio.

Conclusions: Our findings on the association between distance covered and CT suggest that, in ASD, a larger writing pattern may be more functional in both the considered conditions. In the accurate condition, the association between heightened pressure on the surface and increased CT may reflect broader motor impairments, resulting in muscle tension. As concerns the fast condition, contrary to what has been observed for the ND group, the lack of an association between writing/total time ratio and CT might be attributed to either low processing speed or motor speed in the ASD group. Overall, our results underscore the importance of comprehensively addressing handwriting during assessments and intervention planning, given its critical role in academic success.

440.227 Lost in Translation? Assessing Quality and Readability of Autism Diagnostic Reports for Spanish-Speaking Families

C. H. Stoute^{1,2}, **O. K. Wilson**^{1,2}, **J. Yang**^{1,2}, **M. Keller**^{1,2}, **S. Chung**^{1,2}, **J. Howard**^{1,2}, **R. E. Aiello**^{1,2}, **L. Driggers-Jones**^{1,2}, **B. Eichner**³, **L. Franz**^{1,2,4}, **J. Green**^{1,2}, **G. Sapiro**⁵, **S. Sipe**^{1,2}, **M. Spanos**^{1,2}, **S. Vermeer**^{1,2} and **G. Dawson**^{1,6}, (1)Duke Center for Autism and Brain Development, Duke University, Durham, NC, (2)Department of Psychiatry and Behavioral Sciences, Duke University Medical Center, Durham, NC, (3)Department of Pediatrics, Duke University, Durham, NC, (4)Duke Global Health Institute, Duke University, Durham, NC, (5)Department of Electrical and Computer Engineering, Duke University, Durham, NC, (6)Department of Psychiatry and Behavioral Sciences, Duke University, Durham, NC

Background: Autism diagnostic reports often use complex and technical language that can be hard for caregivers to understand, especially for Spanish-speaking families with limited English proficiency (LEP). Cultural and linguistic barriers in Hispanic/Latiné communities can lead to under-diagnosis and delayed intervention, which is costly and increases health inequities. High-quality translations and readable reports can help families make informed decisions and access services, thereby improving outcomes for autistic children in under-resourced and minoritized communities.

Objectives: (1) Conduct a descriptive analysis of common words/phrases in autism diagnostic reports translated from English to Spanish received in the context of a research study (focusing on translation challenges). (2) Assess and compare readability of reports against the highest educational level reported by Spanish-speaking caregivers of toddlers receiving an autism diagnostic evaluation.

Methods: Reviewers analyzed 10 English-Spanish diagnostic report pairs to identify complex translations, ensuring a variety of cases, clinician authors, and translators. Phrases were reviewed by study team translators to compile common/complex examples (Table1). A readability analysis was performed on 20 diagnostic reports (10 previous and 10 additional, randomly selected), with both English and Spanish versions analyzed (40 analyses total). The Fry Readability Graph, validated for both languages, was used to determine and compare grade levels (education level required to read and understand a piece of text; see Table2). This method involved selecting three random 100-word passages from each report and calculating readability based on sentence and syllable counts.

Results: We generated a list of English words/phrases in diagnostic reports, emphasizing those that either have no Spanish equivalent, could be misconstrued through literal translation, or have nuanced meanings that may be challenging to translate (Table1). By evaluating strategies used to develop high-quality translations of autism diagnostic reports, we distilled key recommendations from our pragmatic process that translators can employ to improve quality and understanding. Strategies identified (used within a pragmatic Spanish Translations and Interpreter Training Program developed within our research center) help to promote accuracy, address cultural and linguistic barriers, and make translation procedures more efficient. English reports were, on average, less readable than Spanish reports (Table2), suggesting that translation practices incorporate methods that make written material more comprehensible for Spanish-speaking families. Sixty percent of Spanish reports (and twenty percent of English reports) were within the caregiver's highest level of education, emphasizing the need to provide additional support beyond the diagnostic report to ensure caregivers understand the results of their child's evaluation.

Conclusions: Translations that fail to consider the nuanced meaning of language in clinical reports can easily lead to misunderstanding and inappropriate or offensive language, all of which impede comprehension and exacerbate challenges experienced by Spanish-speaking families with LEP. Pragmatic translation training, autism education for translators, and promoting clinician-translator communication, can help enhance the quality of translations in clinical and research contexts, while improving cultural sensitivity and readability. Findings highlight the importance of providing support for caregivers to understand diagnostic reports beyond written communication, in addition to resource sharing, especially when serving socio-economically and linguistically diverse families of children receiving a first-time diagnosis.

**440.228** Maximizing Accurate Detection of Divergence from Normative Expectation in Behavioral Intervention Outcome Assessment

S. Wohlwend¹, **C. Akouri**¹, **C. Schuppel**¹, **M. Uljarevic**² and **T. W. Frazier**³, (1)John Carroll University, Cleveland, OH, (2)Psychiatry & Behavioural Sciences, Stanford University, Palo Alto, CA, (3)Psychology, John Carroll University, Cleveland, OH

Background: Current norm-referenced measures that assess behavioral intervention outcomes for autism spectrum disorder (ASD) often utilize outdated methods for comparing client scores to neurotypical reference populations. Continuous norming methods account for multiple demographic factors without significantly increasing the sample size, including standard linear, polynomial, and generalized additive models (GAMS). The Neurobehavioral Evaluation Tool (NET) was developed as a comprehensive assessment platform specifically designed for intervention outcome assessments. The third revision of the NET (NET V3.0) was developed to improve outcome assessment for ASD, including optimizing norming.

Objectives: The primary aim was to compare five continuous norming approaches to develop demographically-adjusted (age and sex) normative information and to accurately detect divergence from neurotypical expectation across a range of 12 neurobehavioral domains (55 subdomains) from the NET V3.0 informant-report survey scales.

Methods: NET V3.0 parent/caregiver informants were recruited through an online survey collection platform and provided data for one child or adult participant (N=918). NET V3.0 measures featured 6 symptom and 5 skill domains. Informants also provided demographic and clinical information. Clinical diagnoses were categorized into neurotypical, autism spectrum disorder (ASD), and other developmental disorders (DD). Five norming models were compared across all NET V3.0 measures: standard linear regression models (LM), quadratic polynomial models (QM), cubic polynomial models (CM), GAMS models, and GAMS models that added an interaction between age and sex (GAMSint). Analyses examined sample characterization and evaluated and compared norming methods, including bivariate correlations among demographically-adjusted scores, differences in extreme classifications, and divergence from the normative expectation.

Results: A majority of the 918 participants (Ages 2-80, 50.8% male) were reported to have no clinical diagnosis (NT n=536, 58.4%) and a minority reported a non-ASD DD (n=291, 31.7%) or ASD (n=91, 9.9%) diagnosis. Across most measures, but particularly for skills measures, GAMS models (GAMS or GAMSint) had optimal model fit. Consistent with this, in neurotypical individuals, most NET V3.0 measures showed complex non-linear age trends, including sex-specific non-linear patterns. Several low ICCs were observed between model scores across NET V3.0 measures and meaningful differences in extreme classifications were also observed across norming methods. For the CM, GAMS, and GAMSint, no statistically significant differences in proportion of scores that deviated from the normative expectation were identified, highlighting the importance of selecting models that capture complex non-linear trends.

Conclusions: The present results suggest that outcome measures, such as the NET V3.0 informant-report scales, would benefit from using GAMS models as norming methods. These models provide optimal fit to complex developmental trends and, when needed, can fit trends separately in males and females. Future research should examine and compare norming methods using both legacy and other new assessment instruments to accurately model the neurotypical score distribution and provide highly accurate demographically-adjusted scores. Accurate norming methods are crucial to clinical decision-making and an important feature in maximizing the value of interventions for ASD.

440.229 Measuring Changes in Social Communicative Behaviors of Verbal Adolescents and Adults

K. Byrne¹, E. B. Clarke² and C. Lord³, (1)UCLA Semel Institute for Neuroscience & Human Behavior, Los Angeles, CA, (2)Graduate School of Applied and Professional Psychology, Rutgers University - New Brunswick, Piscataway, NJ, (3)UCLA Semel Institute for Neuroscience and Human Behavior, Los Angeles, CA

Background: Verbal autistic adolescents and adults are often engaged in interventions which target social communicative behaviors necessary to developing and maintaining relationships and vocational placements. The field of ASD intervention research faces a number of significant limitations in its current practices of measuring intervention effectiveness. There is a critical need for the development of outcome measures that adequately and reliably detect changes in the social communicative behaviors of autistic individuals, especially in a short period of time. The Brief Observation of Social Communication Change (BOSCC) has been validated with minimally verbal children (called the BOSCC-MV), young verbally fluent children and individuals of any age who speak in phrases (called the BOSCC-PSYF) but has not yet been validated for use with verbal adolescents and adults.

Objectives: The aim of the present study is to determine the utility of the BOSCC-F1/F2 as an outcome measure of treatment response. The BOSCC-F1 is suitable for early adolescents up to age 11 and the BOSCC-F2 is suitable for adolescents and adults ages 11 and older. This study will analyze the factor structure, examine the initial psychometric properties, including inter-rater and test-retest reliability, and provide evidence of the BOSCCs utility as a measure of change by examining changes in scores over time in autistic individuals receiving behavioral interventions.

Methods: The present study applied the BOSCC-F1/F2 coding scheme to 290 video administrations over 115 participants diagnosed with ASD. The BOSCC-F1 was administered with 49 participants and the BOSCC-F2 was administered with 66 participants. Participants included individuals aged 8 years and older who speak in fluent, complex sentences. The factor structure was determined using exploratory structural equation modeling. Next, growth curve models were used to analyze changes over time in the full sample across domains totals. Test-retest and inter-rater reliability were also examined by assessing absolute agreement using two-way random effects models.

Results: Exploratory structural equation modeling revealed a three-factor structure comprised of the following domains: Early communication, social reciprocity/advanced language, and restricted and repetitive behavior (RRB). Inter-rater reliability was excellent for the early communication and social reciprocity/language domains (ICC = .865 and .866, respectively) and good for the RRB domain (ICC = .676). Test-retest reliability was excellent for the early communication and social reciprocity/language domains (ICC = .858 and .887, respectively) and fair for the RRB domain (ICC = .471). However, results indicated no statistically significant changes on any domains.

Conclusions: While the BOSCC has been validated as a standardized, flexible, and minimally biased assessment of social communication changes in response to treatment in younger and less verbal children, and although the BOSCC-F1/F2 is psychometrically sound, the BOSCC-F1/F2 did not pick up on change in response to 16-week behavioral interventions. More research is needed to elucidate what kinds and what amounts of change should be expected in verbally fluent adolescents and adults in response to behavioral interventions. More research is also needed to understand whether treatment modality (i.e., behavioral vs pharmaceutical) influences changes in social communication for autistic adolescents and adults.

440.230 Misdiagnosis or Missed Diagnosis? a Deep Neural Network Machine Learning Approach for Early Detection of Undiagnosed Autism Spectrum Disorder

M. Voit¹, O. Vsevolozhskaya², W. T. Turner¹, J. Lyons¹, X. Tong³ and M. R. Altschuler¹, (1)Center for Innovation in Population Health, University of Kentucky, Lexington, KY, (2)Biostatistics, University of Kentucky, Lexington, KY, (3)Center for Innovation in Population Health, Department of Health Management and Policy, and Department of Psychology, University of Kentucky, Lexington, KY

Background:

Diagnosis of children with autism spectrum disorder (ASD), when delayed or left undetected, has been found to lead to poor long-term functional outcomes and quality of life across development. Moreover, complex cases of ASD, such as children with dangerous behaviors or psychiatric comorbidities, may prevent detection within health care systems, leading to potential misdiagnosis. Children in public behavioral health systems across all 50 states receive the Child and Adolescent Needs and Strengths (CANS), a person-centered assessment that provides a unique opportunity for identifying potential signs of ASD. Because early diagnosis of ASD and early intervention is associated with better developmental outcomes, it is important to minimize the delay between initial indicators and diagnosis. Enhancing the capacity of public behavioral health systems to proactively recognize youth in care who may benefit from referral to diagnostic services through the CANS person-centered assessment and deep neural networks, has not yet been investigated.

Objectives:

To (1) validate a person-centered machine learning (ML) approach using a deep neural network model (DNN) to identify potential traits of undiagnosed ASD in public behavioral health systems, and to (2) to characterize the needs and strengths of youth at risk for developing ASD.

Methods:

Children ($N = 40,441$) aged 1-21 years-old served by a large state behavioral health system ($n=3,741$ with preexisting DSM-5 ASD diagnosis) were evaluated every 6-months with the Child Adolescent Needs and Strength Assessment (CANS) and asked their existing DSM-5 diagnoses between 2014-2023. 1,060 youth received at least one CANS prior to ASD diagnosis. For children whose penultimate CANS before diagnosis was less than 18 months prior to their diagnosis ($n=981$), a trained DNN ML model was conducted. Then the DNN model was validated on testing controls from the other half of undiagnosed CANS and upon testing cases which used only CANS from youth who entered care with an existing diagnosis ($n=2,681$), who were excluded from the training the DNN. After DNN model validation, calculating sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV), the model was applied to all CANS for non-diagnosis ASD youth to predict likelihood of undiagnosed ASD from 0 to 1.

Results:

A predicted probability greater than or equal to 0.75 was selected, such that the PPV for the final model was 0.33, or 1 in 3 of youth recommended for diagnostic referral ($n=4,331$; 11%) were predicted for diagnostic referral. CANS items such as developmental functioning, social functioning, emotional disturbance, emotional regulation, self-harm, intentional misbehavior, oppositional behavior were elevated in both predicted and diagnosed children (Figure 1).

Conclusions:

Results yielded a high PPV for undiagnosed ASD diagnosis in youth in public behavioral health care settings using a CANS-based person-centered ML approach. We showed a sliding scale of predicted probabilities of undiagnosed ASD using routine assessment information to recognize early referral opportunities, with a sliding probability cutoff that can be adjusted to suit pragmatic decision support needs. Routine person-centered assessment information shows the potential to recognize early referral opportunities and improve long-term developmental outcomes.

440.231 Oral Microbiota Profiling for Diagnosis and Therapeutics of Autism Spectrum Disorder

A. Anamika, Department of Pharmaceutical Sciences, UPES, Dehradun, Uttarakhand, India

Background: Autism Spectrum Disorder (ASD) is a complex neurodevelopmental condition characterised by deficits in social communication, restricted interests, and repetitive behaviours. Despite the increasing global prevalence of ASD, its underlying mechanisms remain poorly understood, and no definitive biological markers have been identified. Diagnosis primarily relies on behavioural assessments, often leading to delayed intervention. While extensive research has been conducted on the gut microbiota's role in ASD, there is a significant lack of microbiota data, particularly within the Indian population.

Objectives: This study aims to explore the potential contribution of oral microbiota to ASD through its impact on the gut-brain axis, a growing area of interest in ASD research. By profiling microbial differences in oral samples from individuals with ASD and neurotypical controls, the study seeks to identify microbial signatures that could serve as early, non-invasive diagnostic markers.

Methods:

A systematic literature review was conducted following the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines, identifying key bacterial species potentially associated with ASD. These species were evaluated and ranked based on their relevance, data quality, and prevalence across studies. To further validate these findings, saliva samples from ASD individuals and neurotypical controls ($n=30$) are being collected. These samples will also support future gene expression studies, aiming to confirm observed microbial differences in line with the literature.

Results:

Analysis revealed 20 bacterial species significantly more abundant in individuals diagnosed with ASD. The most prominent genera included *Clostridium*, *Bacteroides fragilis*, and *Prevotella*, underscoring the diversity of microbial communities associated with ASD. The findings reinforce the hypothesis that these species may influence neurodevelopment through the gut-brain axis. Of particular interest is the role of microbial metabolites in triggering neuroinflammatory responses and behavioral changes, offering new insights into ASD pathophysiology.

Conclusions:

This study establishes a potential link between oral microbiota and ASD, providing a foundation for developing microbiota-based diagnostic tools. Such tools could enable early, non-invasive detection of ASD, especially in regions with limited microbiota data, like India.

440.232 Parental Experiences of Different Preschool Autism Spectrum Disorder Diagnostic Assessments between 2017 and 2022 from a Single Center

M. Thomas¹, **A. Brandt**² and **J. Christiani**³, (1)Dalhousie University / IWK Health, Halifax, NS, Canada, (2)McGill, Montreal, QC, Canada, (3)Nova Scotia Health, Halifax, NS, Canada

Background: Early intervention is regarded as important for optimal outcomes, making timely assessments essential. However, increasing demand for assessments, with referral rates increasing year on year, is leading to unacceptably long wait times in many countries. The Autism Spectrum Disorder (ASD) assessment process itself can substantially influence a family's well-being, with common concerns including uncertainty around processes, wait times, delay in intervention and assessment reliability. Children presenting early, that is less than 36 months of age, can have a clearer diagnostic presentation than those presenting at school age or later. Therefore, a pilot to evaluate whether a single assessment by a single clinician could identify children with or without ASD, and the percentage of children where additional assessments were required to reach a diagnosis was run April 1, 2021 to August 31, 2022. Two hundred and twenty three children were involved in the pilot and data will be shared to provide context to this study. The pilot study was acceptable to the clinicians involved, did not lead to a high frequency of reassessments, and resulted in considerably shorter wait times for families. However, with only informal feedback from families, there was a need for more extensive and comprehensive evaluation from a parental perspective.

Objectives: The aim of this study was to explore parental experiences of the shorter, more timely diagnostic assessment of their preschool child as compared to alternative diagnostic assessments over the previous five years with the objective of informing future assessment processes.

Methods: A retrospective online survey of parents whose preschool aged children underwent an ASD diagnostic assessment between 2017 and 2022 at a single center was conducted. Basic demographics, information about ASD assessment experiences and priorities, and what did and did not work well was collected by a series of Likert scale, forced choice and open-ended questions. Data analysis used descriptive statistics, qualitative analysis of open-ended responses, and triangulation of results to further interpret and understand findings.

Results: Email contact details were available for 327 potential participants and 62 (19%) consented to complete the survey and provided some responses with 36 (11%) completing the whole survey. While overall satisfaction rates were high, there was a wide range of experiences shared and often dichotomous priorities. Nevertheless, a consistent theme for any assessment process to be successful was the need for clear communication before, during and after the diagnostic appointment(s).

Conclusions: Simplifying the assessment process for the youngest children referred reduced wait times without reducing diagnostic clarity or parental satisfaction and confidence. The need for clear communication throughout was a consistent theme and an achievable aim.

440.233 Partnering with Community Providers; Using Information from Primary Care Providers to Best Fit Autism Evaluations Using an Abbreviated Telehealth Assessment Model

E. M. Coan¹, L. Hayutin², A. Angulo³ and D. Swain⁴, (1)Pediatrics, Children's Hospital Colorado, Aurora, CO, (2)University of Colorado Anschutz Medical Campus, Aurora, CO, (3)Childrens Hospital of Colorado, Aurora, CO, (4)Developmental Pediatrics, University of Colorado Childrens Hospital Colorado, Aurora, CO

Background: The rising rates of autism have long exceeded subspecialist capacity for diagnostic services, resulting in the rise of several education and training initiatives to support primary care providers (PCPs) in improved identification and management of autistic youth (Keehn et al., Roberts et al., 2023). The Pediatric Care Network (PCN) is one such initiative, where PCPs are trained to conduct an autism-focused developmental interview (AFDI) that accompanies their referral for subspecialist evaluation. Though over 400 patients have been seen through the PCN pathway, and preliminary survey results indicate improved knowledge, satisfaction and confidence (Coan, et al., 2023) from PCP participants, the PCN clinical team wanted to explore whether the PCP's AFDI might inform a more efficient and "right fit" assessment process. With rising confidence in the use of telehealth for diagnostic assessment (Alfurayden et al., 2020, Liu et al., 2022), PCN subspecialists conducted record reviews to identify patients suspected to be a good fit for an abbreviated telehealth assessment (ATA; 3-4 hours) rather than a standard in-person assessment (6-8 hours). The current study sought to better understand characteristics of patients who can be successfully diagnosed using the ATA model in hopes of creating a more formalized triage process for patients moving forward.

Objectives:

1. Characterize the patients and families referred to the ATA.
2. Identify characteristics of children who completed the evaluation via the ATA model versus those who required additional in-person testing to complete the evaluation.

Methods: Subspecialty clinicians conducted chart-reviews of the PCP's AFDI, and selected patients for expedited access to an ATA. We then analyzed demographic information, diagnostic results and successful completion of the evaluation in the ATA model. Chi-square analyses and independent sample t-tests were run to determine differences across children who successfully completed ATA versus not.

Results: 44 (66% male, 34% female) patients were triaged into ATA slots over a two-year period. Average age seen was 5.4 years (range 1-16). 57% of patients triaged to the ATA pathway successfully completed their evaluation (average time spent 3.36 hours). All patients who completed their evaluation on telehealth received an autism diagnosis. Those who required in-person testing received an autism diagnosis 74% of the time (average time spent 6.79 hours). Chi-square analyses indicated a statistically significant association between successful completion of the ATA and the following variables: a resulting diagnosis of autism, previous identification of autism through school or community provider, and having an immediate family member with an autism diagnosis. Further, Independent sample t-test revealed significant difference between groups regarding age, such that children who successfully completed the ATA were significantly younger (Mage= 4.2 years) compared to those requiring in-person testing (Mage=6.95 years).

Conclusions: The current study suggests that information gathered from trained PCPs may be useful in right-fitting evaluations to improve efficiency. Promising indicators that may inform successful triage to an ATA include a previous autism diagnosis from school or community, an immediate family member with autism, and younger patient age. Future projects will incorporate these findings into a more formalized triage process for patients awaiting evaluation.

440.234 Predicting ADOS-2 Autism Severity Levels By Machine Learning Models

Q. Zhang¹, C. Shu¹, K. Street¹ and L. Green Snyder², (1)Department of Population and Public Health Sciences, University of Southern California, Los Angeles, CA, (2)Simons Foundation, New York, NY

Background:

The Calibrated Severity Scores [CSS; also known as Comparison Score (CS)] in the Autism Diagnostic Observation Schedule, Second Edition (ADOS-2), provide a standardized measure of autism symptom severity and allow for comparison across different age groups and language abilities. However, in large-scale autism cohorts, it is often not feasible to collect in-person ADOS-2 assessments, as compared to common parent-reported surveys, such as the Social Communication Questionnaire (SCQ).

Objectives:

This study aims to predict autism severity as measured by the ADOS-2 CSS using machine learning models and leveraging data from SPARK (Simons Powering Autism Research for Knowledge), a large-scale autism cohort with comprehensive behavioral and medical data.

Methods:

The data for this study were drawn from version 10 of the SPARK phenotype database, updated in July 2023, which contains phenotypic information for 328,973 autistic individuals and their family members, of whom 1,178 individuals aged 1 to 18 years with complete ADOS-2 CSS data were retained for analysis. Four modules of the ADOS were included: Toddler, 1, 2 and 3, which correspond to age and language level, respectively. Autism severity is classified based on ADOS-2 CSS, with CSS 1-5 categorized as little-to-moderate and CSS 6-10 as moderate-to-severe. 276 predictor variables from demographic, medical history, and behavior surveys [SCQ, Repetitive Behavior Scale-Revised (RBS-R) and Developmental Coordination Disorder Questionnaire (DCDQ)] were pre-processed by creating dummy variables, normalizing them to a mean of 0 and a standard deviation of 1, and removing near-zero-variance predictors. The complete dataset was then split into training (70%), validation (15%), and test (15%) sets using stratified sampling. To address class imbalance, the ROSE (Random Over-Sampling Examples) technique was applied to balance the two classes to a 1:1 ratio. Logistic regression was used to evaluate relationships between key variables and autism severity. Several machine learning models were applied, including Linear Discriminant Analysis (LDA), Elastic Net Regression, Support Vector Machine (SVM), and K-Nearest Neighbors (KNN). Model performance was assessed using metrics such as area under curve (AUC), balanced accuracy, and kappa.

Results:

Logistic regression results showed a borderline significant association between ADOS-2 module level (Toddler, 1, 2 or 3) and ADOS-2 CSS, with a p-value slightly greater than 0.05 (Table 1). Among the machine learning models evaluated, Elastic Net Regression and SVM exhibited the strongest predictive performance for ADOS-2 severity levels with AUC values of 0.756 and 0.767 respectively on the validation set (Figure 1). Elastic Net Regression achieved a balanced accuracy of 0.686, indicating moderate classification performance across the ADOS-2 severity spectrum, while SVM demonstrated comparable performance with a balanced accuracy of 0.627. In contrast, KNN and LDA demonstrated suboptimal performance, showing lower AUC and accuracy scores on both the validation and test sets.

Conclusions:

Our findings suggest that ADOS-2 severity levels can be successfully predicted from commonly used parent questionnaires. Elastic Net Regression and SVM are the most effective models for prediction. ADOS module level and relatedly language level, may have some impact on autism severity.

440.235 Professionals' Experiences of Using the Autism Clinical Interview for Adults (ACIA) in Diagnostic Practice

J. R. Parr¹, S. Wigham², B. Ingham³, J. Goodwin⁴ and A. LeCouteur¹, (1)Population Health Sciences Institute, Newcastle University, Newcastle upon Tyne, United Kingdom, (2)Population Health Sciences Institute, Newcastle University, Newcastle upon Tyne, UNITED KINGDOM, (3)Cumbria, Northumberland, Tyne & Wear NHS FT, Newcastle upon Tyne, Tyne and Wear, (4)Other, Newcastle Upon Tyne, United Kingdom

Background:

Identification of autism in adults continues to be an important priority. We developed a new diagnostic interview for use in the assessment of adults with possible autism: the Autism Clinical Interview for Adults (ACIA). The ACIA includes a pre-interview questionnaire (PIQ) and both subject (ACIA-S) and informant (ACIA-I) interview versions. The acceptability for adults attending assessments, and initial utility of the ACIA have been reported. ACIA training for professionals commenced in 2021 and over 1000 people have been trained.

Objectives:

This study aimed to investigate the views of practitioners trained in the ACIA, about (i) their use of ACIA since training, and (ii) the clinical utility of the interview.

Methods:

A bespoke questionnaire was developed, with closed and open-text questions, to explore participants' experiences of the ACIA (training, utility, and implementation). 1092 practitioners were contacted by email. Descriptive statistics and chi-square tests were used to examine quantitative data, and thematic analysis for open text responses.

Results:

330/1092 (30.2%) practitioners responded. 48% of respondents' main employment was in a publicly funded service (e.g., the UK National Health Service); 52% of respondents were employed in privately provided services. The PIQ was used less frequently than expected (47%). 70% of responders had used the ACIA (90% the subject version; 69% the informant version). Responders had completed a mean of nine assessments and had diagnosed a mean of four autistic people using the ACIA. 167 (61%) had formally or informally incorporated the ACIA into their diagnostic service. The ACIA was considered useful for identifying autism spectrum characteristics (99%), and co-occurring conditions (73%); providing information to feedback following assessment (92%); and providing information for writing reports (89%). Most participants (89%) thought people having the autism assessment found the ACIA acceptable and useful. Both publicly funded and private providers found the ACIA training useful. Following training, practitioners in private diagnostic services reported significantly more improvement in skills ($p < 0.001$) and confidence ($p < 0.001$) in assessing possible autism in adults, and being better equipped to support adults under their care ($p < 0.001$) compared to practitioners from publicly funded diagnostic services. 119 (36%) responders will participate in future research to investigate the ACIA psychometric properties. Thematic analysis revealed four themes: 1) Natural flow, "very thorough and comprehensive assessment that has a good natural flow through it"; 2) Rich information, "by the end of the assessment I feel confident that I know the person well"; 3) Affirming for the person being assessed, "allows clients to understand their characteristics of autism and validate them"; and 4) Improved practitioner confidence, "I have improved confidence of interpreting the information and allowing a conversation to occur".

Conclusions:

Evaluation of ACIA use and utility shows most responders use the ACIA, and that the interview facilitates the assessment of autism in adulthood. In the future we will evaluate the psychometric properties of the ACIA interviews, including the range of ACIA scores associated with a clinical autism diagnosis.

440.236 Profiles of Verbal Pre-School Children Completing Autism Tele-Assessment Using the TAP-P

M. Honaker^{1,2}, L. Corona^{2,3}, L. Wagner¹, A. Munoz Lavanderos⁵, T. E. Foster^{2,3}, C. Stone^{2,3}, A. Swanson^{2,6}, A. Vehorn^{2,3}, A. S. Weitlauf^{6,3} and Z. Warren^{2,3}, (1)Vanderbilt University, Nashville, TN, (2)Vanderbilt Kennedy Center, Nashville, TN, (3)Vanderbilt University Medical Center - Treatment and Research Institute for Autism Spectrum Disorder, Nashville, TN, (4)University of Wisconsin-Madison, Madison, WI, (5)University of Oregon, Eugene, OR, (6)Vanderbilt University Medical Center, Nashville, TN

Background: Though early identification of autism is a consistent priority for the field, wait lists for evaluation often increase as children enter pre-school. Telemedicine is increasingly used as an alternate path for autism diagnostic evaluation, with research documenting strong acceptability, family satisfaction, and diagnostic concordance with in-person assessment for the toddler age group. However, few tools to date have been designed and studied specifically for use with preschoolers, who may present with a wide range of verbal and social communication skills. The present data are drawn from a study of the TELE-ASD-PEDS-Preschool (TAP-P), a tele-assessment tool designed for use with children between 36-72 months of age. The TAP-P uses distinct administration and scoring procedures depending on a child's language level (TAP-P Verbal, TAP-P Nonverbal).

Objectives: To examine profiles of children assessed using the TAP-P Verbal version, including tele- and in-person assessment scores, as well as clinician diagnostic certainty and concordance with in-person assessment.

Methods: Sixty-two children participating in this study completed the TAP-P Verbal version (72% male, 26% female; mean age = 51.1 months, $SD = 9.8$, range = 36-71 months). All children received two evaluations during their study participation: an initial visit conducted via telehealth and a second visit completed in-person, by a clinician unaware of tele-assessment outcomes. The telehealth evaluation involved administration of the TAP-P, a clinical interview, and the Developmental Profile 4. The in-person assessment included administration of the Differential Ability Scales-II, Vineland-3, and Autism Diagnostic Observation Schedule, Second Edition. Clinicians documented diagnostic impressions after each appointment.

Results: Following tele-assessment, clinicians indicated the presence of autism for 32% of participants, the absence of autism for 16%, and indicated "unsure" in 52% of cases. Diagnostic concordance with in-person assessment was 90% for cases in which tele-assessment clinicians documented presence or absence of autism ($n=3$ participants identified as "autism absent" on tele-assessment were diagnosed with autism following in-person assessment). Table 1 displays mean scores for tele- and in-person assessments for each group. Tele-assessment clinicians were also asked to identify interview questions that enhanced diagnostic certainty. Within 36 independent responses, the most frequently referenced themes were: rigidity related to routines ($n=13$), sensory differences ($n=11$), peer relationships ($n=10$), early development ($n=7$), play ($n=6$), and general social skills ($n=6$).

Conclusions: This work documents initial use of the TAP-P within a sample of preschool-aged children, demonstrating that a subset of children can be reliably and confidently identified as having autism using these procedures. Clinicians reported less certainty about diagnostic decision-making via telehealth for children with fewer clear autism-related behaviors, but highlighted specific areas in which caregiver information was particularly helpful. Future work will continue to hone and refine tele-assessment procedures, with the dual goals of (1) optimizing both clinical observations and information requested via caregiver report to enhance diagnostic ascertainment and (2) identifying profiles of children and families that can assist with triaging families toward tele-assessment vs. in-person assessment for initial evaluations.

440.237 Psychometric Characteristics of the Aaspire Autistic Burnout Scale-Revised

C. Nicolaidis^{1,2,3}, D. M. Raymaker^{1,2}, L. Q. Yang^{2,4}, N. Kaufman^{1,2}, M. Uretsky¹, A. Joyce², J. Maslak², A. Wallington² and E. Frowner², (1)School of Social Work, Portland State University, Portland, OR, (2)Academic Autism Spectrum Partnership in Research and Education (AASPIRE), Portland, OR, (3)Department of Medicine, Oregon Health & Science University, Portland, OR, (4)Psychology, Portland State University, Portland, OR

Background: While the autistic community has long emphasized the importance of autistic burnout, research on the topic remains scant. Psychometrically sound instruments are needed to diagnose autistic burnout and assess the effectiveness of interventions to prevent or treat it. Previous studies have shown promising preliminary results for the psychometric properties of the original 27-item AASPIRE Autistic Burnout Scale (Mantzas 2024). However, such studies included limited populations. Community members also raised concerns about the scale's accessibility and length.

Objectives: To use a community-based participatory research approach to:

- Revise the original AASPIRE Autistic Burnout Scale (AABS-27).
- To evaluate the reliability and validity of the AABS-revised (AABS-R14) in a diverse sample of autistic adults.

Methods: We collaboratively revised the AABS-27 to increase accessibility, reduce the number of items, and create separate self-report and caregiver-report (CR) versions. We then conducted cognitive interviews with 37 autistic adults and caregivers to assess content validity and iteratively made additional small refinements based on feedback. We used the AABS-R14 in a longitudinal study of autistic adults recruited from healthcare systems, disability services, and the community. This analysis includes baseline data from 865 participants, 600 who participated directly independently (DR), 199 with support (DR-S), and 66 via caregiver report (CR). To assess structural validity, we randomly split the sample into two halves and conducted independent exploratory (EFA) and confirmatory factor analyses (CFA). We used Cronbach's α to measure internal consistency; a priori hypothesis testing to assess construct validity (looking for expected correlations between the AABS-R14 and other wellbeing indicators); and Receiver Operating Characteristic (ROC) analysis to assess criterion validity (as compared to participants' own assessment as to whether they were currently experiencing autistic burnout.) Primary analyses used the full sample. Secondary analyses excluded participants who participated via caregiver report.

Results: EFA confirmed that the 14 items load onto a single Autistic Burnout factor, with high factor loadings (>0.60) and significant Bartlett's tests ($p < 0.001$). The KMO measure (≥ 0.899) indicated excellent sampling adequacy. CFA showed adequate fit for the DR and DR-support subsamples (RMSEA = 0.10; CFI = 0.93; SRMR = 0.04–0.05), but inadequate fit for the CR sample, likely due to its modest sample size (valid $N = 63$). Cronbach's α was 0.95. As predicted, Autistic burnout was significantly correlated with depression ($r = 0.64$), flourishing ($r = -0.47$), quality of life ($r = -0.45$), overall health ($r = -0.56$), and other well-being indicators (all p -values < 0.001 , Bonferroni-adjusted). ROC analysis showed an accuracy rate of 87.4%. Secondary analyses excluding caregiver reported data did not substantially alter findings.

Conclusions: The direct-report version of the AABS-R14 appears to have strong psychometric properties in a diverse sample of autistic adults recruited from a variety of settings in the US. Additional planned analyses will assess its test-retest reliability and responsiveness to change, as well as factors predicting the development of autistic burnout. Future research is needed to further validate the caregiver report version of the instrument, and assess the effectiveness of interventions to prevent or treat autistic burnout.

**440.239 Psychometric Properties of the Autism Diagnostic Interview-Revised (ADI-R) in Mainland of China**

E. W. Bai^{1,2}, E. A. Lee², B. Afsharnejad³, H. Chih⁴, R. Parsons², X. Zou⁵, H. Deng⁶, H. Zhu⁷, S. Bolte⁸ and S. J. Girdler², (1)Child Development and Behavior Center, The Third Affiliated Hospital of Sun Yat-Sen University, Guangzhou, Guangdong, China, (2)School of Allied Health, Curtin University, Bentley, Western Australia, Australia, (3)School of Allied Health, School of Allied Health, Curtin University, Bentley, Western Australia, Australia, (4)School of Population Health, Curtin University, Bentley, Western Australia, Australia, (5)The Third Affiliated Hospital, Sun Yat-Sen University, Guangzhou, Guangdong, China, (6)Third Hospital of SUN YAT-SEN University, GuangZhou, Guangdong, China, (7)Child Development and Behavior Center, The Third Affiliated Hospital, Sun Yat-Sen University, Guangzhou, Guangdong, China, (8)Center for Neurodevelopmental Disorders at Karolinska Institutet (KIND), Department of Women's and Children's Health, Karolinska Institutet, Stockholm, Sweden

Background: The Autism Diagnostic Interview-Revised (ADI-R) is a parent-proxy instrument widely used to assist autism diagnosis for individuals 18 months and above (Lord et al., 1994). The ADI-R has been adapted to different language versions, including Chinese which was approved by the Western Psychological Services (WPS) in 2007 (Huang et al., 2022). However, little is known about the psychometric properties of the ADI-R Chinese version administered in a Chinese mainland population. Participants of this study are drawn from a large clinical sample from a nationally recognized developmental-behavioural centre for neurodevelopmental disorders in southern China.

Objectives: The objective of this study is to evaluate the psychometric properties of the ADI-R in mainland of China, specifically looking at internal consistency reliability, diagnostic validity, and convergent validity.

Methods: This study is part of a large retrospective record review of individuals who visited the centre's outpatient's clinic between January of 2018 to August of 2021. Participants (N=2666, 84% males & 16% females) used in this study were clinically diagnosed with a neurodevelopmental disorder, including autism. Participants were divided into two groups, the autism group and non-autism group, containing 2224 and 442 individuals respectively. IBM SPSS software was used for data analysis. Cronbach's α coefficient was calculated to evaluate internal consistency reliability for each domain of the ADI-R. Sensitivity and specificity tests, as well as area under the receiver operating characteristic (ROC) curves were calculated to investigate diagnostic validity. Autism diagnosis suggested by the ADI-R thresholds was compared to clinician's diagnosis to assess convergent validity.

Results: Preliminary results suggest good internal consistency reliability and diagnostic validity of the ADI-R administered in a Chinese mainland population. Cronbach's α coefficients were 0.852 for the Reciprocal Social Interaction domain (A), 0.761 for the Nonverbal Communication domain (BNV), 0.715 for the Verbal Communication domain (BV), and 0.392 for the Restricted, Repetitive, and Stereotyped Patterns or Behavior domain (C). The area under the ROC curve was 0.768 (0.743-0.793) for domain A, 0.773 (0.728-0.818) for domain BNV, 0.776 (0.748-0.803) for domain BV, and 0.759 (0.733-0.785) for domain C. The positive predictive value (PPV=0.931) was calculated to compare diagnosis suggested by the ADI-R to clinician's diagnosis of autism.

Conclusions: This study gives insight into the administration of the ADI-R in a large clinical sample in mainland of China in supporting the diagnosis of autism. The ADI-R Chinese version has demonstrated good reliability and validity. Further research is suggested on looking more into the administration of the ADI-R with typically developing individuals and comparing the ADI-R to other diagnostic measures.

440.240 Psychometric Properties of the Chinese Version of World Health Organization's Quality of Life Instrument -Disability Version (WHOQOL-DIS) and Autism Spectrum Quality of Life (ASQoL) in Taiwan: A Preliminary Analysis

T. H. Tseng and C. H. Chiang, Department of Psychology, National Chengchi University, Taipei, Taiwan

Background: Quality of life (QoL) has received increasing attention in recent years, recognized as a complex and multifaceted concept. With the development of the rights and advocacy movement for people with disabilities, alongside a neurodiversity perspective on neurodevelopmental disorders, it is necessary to explore individuals' subjective QoL. Previous studies have employed various tools to assess the QoL of people with disabilities. The World Health Organization's Quality of Life Instrument -Brief Version (WHOQOL-BREF) is one of the most widely used QoL questionnaire in Taiwan. Considering the specific characteristics of individuals with Autism Spectrum Disorder (ASD), using the World Health Organization's Quality of Life Instrument -Disability Version (WHOQOL-DIS) and Autism Spectrum Quality of Life (ASQoL) could provide a more comprehensive understanding of the different aspects and experiences of QoL in this population.

Objectives: The objective of this study is to establish the reliability and validity of the Chinese versions of the WHOQOL-DIS and ASQoL, including the analysis of internal consistency reliability, test-retest reliability, construct validity, and criterion-related validity.

Methods: After completing the forward and backward translation and cultural adaptation of the WHOQOL-DIS and ASQoL, three adults with ASD were invited to provide qualitative feedback on the translation of the items, which were then revised into the final versions of the questionnaires. Participants were individuals with ASD aged 18 and older in Taiwan, who either had official disability certification or a clinical diagnosis. The participants completed the WHOQOL-DIS, ASQoL, Autism Spectrum Quotient (AQ), Short Form-36 Health Survey (SF-36), Satisfaction with Life Scale (SWLS), and Perceived Stress Scale (PSS) primarily through online questionnaires, with paper-based questionnaires available as needed. A follow-up retest of the QoL questionnaires was conducted one month later.

Results: A total of 132 participants were recruited, with an average age of 26.47 years. The internal consistency reliability of the WHOQOL-DIS and ASQoL was 0.85 and 0.75, respectively. The test-retest reliability sample size was 93, with test-retest reliability coefficients of 0.78 and 0.85 for the WHOQOL-DIS and ASQoL, respectively. Based on previous research, the WHOQOL-DIS was expected to consist of three factors:

Discrimination (3 items), Autonomy (3 items), and Inclusion (6 items). The results of confirmatory factor analysis (CFA) indicated a poor model fit (CFI = 0.854, RMSEA = 0.117), though consistent with prior studies. Examining the standardized factor loadings revealed that the loadings for the Advocacy item in the Discrimination dimension were particularly low, which may be attributed to cultural and linguistic differences in the use of the concepts of advocacy and support. Correlation analysis showed that the WHOQOL-DIS and ASQoL were moderately correlated with the SF-36 subscales (vitality, social functioning, mental health), as well as with the SWLS and PSS.

Conclusions: The WHOQOL-DIS and ASQoL demonstrated acceptable internal consistency reliability, test-retest reliability, and criterion-related validity. Regarding construct validity, the results did not meet expectations. In the future, while expanding the sample size, the cultural appropriateness of the item constructs also need to be explored.

440.241 Eye-Tracking Measures As Markers of Treatment Response in Autism Intervention: A Meta-Analysis

C. D. Yoon¹, Y. Xia², A. K. Terol³, H. Meadan⁴ and F. Shic⁵, (1)Waisman Center, UW-Madison, Madison, WI, (2)University of Illinois, Champaign, IL, (3)University of California, Davis - M.I.N.D. Institute, Sacramento, CA, (4)University of North Carolina Charlotte, Charlotte, NC, (5)Center for Child Health, Behavior and Development, Seattle Children's Research Institute, Seattle, WA

Background: There is growing consensus on the relation between eye-tracking measures of gaze behaviors and core autism characteristics. Specifically, recent meta-analyses support a concurrent relation between eye-tracking measures and clinical assessments of social behaviors in autistic individuals (Riddiford et al., 2022; Yoon et al., 2024). The current meta-analysis builds upon that foundation by exploring the efficacy of eye-tracking measures in a longitudinal context, particularly concerning autism interventions.

Objectives: The study has two aims: to (a) estimate the effect size of changes in eye-tracking measures from pre- to post-treatment; and (b) evaluate the moderating influence of the type of treatment received on these changes.

Methods: Following the PRISMA guidelines (Page et al., 2021), we identified 17 articles. For the first aim, we conducted a multivariate random-effects meta-analysis with a multilevel structure to account for clustering within studies. We performed a sensitivity analysis under three assumptions (ρ [r] = .3, .6, and .9) to assess the robustness of the results. Small-study effects were examined using standard error as a predictor in the model and visual inspection of the funnel plot. For the second aim, we conducted meta-regression, excluding the influence of small-study effects.

Results: A total of 143 effect sizes were included in the analyses, covering 551 autistic participants (M_{age} = 3-28 years). The sensitivity analysis for the first aim revealed relatively stable small-to-moderate significant effect sizes across different assumptions (r = .3, Hedge's g = .339, 95% CI [.042, .636], p = .025; r = .6, Hedge's g = .319, 95% CI [.031, .608], p = .030; and r = .9, Hedge's g = .286, 95% CI [.004, .569], p = .047). Based on this stability, we proceeded with a single ρ value (r = .6) for subsequent analyses. The assessment of small-study effects identified several influential effect sizes (k = 6). See attached Figure 1 for funnel plots. After adjusting for influential effect sizes, the overall effect size increased but remained in the small-to-moderate range (Hedge's g = .394, 95% CI [.084, .705], p = .013), suggesting that outliers had dampened the original estimate while validating the overall effect size. Heterogeneity among the included effect sizes was observed (Q = 531.888, p < .001, I^2 = 74.4%). For the second aim, the analysis revealed that the treatment type significantly moderated the overall effect size (Q_m = 8.722, p = .013). Notably, both biomedical (b = .213, 95% CI [.039, .387], p = .017) and technology-based treatments (b = .479, 95% CI [.089, .870], p = .016) showed stronger effect relative to behavioral treatments.

Conclusions: While overall effect sizes were modest, findings indicate that eye-tracking measures exhibit noticeable change across treatment periods. Results also suggest that biomedical or technology-based interventions may be particularly amenable to monitoring through changes in gaze behaviors. This work thus supports the potential for eye tracking as a tool for treatment monitoring.

440.242 Racial Bias in the ADOS: Comparison of Differential Item Functioning and Moderated Nonlinear Factor Analysis Among More Than 4,000 Participants from NDAR and Ssc

A. Wyman¹, Y. Y. Yu², Z. Zhang¹, J. D. Herrington², B. E. Yerys² and C. C. Clements³, (1)Psychology, University of Notre Dame, Notre Dame, IN, (2)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (3)Labs of Cognitive Neuroscience, Boston Children's Hospital Labs of Cognitive Neuroscience, Brookline, MA

Background:

The Autism Diagnostic Observation Schedule (ADOS) is one of the most highly regarded autism evaluations. Unfortunately, multiple studies have demonstrated significant differential item functioning (DIF) for individuals from different racial groups, and the mechanism for racial bias in the ADOS remains unknown because DIF effects are inconsistently replicated across items. Although the ADOS consists of 5 modules and 2 historical versions (ADOS and ADOS-2), studies searching for bias using item response theory-based DIF analyses often compromise statistical power to account for these differences by subdividing their samples. A moderated nonlinear factor analysis (MNLFA) is more appropriate because it allows for the presence of multiple moderators, where there may be multiple sources of bias, and it allows the specification of bias receptors (e.g., item-level, factor-level). To date, six studies have used MNLFA to assess differential item functioning in the ADOS for age or sex. No study has used MNLFA to examine racial bias, nor has it been used to examine differences across the different modules and versions of the ADOS.

Objectives:

To test for differential functioning in the ADOS items across race (African-American, Asian, White), module (1-4), and version (ADOS and ADOS-2).

Methods:

The current study is the largest examination of DIF in the ADOS to date (N = 4354+), utilizing data from the Simons Simplex Collection (n = 2851) and the NIMH Data Archive (n = 1503). Data collection is complete for Module 3 and forthcoming for Modules 1, 2, and 4 (due to a recent shutdown of the NIMH Data Archive). First, item response theory-based DIF was conducted on the 14 algorithm items using the lordif package in R. A graded response model was selected given the ordinal response data. Chi-square significance tests were used to detect significant uniform and non-uniform DIF, with an alpha cutoff value of 0.05. DIF analysis will be further conducted with data from all modules and versions aggregated. Second, measurement invariance will be tested via MNLFA, using the OpenMx package in R. A confirmatory one-factor model, specified with the 14 algorithm ADOS items as manifest variables and with race, version, and module as moderating effects for the factor loadings and item intercepts in Figure 1, will be used.

Results:

Within Module 3 aggregated across versions 1 and 2, four algorithm items showed significant DIF: B1 "Eye Contact" ($\text{Pr}(\chi^2_{12})=0.117$, $\text{Pr}(\chi^2_{23})=0.001$), B4 "Shared Enjoyment" ($\text{Pr}(\chi^2_{12})=0.709$, $\text{Pr}(\chi^2_{23})=0.004$), B11 "Quality Rapport" ($\text{Pr}(\chi^2_{12})=0.001$, $\text{Pr}(\chi^2_{23})=0.267$), and D2 "Complex Mannerisms" ($\text{Pr}(\chi^2_{12})=0.021$, $\text{Pr}(\chi^2_{23})=0.675$). The item characteristic curves of B11 and D2 suggest uniform DIF, whereas DIF in B1 and B4 is non-uniform (Figure 2).

Conclusions:

In the largest sample to date, we have identified bias in four ADOS Module 3 algorithm items. We will conduct a larger analysis with MNLFA to determine whether the source of racial bias is due to specific modules or versions of the ADOS. This analysis will allow us to pinpoint specific module items and offer solutions to improve the measure and thereby diagnostic accuracy and equity for diverse individuals.

440.243 Racial Differences in Self-Reported Autism Traits

A. Ajwani¹, A. Garcia¹, J. Tran¹, D. L. Seczon², E. C. Kurtz-Nelson³, M. Santhosh⁴, K. M. Woodard⁵, B. Leonard¹, S. O. Murray², S. J. Webb⁶ and H. Rea⁶, (1)University of Washington, Seattle, WA, (2)Psychology, University of Washington, Seattle, WA, (3)Indiana University School of Medicine, Indianapolis, IN, (4)Center for Child Health, Behavior and Development, Seattle Children's Research Institute, Seattle, WA, (5)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (6)Center for Human Development and Disability, University of Washington, Seattle, WA

Background: Self-reports are often used in adult autism research as they are practical, efficient, and cost-effective (Sandercock et al., 2020). The most commonly-used are the Autism-Spectrum Quotient (AQ) and Social Responsiveness Scale (SRS-2) (Stewart & Austin, 2009). While self-reports provide valuable insights from the autism community, responses may be biased by personal characteristics (e.g., sociocultural factors). For example, Malaysian and Indian adults scored significantly higher than UK adults on the AQ (Freeth et al., 2013). Taiwanese and German participants scored similarly on the SRS-2, but lower than American participants (Wang et al., 2012). Research is needed in more diverse samples and with consideration of racial differences in sensitivity and specificity of such measures.

Objectives: We investigated the impact of race on AQ-28 (Hoekstra et al., 2011) and SRS-2 (Constantino, 2012) scores. Within our sample who resided in the US and were fluent English speakers, we hypothesized that minority populations would score higher on both.

Methods: Participants were part of two NIH funded studies that aim to pinpoint specific neural circuits that are affected in autism. Participants included non-autistic (n=210; 63% female gender, 2% other gender) and autistic (n=87; 42% female gender, 8% other gender) adults aged 18 to 30 years old ($M=23.68$ years, $SD=3.36$) with an $IQ>70$. The sample was primarily White (60%), with 20% identifying as Asian, 8% Biracial/Multiracial, 2% Black, and 3% other. Diagnostic groups were evaluated separately due to differences in racial/ethnic composition. While autism diagnoses were confirmed using recommended measures (ADOS-2, CARS, BOSA, DSM-5 checklist), current analyses focused on participants' self-reports of autism traits on the AQ-28 and the SRS-2. The effect of race on AQ and SRS scores was evaluated with one-way ANOVAs, run separately for each diagnostic group. Post-hoc comparisons were performed using Tukey's test to examine differences between the racial groups. For sensitivity/specificity analyses, two cut points were evaluated for the AQ-28: 65 (Hoekstra et al., 2011) and 70 (deVries et al., 2023). For the SRS-2 a T-score <60 indicates "Within Normal Limits" was therefore used as the cut point (Constantino & Gruber, 2012).

Results: There was not a main effect of race for the autistic ($F(3,62)=0.15, p=.861$) or non-autistic participants ($F(5,172)=2.11, p=.067$) on AQ scores. As results approached significance for the non-autistic group, a post-hoc Tukey's test indicated Asian participants scored higher than White participants (mean difference=4.80, $p=.053$). Similarly, there was not a main effect of race on the SRS-2 for the autistic ($F(3,52)=1.27, p=.295$) or non-autistic participants ($F(4,106)=0.54, p=.707$). Results are presented in Figure 1. As exhibited in Table 1, the sensitivity was higher when the AQ cut-off was 65, but specificity was lower. This trend was true for all races.

Conclusions: Although there were no major differences between races and sensitivity and specificity were fairly similar, there may be residual differences in AQ scores between non-autistic White and Asian participants. Future qualitative research should aim to understand how personal experiences and culture may affect self-endorsement of autism traits.

**440.244** Rasch Analysis of the Modified Checklist for Autism in Toddlers, Revised with Follow-up (M-CHAT-R/F)

E. Bonney¹, L. Hantzsch² and J. T. Ellison², (1)University of Minnesota - Twin Cities, Minneapolis, MN, (2)University of Minnesota, Minneapolis, MN

Background: The Modified Checklist for Autism in Toddlers, Revised with Follow-up (M-CHAT-R/F) is a 20-item scale designed to facilitate early identification of autism in low-risk populations. Despite its widespread use across various cultures, its psychometric integrity has not been comprehensively investigated, particularly in community samples.

Objectives: This study examined the measurement properties of the M-CHAT-R/F using Rasch Analysis.

Methods: Rasch analysis was undertaken on M-CHAT-R/F data collected from a community sample of 1355 Minnesotan children (670 girls, 685 boys) with an average age of 21.4 (SD: 2.5) months (range: 17-42) using the WINSTEPS software. Analyses were performed on the full 20 items to evaluate overall model fit, suitability of response options, unidimensionality, targeting, and item fit.

Results: Several properties of the scale were deemed satisfactory. The response options performed adequately well, and the scale met the criterion of unidimensionality. The item separation index (10.7) and reliability (0.9) were observed to be very high, suggesting that items could precisely discriminate ten levels of difficulty. However, person separation (0.1) and reliability (0.01) were very low, and the scale demonstrated poor targeting, indicating a mismatch between item difficulty and respondent's abilities. Out of the twenty items, five were also identified as misfits.

Conclusions: The Rasch model showed that the 20-item M-CHAT-R/F could be reduced to a 15-item instrument as this will potentially make the scale more efficient in measuring autistic traits in community dwelling infants or toddlers. Further, the present findings highlight that the inclusion of 5 misfit items in the current measure may have unintended practical consequences (e.g., misidentification). Although the M-CHAT-R/F showed promise in discriminating between ability levels, the poor targeting demonstrated that it may not be effective or particularly granular in a general population or community sample.

440.245 Reliability of the Intolerance of Uncertainty Scale for Children (IUS-C) for Use with Autistic Adolescents

M. Berman¹, M. K. Guelf², S. A. Lehman³, E. Burke⁴, B. Lindell¹, E. J. Adler², D. M. Glad¹, P. Catlin¹, F. Harb¹ and A. V. Van Hecke², (1)Psychology, Marquette University, Milwaukee, WI, (2)Psychology, Marquette University, Milwaukee, WI, (3)Marquette University, Milwaukee, WI, (4)University of Wisconsin-Milwaukee, Milwaukee, WI

Background: Intolerance of uncertainty (IU) is a dispositional tendency to find ambiguous situations overwhelming. 39.6% of autistic youth are diagnosed with at least one anxiety disorder (van Steensel et al., 2011). Both autistic and non-autistic youth who experience IU are at heightened risk for anxiety (Jenkinson et al., 2020; Osmanağaoğlu et al., 2018). The Intolerance of Uncertainty Scale for Children (IUS-C) is a commonly used 27-item questionnaire that has been validated to measure IU in children from the general population (Comer et al., 2009). The IUS-C has been used to study relationships between IU, anxiety, and autism in autistic youth (Boulter et al., 2014; Keefer et al., 2024). However, the questionnaire's reliability for use with this population has yet to be fully evaluated.

Objectives: The objective of the present study is to (1) assess the reliability of the IUS-C when using it to measure IU in autistic adolescents, (2) compare IUS-C self-report scores to parent-report scores, and (3) compare scores across age groups.

Methods: As part of larger study about social skills in autistic adolescents, participants (N = 55) ages 11-17 ($M = 13.58$; 20% female) were given the IUS-C self-report questionnaire. Parents were given the IUS-C parent version of the questionnaire. Items are rated on a 5-point scale, and scores range from 27 to 135. Both questionnaires were completed via a Qualtrics survey. Adolescents included in the research had a confirmed autism diagnosis and were screened for Intellectual Disability diagnoses.

Results: The IUS-C self-report measure showed excellent internal consistency in a sample of autistic adolescents ($\alpha = .96$). The parent report measure also showed excellent internal consistency in this sample ($\alpha = .96$). For both questionnaires, the reliability would not be substantially improved by deleting any items. On the self-report measures, total scores were $M = 61.93$, $SD = 24.40$; on parent measures, total scores were $M = 66.05$, $SD = 23.61$. Using $\alpha = 0.05$, a paired-samples t test indicated that child self-report scores were not significantly different from parent scores, $t(54) = 1.115$, $p = .27$ (two-tailed), Cohen's $d_z = .15$. A Welch's ANOVA was conducted to compare the effect of age on self-report IUS-C score. The analysis revealed a statistically significant difference in means, Welch's $F(6, 19.624) = 3.71$, $p = .012$, $\eta^2 = .16$. Tukey's HSD Test for multiple comparisons did not find any specific group-to-group differences that were statistically significant. Descriptive statistics for each age group are in Table 1.

Conclusions: This study shows excellent reliability for the IUS-C when used to measure IU in autistic adolescents. Both the self-report and parent-report versions showed this reliability and there was not a significant difference between their scores. These results provide support for using the IUS-C with this population. In cases where it is not possible to get IUS-C scores from the adolescent, it may be appropriate to rely on parent report. Across ages, group differences in IUS-C scores exist but are subtle, which may reflect changes in understanding of the questions as adolescents get older.

440.246 Remote Monitoring of Key Social and Cognitive Processes in Neurogenetic Syndromes and Idiopathic Neurodevelopmental Conditions

M. Uljarevic¹, A. Y. Hardan¹, E. Youngstrom² and T. W. Frazier³, (1)Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA, (2)University of North Carolina at Chapel Hill, Chapel Hill, NC, (3)Psychology, John Carroll University, Cleveland, OH

Background:

Individuals with autism and other neurodevelopmental (NDD) and neurogenetic (NGDs) conditions present with a wide range of social and communication difficulties that have a significant impact on their functioning. However, at present, there are no objective, scalable instruments for comprehensive characterization of social and neurocognitive aspects of autism, NDD and NGDs clinical phenotypes.

Objectives:

This study focused on the development and initial psychometric evaluation of a set of online, webcam-collected, and artificial intelligence-derived patient performance measures for autism, NDD and NGDs. The primary aim was to examine the psychometric properties of webcam-collected social attention measurements in three NGDs (PTEN Hamartoma Tumor Syndrome - PHTS, Malan Syndrome - NFIX, and SYNGAP1-related disorder - SYNGAP1), a mixed group of other NGDs, idiopathic NDD and autism. The secondary aim was to evaluate the construct validity of these performance measurements, including evaluating known-groups validity across study groups and concurrent validity for separating autism and non-autism cases.

Methods:

The remote, online webcam paradigms capturing social and cognitive processes, including social attention, receptive vocabulary, processing speed, and single-word reading, were administered to a sample of 467 participants aged 3-45 years (PHTS $n=102$, NFIX $n=23$, SYNGAP1 $n=42$, other NGDs $n=63$, idiopathic NDD and autism $n=53$, neurotypical siblings $n=71$, and unrelated neurotypical controls $n=113$). Participants completed paradigms at three timepoints (baseline, 1-month, and 4-month follow-up).

Results:

Good to excellent internal consistency reliability ($\alpha = 0.67$ to 0.95) was observed across measures. Test-retest reproducibility at 1-month follow-up and stability at 4-month follow-up was fair to good ($r = 0.40$ – 0.73) for 8 of the 12 measures. All gaze-based measures showed evidence of convergent and discriminant validity with parent-report measures of other cognitive and behavioral constructs. Unique patterns of emerged across study groups. For instance, in terms of social attention, there were near neurotypical levels in PHTS and weaker social attention in NFIX and SYNGAP1 relative to controls. Global social attention had good accuracy in detecting autism within neurogenetic syndrome participants.

Conclusions:

Webcam-collected performance measures appear to be a reliable and potentially useful method for objective characterization and monitoring of phenotypic profiles and tracking the natural history of distinct NDGs and idiopathic NDD as well as identifying autism within NDGs. Given their reproducibility and stability, social and cognitive processes captured using the existing, AI-enabled remote objective measurement protocol may be useful outcomes for future clinical trials.

440.247 Review and Comparison of Factor Analysis Models of the Childhood Autism Rating Scale 2 – Standard Version

J. M. Campbell¹, P. Feghali², L. Powell³, A. Broomell⁴ and L. Gardner⁴, (1)Psychology, Western Carolina University, Cullowhee, NC, (2)Johns Hopkins All Children's Hospital, St Petersburg, FL, (3)Johns Hopkins All Children's Hospital, St. Petersburg, FL, (4)Western Carolina University, Cullowhee, NC

Background: Autism Spectrum disorder (ASD) is a neurodevelopmental disorder that is characterized in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition, Text Revision (DSM-5-TR; American Psychiatric Association, 2022) by both impairments in social communication and interaction, and the presence of restricted and repetitive patterns of behaviors (RRBs) in the early developmental period. There have been several assessment measures developed for screening for and ASD, which include clinical observation, caregiver reporting, and objective performance on assessment measures. The Childhood Autism Rating Scale, Second Edition – Standard Version (CARS2-ST; Schopler et al., 2010) is a 15-item observation-based rating scale that is intended to provide brief, specific, and comprehensive information that can be used to help inform diagnosis for individuals suspected of having ASD. There have been several independent psychometric studies completed of the CARS (initial edition) and CARS2-ST, which have varied given the changes in diagnostic criteria for ASD and related disorders since 1980. Similarly, the factor structure has been explored by researchers both before and after the 2014 DSM-5 changes to the ASD diagnostic criteria; however, few psychometric studies have been completed since the DSM-5-TR was published in 2022.

Objectives: The present study was completed to provide an a-priori model of factor structures for the CARS2-ST in comparison to previous factor structures of the CARS2-ST.

Methods: The CARS2-ST was completed by a licensed psychologist with children referred for diagnostic evaluation at a tertiary diagnostic clinic. Participants were 304 children who received a primary diagnosis of ASD following a comprehensive psychological evaluation based on DSM-5-TR diagnostic criteria. The sample was predominantly male ($N = 225$, 74%) with a mean age of 42.15 months ($SD = 20.3$). The first and last authors conducted a review of the literature for prior research in factor analysis of both the CARS and CARS2-ST. The review of the literature informed a proposed three-factor structure model consisting of: *Social Communication*, *Emotional Dysregulation*, and *Stereotyped Behavior and Sensory Differences*. Both the first and last author independently sorted CARS2-ST items into the three factors, which resulted in favorable agreement across raters. Five models were evaluated using confirmatory factor analysis (CFA) using the R package *lavaan* (version 0.6.17) using maximum likelihood (ML) estimation.

Results: The proposed three-factor model resulted in a satisfactory fit to the data [Comparative Fit Index (CFI) = .93; Tucker-Lewis Index (TLI) = .92, Root Mean Square Error of Approximation (RSMEA) = .056; Standardized Root Mean Square Residual (SRMR) = .053] and demonstrated significantly better fit than the two-factor model identified in the CARS-2 manual (Schopler et al., 2010), and a two-factor model based on DSM-5-TR criteria.

Conclusions: A proposed three-factor model for the CARS2-ST consisting of Social Communication, Emotional Dysregulation, and Stereotyped Behavior and Sensory Differences may be useful in organizing and reporting CARS2-ST ratings. Future research should examine the invariance of the proposed model across important demographic variables, such as gender and race.

440.248 Screening Tool for Autism in Toddlers and Young Children (STAT) Training Follow-up Survey: Clinician Confidence, Feedback, and Barriers to Implementation

G. Zilinskaite¹, T. E. Foster², J. F. Hine³, A. Swanson³ and Z. Warren⁴, (1)Vanderbilt University Medical Center / VKC TRIAD, Nashville, TN, (2)Division of Developmental Medicine, Vanderbilt University Medical Center / VKC TRIAD, Nashville, TN, (3)Vanderbilt University Medical Center, Nashville, TN, (4)Vanderbilt University Medical Center - Treatment and Research Institute for Autism Spectrum Disorder, Nashville, TN

Background: Due to significant resource shortages and limited availability of specialists, there has been a growing push to develop new diagnostic models and provide autism-focused training to primary care providers (PCPs). One training program, the STAT-MD model, utilizes one- to two-day workshops to provide training in conducting autism-focused assessments with toddlers and young children. Training components include performing interactive screening with the Screening Tool for Autism in Toddlers and Young Children (STAT), conducting developmentally sensitive caregiver interviews, formulating diagnostic impressions and communicating them to caregivers, and utilizing appropriate billing and coding procedures.

Objectives: While research has shown that this training can have a significant effect on PCPs' practice in clinic, there are also well-known barriers that likely limit its impact. It involves time-consuming workshops, expensive materials, and added tasks/responsibilities that make participating difficult for most "real-world" PCPs. In addition, these time-limited trainings do not provide participants with ongoing support to apply training content within their practice. To improve the quality and impact of future training efforts, we asked past training participants about their use of the STAT-MD model, barriers to implementation, and how the training affected their confidence in diagnosing autism.

Methods: Eligible participants ($N = 1190$) were pulled from our rosters from past STAT trainings (2004-2024) and invited to complete a one-time online survey through REDCap. 24% of attempted contacts did not go through, and only 6% of completed the survey, highlighting how these one-time trainings did not lead to sustained support and contact with participants. For participants that did respond ($N = 58$), we collected information about past training and current practice, number of STAT administrations and autism diagnoses since training, confidence in autism assessment-related practice behaviors (see Table 1), and any self-reported barriers to diagnosing autism in their practice.

Results: Participants' self-reported levels of confidence in implementing assessment-related practice behaviors increased after STAT training; Wilcoxon Signed-Rank tests indicated statistically significant increases across all practice domains (Table 1, $p < .001$). However, despite significantly increased clinician confidence in identifying, diagnosing, and discussing autism, only 64% of participants reported administering the STAT after training (range: 1-600 administrations), and only 54% reported diagnosing autism (range: 1-2200 diagnoses). Many participants endorsed multiple barriers to implementation (Table 2) and provided feedback on further needs for support.

Conclusions: Even though only a fraction of past training participants completed our survey and implemented the STAT, those who did reported significantly increased confidence across practice domains and substantial within-practice contributions (2304 administrations of the STAT and 5955 autism diagnoses). This suggests that even with their practical limitations, training approaches that seek to equip PCPs can have a sizable influence on their communities. In order to maximize the impact of future training models, it will be important to address identified barriers to implementation and establish mechanisms for continued support to ensure successful application of learned content. Preliminary strategies (e.g., continued contact and follow-up via additional training sessions and recurring needs surveys) and novel resources, developed with these goals in mind, will be summarized and shared.

440.249 Self-Reported Adequacy of Supports and Information for Autistic Adults: Instrument Validation and Preliminary Investigation of Predictor Variables

R. K. Schuck^{1,2,3}, M. J. Baker-Ericzen^{2,3,4}, I. Moura^{3,5}, R. Caldwell^{2,3}, J. Love^{3,6}, J. Maslak³, R. Kripke-Ludwig³, E. Frowner³ and C. Nicolaidis^{3,7},
(1)Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Stanford, CA, (2)San Diego State University Research Foundation, San Diego, CA, (3)Academic Autism Spectrum Partnership in Research and Education (AASPIRE), Portland, OR, (4)Administration, Rehabilitation and Post-Secondary Education, San Diego State University, San Diego, CA, (5)Lurie Institute for Disability Policy, Brandeis University, Waltham, MA, (6)Multnomah County Intellectual and Developmental Disabilities Services, Portland, OR, (7)School of Social Work, Portland State University, Portland, OR

Background: Disabled people may have trouble getting all of their needs met due to lack of available supports and information. It is crucial to assess how satisfied individuals feel with support they receive (from both formal disability services or informal support systems) in order to know how to best support disabled people. However, little research has investigated the adequacy of supports from the point of view of autistic adults. Furthermore, measures to assess self-reported adequacy of supports have not been developed for or tested specifically with autistic individuals.

Objectives: 1) assess the factor structure of a self-report adequacy of supports scale (modified from a prior scale developed for use with adults with intellectual/physical disabilities); 2) use the measure to characterize adequacy of supports in a sample of autistic adults; 3) assess factors that are associated with adequacy of support and information.

Methods: Autistic adults throughout the United States filled out the 9-item AASPIRE Adequacy of Supports and Information Scale (a modified version of two subscales of the Quality of Care and Support scale [Lucas-Carrasco et al., 2011]) as part of a longitudinal cohort study. Participants were recruited from healthcare and disability service settings, as well as via community organizations, social media, and word of mouth (“community cohort”). Items were rated on a scale from 1=not at all to 5=totally supported; the two subscales were named *Supports* and *Information*. N=738 participants filled out the instrument (30.6% Female, 35.2% Male, 33.3% other; 28.5% identified as BIPOC; 61.5% non-heterosexual; 29.9% reported receiving disability services). The existing 2-factor structure was assessed with the confirmatory application of exploratory equation modeling. Binary logistic regression was used to assess predictors of feeling adequately supported (defined as feeling on average “totally” or “mostly” supported).

Results: Fit for the 2-factor model was excellent across most fit statistics (CFI = .983, TLI = .968, RMSEA (90% CI) = .103 (.089, .117), SRMR = .022); all items loaded as expected with minimal cross-loading (see Table 1). Average scores (out of 5) for the Supports subscale (M=3.94, SD=1.03) approximately corresponded to feeling “mostly” supported. Average scores for the Information subscale (M=3.14; SD=1.05) corresponded to feeling “moderately” supported. Our preliminary regression model was significant ($X^2 = 177.85, p < .001$) and predicted 33.4% of the variance (Nagelkerke R^2). Being satisfied with supports was associated with higher self-determination, identifying as white, being in the healthcare or disability cohort versus community cohort, identifying as male versus non-binary/gender-fluid/agender, and reporting greater informational social support on a separate Social Support measure (see Table 2).

Conclusions: This study serves as an initial validation of a self-report adequacy of supports and information instrument for autistic adults. On average, participants in our diverse sample reported fairly high satisfaction with both supports and information about available supports. However, preliminary results indicate that some individuals, such as racial and gender minorities, would benefit from additional support. More research is needed to further assess the nature of these relationships, for example with regards to intersectionality and causal influences.

440.250 Sex Assigned at Birth and Diagnostic Status Considerations in Outcome Measures for Children with Late-Diagnosed Autism

H. Lundblad¹, S. Zheng², A. N. Esler³, S. Bishop⁴ and C. A. Burrows⁵, (1)University of Minnesota, Minneapolis, MN, (2)Psychiatry and Behavioral Sciences, The University of Texas at Austin, San Francisco, CA, (3)Department of Pediatrics/Masonic Institute for the Developing Brain, University of Minnesota Medical School, Minneapolis, MN, (4)Psychiatry and Behavioral Sciences, University of California, San Francisco, San Francisco, CA, (5)Department of Pediatrics, University of Minnesota, Minneapolis, MN

Background: While much progress has been made in early identification and diagnosis of autism spectrum disorder (ASD), many children are not identified as having ASD until school age or later (Sheldrick et al. 2017). Females (sex assigned at birth) may be more likely to be diagnosed late (Shattuck et al. 2009), and may show different symptom profiles over time, particularly in their restricted and repetitive behaviors (Kaat et al. 2020). Emerging evidence suggests that children diagnosed with ASD late (i.e., after age 5) show comparable difficulties with social skills, but are less likely to show unusual preoccupations, rituals, or repetitive motor movements than those diagnosed in early childhood (Goodwin et al. 2019). Little is known surrounding profiles of co-occurring symptoms in late-diagnosed males and females.

Objectives: Examine sex and diagnostic status differences in current social affect (SA), restricted and repetitive behavior (RRB), emotional-behavioral functioning, and adaptive functioning in late-diagnosed males and females with ASD.

Methods: Participants included 140 children (25% female) who received comprehensive ASD evaluations in the Autism and Neurodevelopment Clinic at the University of Minnesota. Inclusion criteria were: (1) seen for first time ASD diagnostic evaluation at or after age 5; and (2) had fluent speech. ASD symptoms in the SA and RRB domains were measured using the Autism Diagnostic Observation Schedule, 2nd Edition (ADOS-2). Emotional-behavioral functioning was measured using the externalizing (EXT) and internalizing (INT) composite indices from the Behavior Assessment System for Children, 3rd Edition (BASC-3). Adaptive functioning was measured using the adaptive behavior composite score from the Vineland Adaptive Behavior Scales, 3rd Edition (VABS-3). A factorial Analysis of Variance tested the main effects of ASD diagnosis and sex, as well as their interaction.

Results: There was a main effect of diagnostic status on both SA and RRB total scores ($p < 0.001$), as well as a main effect of sex on RRB total scores only ($p = 0.03$). There was a main effect of sex on INT composite indices ($p = 0.01$), as well as a main effect of diagnostic status on EXT composite indices ($p = 0.02$). There were no interaction effects of sex and diagnostic status on any of the dependent variables.

Conclusions: While we observed diagnostic group differences in SA and RRBs, there were smaller group differences in internalizing problems and adaptive behavior. This likely reflects that children referred for ASD evaluations generally have emotional-behavioral and adaptive skill challenges. Females scored lower than males on the RRB total scores, regardless of ASD diagnosis (Messinger et al. 2015; Lai et al. 2020). Females also scored higher on BASC internalizing problems, regardless of diagnosis, highlighting the need to understand these specific challenges for females within the context of societal expectations. Considering co-occurring symptoms in late-diagnosed children can lead to more effective, targeted treatments. It will be important to consider sex differences in the general population and non-diagnosed clinically-referred children. Some sex differences may not be ASD-specific but exist across the spectrum of ASD concern.

**440.251 Sex-Specific Clustering in Autism: Implications for Female Identification and Assessment**

U. Vurgun¹, S. Cho², R. Fusaroli³, A. Knox⁴, A. Hauptmann⁵, M. L. Covello⁶, M. Madya¹, M. Lyons¹, A. L. Lee¹, L. J. Fulop¹, A. S. Russell¹, G. Hicks¹, J. Fiumara¹, J. Pandey¹, B. Tunc¹, E. Sariyanidi¹, M. Liberman¹, R. T. Schultz¹ and J. Parish-Morris¹, (1)Institute for Biomedical Informatics, Penn Institute for Biomedical Informatics (Richards Building), Philadelphia, PA, (2)Linguistic Data Consortium, University of Pennsylvania, Philadelphia, PA, (3)Aarhus University, Aarhus, Denmark, (4)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (5)The Center for Autism Research/CHOP, Philadelphia, PA, (6)University of North Carolina at Chapel Hill- Carolina Institute for Developmental Disabilities, Chapel Hill, NC

Background: Autism presents with significant heterogeneity across a variety of domains. To address this variability and provide personalized support for autistic individuals, accurately identifying and characterizing subgroups within autism is essential. A data-driven approach can provide valuable insights into the identification of distinct subgroups in autism. Growing evidence suggests sex-specific differences in symptom presentation (Lai et al., 2015). Recent studies indicate that autism may present differently in females, potentially leading to underdiagnosis or misdiagnosis in girls and women (Loomes et al., 2017; Hull et al., 2020). In this study, we identified subgroups of autism, and examined how these groupings vary by sex assigned at birth.

Objectives: To identify distinct clusters (i.e., phenotypes) within autism and investigate the relationship between these clusters and sex, with a focus on autistic females.

Methods: Participants included 99 individuals (55 autistic (AUT), 44 neurotypical[NT]). AUT group: 35 males, 20 females; NT group: 23 males, 21 females. AUT (mean±SD: 15.5±1.6) and NT (mean±SD: 14.6±1.9) groups differed significantly on age ($t=2.61$, $p=0.01$, $d=0.52$), with the AUT group being slightly older. However, they did not differ significantly in cognitive estimates ($t=0.32$, $p=0.75$, $d=0.07$) or sex ratio ($\chi^2=0.87$, $p=0.35$, $V=0.07$). Unsupervised k-means clustering was applied using a set of measures including participant self-report measures of thoughts and feelings (BASC-3 SRP, MASC-2), parent-reported social behavior and behavioral/emotional functioning (SRS-2, BASC-3 PRS), and clinician-administered assessments (CRS, OARS). Uniform Manifold Approximation and Projection (UMAP) was used for dimensionality reduction. Covariate-adjusted analyses controlling for age and cognitive estimates were conducted using linear regression models.

Results: UMAP analysis revealed two key dimensions (see Figure): UMAP1, strongly associated with behavioral and emotional traits (correlating strongly with behavioral symptoms index, adaptability, social motivation, and depression; r 's = 0.75-0.83), and UMAP2, primarily capturing cognitive and regulatory features (showing correlations with attention, cognitive regulation, and behavioral control measures; r 's = 0.68-0.79). Two distinct clusters emerged: AUT_A ($n=36$) scored higher on social-behavioral challenges (UMAP1), while AUT_B ($n=19$) had fewer emotional regulation issues (UMAP2). AUT_B also had lower internalizing symptoms (anxiety, depression, panic) and higher positive traits (self-esteem, adjustment) than AUT_A ($p<0.001$). AUT_B scores were closer to NT scores, suggesting a milder presentation. NT_A and NT_B differed, with NT_B showing more emotional regulation challenges. AUT_B was predominantly male (84.2%), while AUT_A had a more balanced gender ratio (52.8% male). Females were more likely to be in AUT_A (89.5%) than males (61.1%) ($p<0.05$).

Conclusions: Our study identifies two distinct AUT clusters, AUT_A and AUT_B, with clear sex differences. AUT_B, with milder symptoms, overlaps significantly with typically developing controls, especially in anxiety, depression, self-esteem, and locus of control. Females are overrepresented in the more severe AUT_A cluster, while those in AUT_B may go undetected due to camouflaging behaviors or diagnostic tools that lack sensitivity to sex-differentiated manifestations of autism symptoms. As a result, females with AUT_B traits, resembling typically developing peers, might face a higher risk of delayed or missed diagnoses. These findings emphasize the need to consider sex-sensitive diagnostic tools to detect subtler autism presentations in females.

440.252 'Mind Readers': The Italian Version of the Short Story Task to Assess Theory of Mind in Autistic and NON-Autistic Adults
S. Frassy¹, C. Guiot¹, E. Galetti¹, S. Fontana¹, C. Giovagnoni¹, M. Nola¹ and N. Brondino², (1)Department of Brain and Behavioral Sciences, University of Pavia, Pavia, Italy, (2)Department of Brain and Behavioral Sciences, University of Pavia, Pavia, ITALY

Background:

The ability to attribute mental states, conceptualized as Theory of Mind (ToM), has been found to be decreased in autistic individuals, leading to the hypothesis that ToM alterations may underpin difficulties in social functioning in autism. However, standard ToM tasks often suffer from ceiling effects when administered to adults, being mostly adapted from measures for children. The Short Story Task (SST) seems less prone to ceiling effects and incorporates a range of mental states which are representative of real-world social interactions.

Objectives:

Our primary aim was to determine if the understanding of characters' mental states, as measured by the SST-MS, was decreased in autistic subjects compared to non-autistic subjects from a non-clinical population. As a secondary aim, we explored the potential of this measure to predict autism diagnosis and identify a reliable cutoff to distinguish autistic from non-autistic individuals.

Methods:

We enrolled all consecutive admissions for autism diagnostic assessment since September 2021. Non-clinical control subjects (CT) were recruited in the general community. We included participants in the age range 18-55 years who were Italian speakers, with at least 8 years of education. Exclusion criteria were IQ < 100 and SST comprehension subscale < 5 points. For CT, we also excluded individuals with previous psychiatric diagnoses, substance abuse problems, presence of clinically relevant psychiatric symptoms or history of psychoactive drug use for more than 6 months. SST was administered as follows: after reading a short story by Ernest Hemingway, participants were asked questions that assessed mental state reasoning (SST-MS) and comprehension of non-mental content (SST-C). An investigator blind to SST outcome conducted the ADOS-2 interview. IQ was measured with WASI-II.

Results:

Participants were 33 autistic individuals (16 M and 17 F) and 32 non-autistic individuals (16 M and 16 F). No significant difference was found between the two groups in sex assigned at birth, numerosity, age, IQ. A difference in education years was found between the two groups (AUT 16,09 years, CT 17,88 years, $p=0,0032$). A significant difference ($p=0,0026$) was found between average scores in SST-MS (AUT 7,061, CT 9,156). Selecting a cut-off of 8 resulted in a sensitivity of 69,70% and a specificity of 68,75% in identifying autistic adults when scores below this threshold were obtained. A significant ($p=0.0074$) but smaller difference in SST-C was found between AUT (8,970) and CT (9,625) groups.

Conclusions:

SST-MS seems to be a promising support tool to include in the diagnostic assessment of autism since it seems able to highlight individual differences in the ability to infer mental states in clinical and non-clinical populations. Unlike gold standard diagnostic tools, no specific training is needed for administration of SST. Inter-rater reliability confirmed that it is an easy tool to master. However, sensitivity and specificity can easily change depending on the population analyzed, therefore, it is necessary to recruit a larger number of cohorts, potentially determining different cut-offs based on socio-demographic and cognitive characteristics.

440.253 Socioeconomic Status and Adaptive Function in Autistic Children: Results from the Autism Biomarkers Consortium for Clinical Trials (ABC-CT)

S. Eberle¹, J. M. Wolf², A. Naples³, C. Carrow³, K. Chawarska⁴, G. Dawson⁵, S. Jeste⁶, J. Dziura¹, S. J. Webb⁷, S. Faja⁸, N. Kleinbans⁹, C. Sugar¹⁰, F. Shic¹¹ and J. McPartland¹², (1)Yale University, New Haven, CT, (2)Child Study Center, Yale Child Study Center, New Haven, CT, (3)Yale Child Study Center, Yale University School of Medicine, New Haven, CT, (4)Child Study Center, Yale University School of Medicine, New Haven, CT, (5)Department of Psychiatry and Behavioral Sciences, Duke University, Durham, NC, (6)Children's Hospital Los Angeles, Los Angeles, CA, (7)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (8)Boston Children's Hospital / Harvard Medical School, Boston, MA, (9)University of Washington, Seattle, WA, (10)University of California, Los Angeles, Los Angeles, CA, (11)Center for Child Health, Behavior and Development, Seattle Children's Research Institute, Seattle, WA, (12)Yale Child Study Center, Yale Child Study Center, New Haven, CT

Background: Previous literature reports that children with autism spectrum disorder (ASD) have significant weaknesses in adaptive functioning that impact their self-sufficiency and quality of life. While lower cognitive ability and greater autism symptom severity have been associated with lower adaptive functioning, other factors such as socioeconomic status (SES) may impact adaptive functioning. For example, SES could impact accessibility to healthcare, timeliness in diagnosis, and intervention for ASD, all of which may relate to variability in adaptive functioning.

Objectives: The current study aimed to investigate the extent to which socioeconomic factors explain variability in adaptive functioning scores in a large and geographically diverse sample of autistic children.

Methods: Data were collected across five U.S. sites (Yale University, Boston Children's Hospital, Duke University, University of Washington, and University of California, Los Angeles) through the Autism Biomarkers Consortium for Clinical Trials (ABC-CT). 280 autistic children (ages 6-11) were included ($M_{\text{age}} = 8.53$ years, $SD = 1.63$; 74.68% male; 72.18% white). ASD diagnoses were confirmed with the Autism Diagnostic Observation Schedule-2nd Edition, Autism Diagnostic Interview-Revised, and clinician endorsement of DSM-5 criteria for ASD. Sociodemographic information including yearly household income and parental education was obtained from caregivers. Parent-reported adaptive functioning skills were assessed by the Vineland Adaptive Behavior Scales-3rd Edition (Vineland-3). Household-level economic status was estimated using the income-to-needs ratio (INR) by dividing an individual's household income by the U.S. Census Bureau-based poverty threshold that accounts for family size. Neighborhood SES was estimated by dividing annual household income by the median income for the participant's postal code derived from publicly available census data.

Results: Multiple regression was used to predict Vineland-3 Composite scores from INR, neighborhood SES, and parental education. The overall model was significant ($F(4, 244) = 7.12, p < .001, R^2 = .1045$). INR ($\beta = 1.52, t = 3.61, p < .01$) emerged as a significant predictor of composite scores. A second multiple regression analysis was conducted to examine INR, neighborhood SES, mother's education level, and father's education level as predictors of the Vineland-3 Communication domain score. The overall model was significant ($F(4, 244) = 11.10, p < .001, R^2 = .154$). INR ($\beta = 1.60, t = 2.87, p < .01$), mother's education level ($\beta = 0.85, t = 2.15, p < .05$), and father's education level ($\beta = 0.75, t = 2.34, p < .05$) emerged as significant predictors of communication scores. Both mothers' ($r = .42, p < .05$) and fathers' ($r = .38, p < .05$) education levels were moderately correlated with INR.

Conclusions: These results suggest that individual and contextual socioeconomic factors have a significant role in predicting adaptive behavior and communication skills in autistic children. Specifically, family income relative to need and parental education were significant predictors. These findings emphasize the importance of addressing socioeconomic inequalities, particularly in access to educational resources and intervention services, to better support families of autistic children from lower socioeconomic backgrounds.

440.254 Stability of Early Identification for Toddlers with Autism Spectrum Disorder before Age of 3 Years: A 5-Year Follow-up
C. C. Wu¹ and Y. M. Hou², (1)Department of Psychology, Kaohsiung Medical University, Kaohsiung, Taiwan, (2)Department of Psychiatry, Ditmanson Medical Foundation, Chia-Yi Christian Hospital, Chiayi, Taiwan

Background: Autism spectrum disorder (ASD) is thought as an innate neurodevelopmental disorder and characterized by impaired social communication and social interaction, as well as restricted and repetitive patterns of behavior and interest. Recently, the prevalence of ASD increases significantly beyond than 2 in 100 children (Li & He, 2024; Wallis et al., 2023). The increasing prevalence highlights the importance of the early identification. In addition, the importance of early detection for ASD is underscored by the benefits of early intervention (e.g., Fuller et al., 2020; Gabbay-Dizdar et al., 2022).

Objectives: Previous studies supported that early diagnosis of children with ASD appears to be stable in children as early as age 3. However, few studies examined long-term stability and change of early detection for toddlers with ASD, especially for young children before age 3. In this current study, a longitudinal design was used to examine stability and change of early identification for toddlers with ASD before 36 months of age.

Methods: There were 125 toddlers with developmental disabilities before 36 months of age including 59 toddlers with ASD and 66 toddlers with developmental delays (DD) from Southern of Taiwan. These participants who had administrated all of the Taiwan version of the Screening Tools for Autism in Two-Year-Olds (T-STAT; Chiang et al., 2013), Modified Checklist for Autism in Toddlers (M-CHAT; Wong et al., 2018) and Autism Diagnostic Observation Schedule (ADOS; Lord et al., 1999) between 18 and 36 months of age (Time 1, mean chronological age = 25.6 months) and received re-assessment for diagnostic reassessment after 5 years (Time 2, mean chronological age = 86.8 months). At Time 2, all participants were assessed and diagnosed according to DSM-5 and with reference to developmental history and current concerns from parents, results of cognitive and adaptive function measures, observations of the child, and the results of ADOS by a multidisciplinary team.

Results: Based on classification of the T-STAT (cutoff = 2.25 or 2) at Time 1, the results showed that the sensitivity and specificity are .78 and .70, respectively. In addition, according to classification of the M-CHAT (cutoff = 4) at Time 1, the results indicated that the sensitivity and specificity are .71 and .61, respectively. While, the Brief-14 (cutoff = 4) revealed that both the sensitivity and specificity are .71. Finally, with reference to classification of the ADOS (Time 1), the results showed that the sensitivity and specificity are .85 and .79, respectively.

Conclusions: The results of this current study showed that early identification or diagnosis for toddlers with ASD was reliable before age 3 and have good long-term stability. In addition, the findings of this study revealed that all of the T-STAT, M-CHAT (i.e. Brief-14) and ADOS are promising tools to differentiate toddlers with ASD and those with DD before 36 months of age. The findings also supported that toddlers with ASD could be detected or diagnosed as early as age 3 and then provided with early intervention.

440.255 Standardized Assessment of Strengths, Challenges, Barriers and Facilitators in Autism: Pilot Validation of the ICF Core Sets Platform

L. Alehagen¹, J. Hasslinger² and S. Bolte¹, (1)Center for Neurodevelopmental Disorders at Karolinska Institutet (KIND), Department of Women's and Children's Health, Karolinska Institutet, Stockholm, Sweden, (2)Department of Clinical Neuroscience, Karolinska Institutet, Stockholm, Stockholm, Sweden

Background:

Functioning, not to be confused with impairment, is a multifaceted construct that emerges in interaction between an individual's strengths and challenges and facilitating and hindering environments. WHO's International Classification of Functioning (ICF) applies a model integrating biological and psychosocial dimensions of functioning. To facilitate use of the ICF, ICF Core Sets for autism have been developed in cooperation with WHO, ICF Research Branch, researchers, clinicians, and stakeholders from all WHO regions (Bölte et al., 2024). Core Sets are shortlists of the ICF pertaining only the most relevant areas of functioning within a certain diagnosis. ICF Core Sets for autism have been validated in educational and clinical settings and are now operationalized as rating scales on an internet platform for user friendly application.

Objectives:

The objective of this study was to pilot the validity of the ICF Core Set rating scales for autism. Particularly, we sought to examine whether self-reported autistic functioning profiles in terms of the ICF domains of body functions, activities and participation, and environmental factors would mimic current research evidence on strengths and challenges of autistic people, and environmental barriers and facilitators they encounter.

Methods:

The digital ICF core set rating scales for autism were piloted in a group of 48 adolescents and adults (17-65y, M=38.9, SD=12.3; 35 female) diagnosed with autism and 203 (17-82 y, M=43.4, SD= 15.2; 110 female) neurotypical participants. ICF profiles per group (autism vs. neurotypical) were analyzed and compared on ICF domain and item levels. In addition to self-ratings, a subset was also assessed by a proxy-ratings. For 107 individuals paired assessments were collected to determine inter-rater agreement

Results:

Autistic individuals perceived most environmental factors as significantly more hindering than neurotypical participants. Some items, such as melatonin and assistive products for school and daily life, were rated as more helpful by the autistic group. They reported higher scores for body functions like curiosity, trustworthiness, and responsibility, and low scores for appropriateness of emotional involvement, control over thoughts, and adaptability. In the domain of activities and participation, autistic individuals scored higher than neurotypical participants on avoiding alcohol, tobacco use, and sexual risks, but lower on adapting to changes in daily routines, managing stress, and new situations. For instance, in the domain activities and participation, the intraclass correlation for Demands and Changes (d240, d250) was high at 0.85 (95% CI: 0.79-0.92). In contrast, it was lower for Giving Information (d330), at 0.46 (95% CI: 0.16-0.65).

Conclusions:

Results indicate that the digital ICF core sets rating scales generate valid information on functioning profiles in autism regarding both individual strengths and challenges and environmental facilitators and barriers. These results give a balanced and holistic picture of functioning in autism beyond clinical diagnosis and symptomatology to serve support planning, environmental adaptations to needs, and strengths-based approaches. Larger scale data collections on the ICF CoreSets platform and psychometric evaluation is required to make firm conclusions about its usefulness and scientific properties. These studies are currently in progress.

440.256 Streamlining Autism Diagnostics: A Machine Learning Approach to Simplifying the ADOS-2 for Accessible ASD Assessment

A. Venkadesh¹, A. L. Farmer², B. J. Brintz³, M. D. Prigge³, S. Nelson², C. Traiser², E. Bigler⁴, A. L. Alexander⁵, J. E. Lainhart⁶ and B. A. Zielinski⁶, (1)Pediatric Neurology, University of Florida, Gainesville, FL, (2)Pediatrics, University of Florida, Gainesville, FL, (3)University of Utah, Salt Lake City, UT, (4)Brigham Young University, Provo, UT, (5)University of Wisconsin-Madison, Madison, WI, (6)Pediatrics, Neurology, and Neuroscience, University of Florida, Gainesville, FL

Background: The Autism Diagnostic Observation Schedule-2 (ADOS-2) is a widely used tool for diagnosing Autism Spectrum Disorder (ASD), designed to assess key areas such as communication, social interaction, and repetitive behaviors. However, the administration of the ADOS-2 is resource-intensive, requiring specialized training and significant financial investment, leading to delays in diagnosis and limited availability, particularly in certain geographic regions. Additionally, the increasing prevalence of ASD in the United States has placed further strain on the healthcare system, exacerbating these barriers. As a result, many children face significant obstacles in obtaining a timely ASD diagnosis, crucial for accessing early intervention services. This study aims to explore ways to reduce the complexity and cost of the ADOS-2 assessment by identifying key predictive items, thereby improving accessibility to diagnosis and care.

Objectives:

- Identify key predictive items from the ADOS-2 that can reduce the complexity and financial burden of the assessment.
- Determine whether a reduced set of items from the ADOS-2 can accurately predict overall ASD severity scores.

Methods: This study utilized existing data from 108 children aged 4 to 13. Of these participants, 50 were classified as non-autistic, 58 were categorized as having ASD. A recursive feature elimination (RFE) algorithm was employed to identify and reduce the number of ADOS-2 features, narrowing them down to the most impactful ones. The five most prevalent features identified through RFE were then tested using a multivariate linear regression model to assess their correlation with the final ADOS-2 severity score. A simple linear model was selected to avoid the risk of overfitting, ensuring the model's results would be more generalizable to other populations. This approach allowed for a streamlined analysis, focusing on the most predictive features without compromising the robustness of the findings.

Results: The analysis identified five key features from the ADOS-2 assessment that played a critical role in predicting the overall ASD severity score: echolalia, stereotyped words, conversation, eye contact, and quality of rapport. Using a multivariate linear regression model, these features were found to be highly predictive of the final ADOS-2 score. The Pearson correlation coefficient for this model was 0.94, indicating a strong positive correlation between these five features and the overall severity score. This suggests that these core features alone can serve as reliable predictors of ASD severity, significantly reducing the complexity of the ADOS-2 while maintaining diagnostic accuracy.

Conclusions:

- A reduced set of five features may accurately predict ADOS-2 severity score, simplifying the assessment process.
- Streamlining ADOS-2 assessment could make ASD diagnosis more accessible and cost-effective without sacrificing diagnostic reliability.
- Nevertheless, further research is required to validate these findings in larger and more diverse populations, and to explore the potential for integrating these key features into a simplified diagnostic tool for broader clinical use.

440.257 Tele-ASD-Kids: A Telehealth Diagnostic Protocol for School Aged Children

K. K. Meltzoff, J. Blacher² and C. J. Alexander³, (1)School of Education, University of California Riverside, Riverside, CA, (2)School of Education, University of California, Riverside, CA, (3)School of Education, School Psychology, University of California, Riverside, Riverside, CA

Background:

Accurate ASD diagnosis is important for improving outcomes. However, obtaining traditional ‘gold standard’ in-person assessments can be challenging due to accessibility (e.g. distance, transportation, childcare). These issues were heightened during the COVID-19 pandemic, spurring researchers to create and validate telehealth assessments.

Objectives:

Using the Tele-ASD-Peds (TAP; Corona et al., 2020) and Tele-ASD-KIDS (TAK; Stavropoulos et al., 2022), we measured the accuracy of diagnosis using telehealth. This is the first time sensitivity, specificity, and ‘cut-off points’ for scoring the TAK is presented.

Methods:

Participants (n = 39) were seen twice: telehealth, and in-person, by separate clinical teams. Teams were blinded to each other’s impressions. When disagreements occurred, teams met to determine a final diagnosis. Both the TAP and TAK used a Likert scoring system from 1-3, where 3 indicates behavior indicative of ASD. Clinician confidence/certainty was measured using a Likert scale where higher scores indicate higher confidence.

Results:

For the TAP (n = 10), sensitivity was 87.5%, specificity could not be calculated as no ‘true negatives’ were found. A cut-off score of 17.5 yielded sensitivity of 77.8% and specificity of 100% (min-max score = 7-21).

For the TEK module 2 (n = 7), sensitivity and specificity were 100%. A cut-off score of 15 yielded sensitivity and specificity of 100% (min-max score = 9-27).

For the TEK module 3 (n = 22), sensitivity was 50% and specificity was 64.2%. A cut-off score of 16.5 yielded sensitivity of 75% and specificity of 50% (min-max score = 10-30).

Participants were separated into three groups based on in person—telehealth diagnostic impressions: ASD—ASD (n = 16), disagreement about ASD/no ASD (n = 14), or no ASD—no ASD (n = 9). ANOVAs revealed a significant effect of group on telehealth clinician confidence ($p = .047$) such that clinicians were less confident in their diagnostic impressions related to children in the ‘disagreement’ versus other groups, and age ($p = .002$), such that children in the ASD-ASD group were younger than those in the other groups. As expected, TAP, TAK, and ADOS-2 scores were highest for the ASD—ASD group, and lowest for the No ASD—No ASD group (all $ps > .05$).

Conclusions:

The current study is the first, to our knowledge, to measure diagnostic accuracy of telehealth with traditional in-person assessment with verbal children. Most telehealth assessments for ASD focus on young, minimally verbal children (e.g. BOSA, TAP). Results indicate high sensitivity and specificity for children with phrased speech (‘module 2’), but less reliable results for children with fluent speech (‘module 3’). It is not clear whether decreased accuracy for older children versus younger is a limitation of the measure itself (e.g. if refinement to the TEK ‘module 3’ would improve accuracy) or if results highlight diagnostic complexity of older children presenting for an initial diagnosis. It may be that telehealth is less reliable with older children who have fluent speech due to the subtle nature of social challenges or the need for nuanced differential diagnosis (e.g. distinguishing between ADHD, ASD, or both).

440.258 Telehealth and Autism Diagnosis: Who Slips between the Cracks?

C. J. Alexander^{1,2}, J. Blacher¹, A. Hoffman¹ and K. Meltzoff³, (1)School of Education, School Psychology, University of California, Riverside, Riverside, CA, (2)School of Education and MIND Institute, University of California, Davis, Davis, CA, (3)School of Education, University of California, Riverside, CA, (4)School of Education, University of California, Riverside, Riverside, CA, (5)University of California, Riverside, Riverside, CA

Background: Although research suggests the potential effectiveness of telehealth for autism diagnosis, there remains a gap in understanding the accuracy of telehealth diagnoses and for whom a telehealth assessment may not be appropriate (Stavropoulos et al., 2022).

Objectives: We aim to investigate what factors interfere with accurate autism assessments via telehealth.

Methods: All children (N=39) participated in two autism assessments: a telehealth assessment (either Vanderbilt TELE-ASD-PEDS; Corona et al., 2020 or Tele-ASD-KIDS; Stavropoulos et al. 2021, based on level of expressive language) and an in-person assessment (ADOS-2; Lord et al., 2012). The order of assessments was randomly assigned. Clinicians were blinded to the diagnostic impressions of the other assessment team until both appointments were completed. Parent measures were collected, along with cognitive ability assessments.

Results: Teams agreed on 25 cases and disagreed on 14. For cases where a disagreement occurred, teams met and decided on a final diagnosis. In 12/14 cases, the final diagnosis aligned with the in-person assessment, in the remaining two cases, the final diagnosis aligned with telehealth. Independent-sample t-tests revealed significant effects of participant age on clinician agreement for the disagree (M = 99.43 months, SD = 37.48) and agree (M = 74.88 months, SD = 38.09) groups, $t(37) = 1.941$, $p = 0.03$, such that children were older in cases of clinical disagreement versus agreement. Chi-square analysis (figure 1) examining effects of diagnosis type on diagnostic agreement was significant, $\chi^2(1, N = 39) = 3.80$, $p = 0.05$, such that there was more disagreement between clinicians for individuals who did not have autism but had a different condition (i.e., ADHD, intellectual disability (ID)). Figure 2 shows final clinical impressions and agreement. The problem behaviors domain of the Social Skills Improvement System (Gresham & Elliot, 2008) revealed marginally significant differences between the agree (M = 122.90, SD = 30.62) and disagree (M = 139.50, SD = 17.32) groups, $t(29) = 1.58$, $p = 0.06$, such that children with more reported problem behaviors were more likely to have diagnostic disagreement. Additionally, there was a marginally significant difference between the agree (M = 67.68, SD = 17.92) and disagree (M = 77.79, SD = 11.80) groups on parent-reported communication on the Vineland Adaptive Behavior Rating Scale 3 (Sparrow et al., 2016), $t(36) = 1.55$, $p = 0.06$, such that children for whom there was diagnostic disagreement tended to have more adaptive communication challenges.

Conclusions: Age and diagnostic factors influenced clinician agreement in telehealth contexts. We hypothesize that older children present with increased clinical complexity (e.g., less stereotyped speech and restrictive and repetitive behavior), which likely increases the discrepancy. Additionally, presence of non-autism conditions, such as ADHD and ID, affected clinical agreement. This may be due to the overlap in behavioral symptoms between autism and other diagnoses impacting social skills (e.g., ADHD), making it challenging for telehealth teams to distinguish and observe nuanced behaviors needed for an accurate diagnosis.

440.259 Testing the Reliability and Validity of the 3Di-Adult, an Informant-Report Interview for Use in Adult Autism Assessment
W. Mandy¹, L. Hull², G. R. Stewart³, C. Allison⁴, S. Baron-Cohen⁴, P. Burgess⁵, A. Cape⁶, J. Crabtree⁷, J. Cusack⁸, I. Ensum⁹, F. Matthews¹⁰, J. R. Parr¹¹ and J. Robinson¹², (1)Research Department of Clinical, Educational & Health Psychology, University College London, London, United Kingdom, (2)Population Health Sciences, University of Bristol, Bristol, UNITED KINGDOM, (3)Social, Genetic and Developmental Psychiatry Centre, King's College London, London, United Kingdom, (4)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, Cambridgeshire, United Kingdom, (5)UCL, London, United Kingdom, (6)AWP, Bristol, Bristol, United Kingdom, (7)UCL, Clinical Psychology Course, London, London, United Kingdom, (8)Autistica, London, United Kingdom, (9)BASS, Avon and Wiltshire Mental Health Partnership NHS Trust, Bristol, United Kingdom, (10)University of Hull, Hull, Yorkshire, United Kingdom, (11)Population Health Sciences Institute, Newcastle University, Newcastle upon Tyne, United Kingdom, (12)CLASS, Cambridgeshire and Peterborough NHS Foundation Trust, Cambridge, United Kingdom

Background:

A resource-efficient, well-validated interview to collect informant reports for the assessment of autism spectrum disorder (henceforth 'autism') in adults is needed. The 3Di-Adult, which collects information about current and pre-adulthood autistic characteristics, as specified in DSM-5 and ICD-11, could potentially fill this gap in practice. Many adults seeking autism assessment do not have an informant, e.g., a parent, who can report on their pre-adulthood. Therefore, we developed a version of the 3Di-Adult ('the 3Di-Adult-Current') that limits questions to current behaviours. To understand their suitability for clinical use, investigation is needed of how the 3Di-Adult and 3Di-Adult-Current perform in the settings for which they are primarily designed, namely, adult autism assessment services.

Objectives:

We aimed to test the reliability and validity of the 3Di-Adult and 3Di-Adult-Current by estimating their: (i) consistency of scores over time; (ii) agreement with other autism measures; (iii) capacity to predict diagnostic outcomes of independent clinical assessments for autism.

Methods:

We recruited 148 people about to receive an adult autism assessment from one of three English NHS trusts (mean age=37.1 years, mean verbal IQ=104.2, 77 [52%] women, 126 [85.1%] identifying as 'White'). Sixty-two percent subsequently received a clinical autism diagnosis. Prior to assessment, each nominated a 'historic informant' (someone who knew them since childhood) to do the 3Di-Adult (n=104) and/or a 'current informant' (someone who knows them now, but not in childhood) to do the 3Di-Adult-Current (n=121). In addition to the 3Di, historic informants completed the Relatives Questionnaire (RQ), which is a retrospective-report version of the Childhood Autism Spectrum Test (CAST). Participants awaiting autism assessment completed the 10-item Autism Spectrum Quotient (AQ-10) and the Empathy Quotient (EQ). Informants were invited to repeat the interview after ~8 weeks, to assess test-retest reliability. Using ROC analysis, we evaluated the interviews' ability to predict subsequent outcome (autism v not autism) of clinical autism assessment, which was blind to 3Di scores.

Results:

The 3Di-Adult (mean administration time=56 minutes) and 3Di-Adult-Current (mean administration time=38 minutes) showed good internal consistency (α 's $\geq .79$) and test-retest reliability (ICCs $\geq .80$). Both interviews correlated in the expected direction, albeit it modestly, with the EQ (3Di-Adult $r=-.36$; 3Di-Adult-Current $r=-.26$). The 3Di-Adult was strongly associated with the RQ (r 's $\geq .69$). People diagnosed as autistic attained higher 3Di scores than those not diagnosed autistic (Cohen's D's .40-.67). However, on our key test of validity, neither the 3Di-Adult nor the 3Di-Adult-Current diagnostic algorithms were acceptably accurate at predicting clinical autism diagnosis (all AUC's $\leq .69$).

Conclusions:

When used in adult autism assessment services, the 3Di-Adult and 3Di-Adult-Current diagnostic algorithms are not, on their own, adequate predictors of diagnostic outcome. Nevertheless, the interviews are reliable and resource effective: they can be one component of a multi-modal adult autism assessment, collecting qualitative information in a structured way to inform expert clinical discussion.

440.260 The Interrelationships Among Cognitive Ability, Symptom Severity, and Adaptive Behavior in Toddlers with Autism Spectrum Disorder: A Cross-Lagged Panel Analysis

J. C. WU¹ and C. C. Wu², (1)Kaohsiung Medical University, Kaohsiung, Kaohsiung, Taiwan, (2)Department of Psychology, Kaohsiung Medical University, Kaohsiung, Taiwan

Background: To date, the association among cognitive ability, symptom severity, and adaptive behavior in young children with autism spectrum disorder (ASD) has been widely discussed and extensively scrutinized. Previous studies have established the significance of the well-documented correlation among these variables, which may influence developmental outcomes in ASD. However, few studies have focused specifically on toddlers with ASD. To investigate whether predictive relationships exist among cognitive ability, symptom severity, and adaptive behavior in toddlers with ASD, and to provide a more precise direction for early interventions, we conducted this study.

Objectives: This study examines the transactional relationships among cognitive ability, symptom severity, and adaptive behavior in toddlers with ASD. Based on previous research findings, we hypothesized that: (1) each variable would predict itself over time; (2) cognitive abilities would predict both autistic symptom severity and adaptive behaviors; and (3) autistic symptom severity would predict both cognitive abilities and adaptive behaviors.

Methods: We recruited 80 toddlers with ASD (69 males, 11 females), aged 18 to 35 months at the first assessment (Time 1, T1), and followed up 18 months later (Time 2, T2), when they were 36 to 54 months old. Assessments at both time points included: (1) cognitive abilities measured by the Mullen Scales of Early Learning (MSEL; Mullen, 1995), with the Developmental Quotient (DQ) calculated to represent cognitive abilities; (2) autistic symptom severity assessed through the Autism Diagnostic Observation Schedule (ADOS; Lord et al., 1999), represented by the sum of scores from the social affect and reciprocal social interaction domains (hereafter, symptom severity); and (3) parent-reported adaptive behaviors using the Adaptive Behavior Assessment System-Second Edition (ABAS-II; Harrison et al., 2003), represented by general adaptive composite score (GAC). A cross-lagged panel analysis examined the interrelationships among the variables across two time points, controlling for chronological age (CA).

Results: After controlling for participants' CA, which was considered a confounding variable, all three cross-lagged models (i.e., DQ and symptom severity, DQ and GAC, and symptom severity and GAC) showed excellent model fit. In terms of temporal stability, the autoregressive paths in all models were significant. In the main analysis of cross-lagged effects, the effect of DQ at T1 on symptom severity at T2 was significant ($\beta = -0.27$, $p = 0.01$), as was the effect of symptom severity at T1 on GAC at T2 ($\beta = -0.24$, $p = 0.02$). However, no significant cross-lagged effects were found in the 'DQ and GAC' model.

Conclusions: The results demonstrate the stability effects among cognitive ability, symptom severity, and adaptive behavior were significant over time in toddlers with ASD. Moreover, we found that cognitive ability significantly predicted symptom severity, and the symptom severity was a significant predictor of adaptive behavior in toddlers with ASD over an 18-month period. These findings underscore the importance of early intervention strategies tailored to the interrelated development of these abilities in toddlers.

440.261 A Novel Approach to Ascertaining Autism Risk from Birth

J. Gargus¹, D. Justus¹, J. Dolinsky¹, J. Limon¹, E. Chao² and I. Smith², (1)NeuroQure, Dana Point, CA, (2)University of California, Irvine, Irvine, CA

Background: Autism spectrum disorder (ASD) has no defined biomarkers for diagnostics or novel drug discovery, though identifying such targets could allow for early, definitive diagnosis of ASD risk, unlocking the opportunity to utilize earlier treatments and meeting developmental milestones nearer to an age-appropriate time. One such potential biomarker includes a functional node of calcium signaling proteins associated with a major synaptic cluster of GWAS-associated ASD loci.

Objectives: We aimed to develop a Ca^{2+} signaling assay that will be adopted as an ASD risk detection test.

Methods: We have previously reported defective IP_3 -mediated intracellular Ca^{2+} release in skin fibroblasts from monogenic ASD syndromes (*fmr1*, *tsc1*, *tsc2*), and identified an associated defect in single channel gating of this ER resident calcium channel. Using novel superresolution imaging technologies to resolve single channel kinetics of the IP_3R within intact cells, we have reported reduced mean open-time (an unstable flicker opening) and therefore low flux, while channel abundance, selectivity, conductance, and latency are unchanged. A high-throughput FLIPR screen was used to image global IP_3 -mediated Ca^{2+} signals from the IP_3R channel.

Results: These were revealed as depressed signals from P2Y purinergic stimuli, first in a broader set of monogenic ASD syndromes, but also in skin fibroblasts from sporadic ASD subjects, validated with research-grade ADOS testing. ROC curves generated from IP_3 -mediated calcium signals in normotypic and autism fibroblasts can distinguish at 84% AUC high sensitivity and specificity for both syndromic and sporadic ASD samples, which signal with a small, slow Ca^{2+} wave, while samples from neurotypical individuals display a fast, large signal.

Conclusions: Therefore, IP_3R signaling appears to be at a node in a signaling pathway at which many forms of ASD are unified into a shared defective output that limits intracellular Ca^{2+} release. Defects in IP_3R signaling could contribute to many of the peripheral phenotypes reported in ASD where that signaling pathway plays key physiological roles, such as GI and immune dysfunctions. IP_3R signaling triggers the final step in axonal synaptic neurotransmitter vesicle release impacting the excitation/inhibition ratio. Importantly, it is also functionally coupled to mitochondrial VDAC channels, serving as the sole source of the rate-setting calcium flux that controls ATP production. Since the ER is also the key cellular stress sensor, it perhaps contributes as the environmental stressor to influence ASD pathogenesis. Together, this suggests ASD is potentially another organellar and channelopathy disease and establishes this IP_3R signal as a biomarker potentially useful as a clinical trial surrogate outcome measure or entry criterion, and in a screen for novel therapeutics. Most importantly, it will be clinically available as a risk detection tool from birth, maximizing access to early interventions. As a preliminary gauge of parental interest in obtaining this biomarker data for autism risk, at the 2024 TACA Annual Conference we offered to test a currently diagnosed child and younger sibling, once it is clinically available. The TACA conference attendees included >900 people, the majority being parents of children with ASD. Our assay was well-received overall, including 31 families who registered for our offer.

440.262 The Role of Camouflaging in Adult Autism Assessments

A. U. Tassone, T. Andrzejewski, K. E. Breitenfeldt and C. G. McDonnell, Department of Psychology, University of Wyoming, Laramie, WY

Background: Camouflaging refers to when an autistic individual engages in strategies to compensate for or mask their autistic traits. As such, others (including possibly clinicians) may not notice ways they are autistic. Researchers and autistic individuals have both identified camouflaging as a potential reason for delayed or missed autism diagnoses (Milner et al., 2019), which may impact self-understanding, delay autistic community connections, and postpone access to support (Riccio et al., 2021). However, little is known about how clinicians think about camouflaging, whether they assess camouflaging behaviors, and ultimately how they use that information to make diagnostic decisions. A better understanding of camouflaging and how it is currently considered in adult autism assessments may ultimately help advance diagnostic practices and improve outcomes for autistic individuals.

Objectives: The present study sought to better understand the role of autistic camouflaging in adult autism evaluations and diagnostic decisions by (1) presenting survey information on how clinicians assess and consider camouflaging behaviors when conducting autism evaluations in adults, and (2) evaluating how autistic adults and diagnosing clinicians differ in their perceptions of autistic camouflaging.

Methods: Participants included 141 autistic adults ($M_{age} = 35.2$ years, 43.3% cisgender men, 66.7% white) recruited through Prolific and 41 diagnosing clinicians ($M_{age} = 34.9$ years, 81.1% cisgender women, 73.0% white) recruited through professional listservs and networks. Clinicians (licensed providers, as well as trainees, residents, and post-docs) were required to have experience diagnosing autism in adults. All participants completed an online survey broadly focused on adult autism assessments and perspectives about camouflaging.

Results: Most clinicians agreed that camouflaging impacts the diagnostic process (87.8%). The majority also reported they assess for camouflaging behaviors in adult autism assessments (73.2%) and discuss camouflaging during the assessment process (73.2%). Nearly 90% of clinicians indicated they discuss camouflaging during the feedback session. Most clinicians felt camouflaging has *not* prevented them from giving an autism diagnosis (60.0%). When comparing autistic adults and clinicians on their perspectives of camouflaging, independent samples *t*-tests revealed the autistic group felt more strongly that camouflaging is essential to both ask about during testing visits ($p = .005$) and discuss during feedback sessions ($p = .001$). There was also a significant group difference in response to the statement positing that camouflaging leads to mental health difficulties, with clinicians rating higher levels of agreement compared to autistic adults ($p = .004$). See Table 1 for a detailed breakdown of these perspectives and practices. A sample of open-ended responses from autistic participants about camouflaging and assessment are included in Table 2. Open-ended responses indicated a broad range of qualitative perspectives regarding definitions of camouflaging (often emphasizing the exhaustion and effort associated with masking), and suggestions for assessing camouflaging.

Conclusions: Both groups indicated they see camouflaging as an important factor in adult autism assessments. However, there were differences between autistic adults' and clinicians' responses, particularly regarding whether asking about camouflaging during evaluations is essential. Autistic open-ended responses provided unique suggestions for how camouflaging should be considered during assessments and future ways that might be accomplished.

440.263 The Trajectory of Diagnostic Rate and Traits of Autism Spectrum Disorder in Children Born Preterm

Y. Nagai¹ and K. Nomura², (1)Department of Neurodevelopmental Disorders, Nagoya City University Graduate School of Medical Sciences, Nagoya, Aichi, Japan, (2)Faculty of Education, Gifu Shotoku Gakuen University, Gifu, Gifu, Japan

Background: We reported that the diagnostic rate of autism spectrum disorder (ASD) in a high-survival Japanese cohort of children born very preterm (<32 weeks of gestation) was as very high as 21% in 2022 and autistic traits of them were similar to those in the children born full term in 2023. In the study, children at age 4-6 years old and their parents were assessed using the Autism Diagnostic Observation Schedule, 2nd edition (ADOS-2) and the Diagnostic and Statistical Manual of Mental Disorders, 5th edition (DSM-5). Many researchers have reported a high prevalence of ASD in preterm infants, but the mechanism and etiology of the disorder remain unclear.

Objectives: We tried to evaluate the trajectory of the diagnostic rate reassessing the children born very preterm and term at the age of 10-12 (fourth through sixth grade of elementary school). Autistic traits were also assessed and compared to the previous study.

Methods: The 77 children born before 32 weeks of gestation and 32 children with ASD (by DSM-5) born term in our previous study were eligible in the study. The children and their parents were recruited for the current follow-up study. Informed consent was obtained from the parents and children of 62 of the 77 in the preterm group and 24 of the 32 in the term group respectively. In addition to ADOS-2 and DSM-5, Autism Diagnostic Interview Revised (ADI-R) was administered in this study. For the trajectory of the diagnostic rate, "confirmed ASD" was defined if a child was diagnosed as both ASD positive in the DSM-5 criteria and autism in the ADOS-2 criteria as in our previous study. In the present study, the new diagnostic rate was considered confirmed when all three of DSM-5, ADOS-2 and ADI-R were positive. This study was approved by the ethics committee of the hospital.

Results: At present 43 parents in the preterm group and 14 in the control group have completed DSM-5 and ADI-R. In DSM-5, 20 and 13 have tested positive and in ADI-R, 9 and 10 have tested positive in the preterm and control group respectively. In our previous study, 20 of the 77 and 15 of the 32 children have tested positive in the preterm and control group respectively.

Conclusions: Currently, more children than in our previous study have tested positive for DSM-5 in the preterm group. More details regarding DSM-5, ADOS-2 and ADI-R will be reported in the day's presentation. We will discuss whether there is a relationship between the trajectory on diagnosis and autistic traits in the preterm group.

440.264 The Use of the Autism Diagnostic Observation Schedule, Second Edition (ADOS-2) with English-Spanish Bilingual Individuals in the United States

M. A. Tafolla¹, N. Benrey Grinberg², N. E. Rosen³, J. E. Lerner⁴ and C. Lord⁵, (1)UCLA, Los Angeles, CA, (2)Psychiatry, UCLA Semel Institute for Neuroscience and Human Behavior, Los Angeles, CA, (3)University of California, Los Angeles, Los Angeles, CA, (4)UCLA Semel Institute for Neuroscience and Human Behavior, UCLA Lord Research Lab, Los Angeles, CA, (5)UCLA Semel Institute for Neuroscience and Human Behavior, Los Angeles, CA

Background: The Autism Diagnostic Observation Schedule, Second Edition (ADOS-2; Lord et al., 2006) is a semi-structured observation that is part of the gold standard battery for informing a clinical diagnosis of ASD (Falkmer et al., 2013). While the ADOS-2 has been translated into more than 20 languages (including Spanish) and validated with monolingual populations, no study has tested the reliability and validity of the ADOS-2 with bilingual individuals. Clinicians are often faced with decisions about which language to assess a bilingual individual in when they are exposed to two different languages, with no objective data to guide them. This is particularly important in diverse countries such as the United States, where Spanish is the most common language other than English (U.S. Census Bureau, 2022) and an estimated 1 in 4 children with autism are believed to be raised in a bilingual environment (Trelles & Castro, 2020).

Objectives: The goal of this study is to assess whether autism symptoms, including social affect and restricted and repetitive behaviors, differ depending on the language of the ADOS-2 administration.

Methods: A total of 86 community-referred English-Spanish bilingual participants with pre-existing autism diagnoses, or concerns about autism, were recruited across Southern California. Participants were all Latinx and mostly from low-income households (>80%). Participants ranged in age from 18 months to 45 years of age and varied in language abilities from no words to fluent sentences. Additional demographic information is included in Table 1. There are five ADOS-2 modules that vary in activities and coding schemes based on age and language abilities; all yield standardized comparison scores (CSS) that account for age and language and can be compared across modules. All participants were randomized to receive the ADOS-2 in Spanish or English first and to which of three English-Spanish bilingual clinicians administered each version. All participants completed both English and Spanish versions of the ADOS-2 across two visits. Most participants completed both administrations within four weeks. Participants chose where the assessment took place, which included a university clinic, their residence, or a community-based setting (e.g., park or library). Assessors were blind to the ADOS-2 scores of the previous administration. In addition to the ADOS-2, we completed cognitive testing and collected demographic information (e.g., sex and primary language spoken in the home). T-tests were used to compare the CSS means between the Spanish and English administrations.

Results: Based on pre-liminary findings, the data suggests there are no significant differences in autism symptom severity scores between the Spanish and the English administrations of ADOS-2 across all modules ($p > .05$; Table 2).

Conclusions: Results demonstrate a lack of differences in autism symptoms observed between Spanish and English administrations of the ADOS-2 with bilingual individuals. It is important, however, that providers continue to provide culturally sensitive care to families across the globe. Next steps include additional analyses focused on testing of reliability while accounting for critical factors like consensus autism diagnosis, IQ and language dominance, which will be included in the final presentation.

440.265 The Utility of Home Video Analysis in New Perspectives of Regression

S. Hakimi, Monash University & Monash Health, Melbourne, VIC, Australia

Background:

Research regarding skills loss in children (developmental regression) is predominantly understood in condition-specific terms and varies in definitions, measures, and standard diagnostic criteria. The resulting variation and lack of clarity for assessment and intervention has prompted research to consider skills-based perspectives that incorporate transdiagnostic approaches to capturing regression. Alternatively, regression can be considered as a symptom or sign in order to identify areas of loss and implement supports while a diagnosis is sought. Appropriate diagnostic tools will therefore need to be dimensional, and this approach can be applied to home video analysis. Clinical use of this tool is limited to date, awaiting research to understand how to optimise video submissions and their yield.

Objectives:

To apply a dimension lens to home videos in order to understand their utility in capturing relevant information for all developmental domains and identifying optimal video types for maximum yield.

Methods:

A selection of 60 home videos of six children (five males) with reported regression were categorised according to video characteristics including duration, featured interactions on screen, context, and activity (indoor/outdoor). Five participants were children with a diagnosis of autism. Following inter-rater reliability calculation and discrepancy resolution, a novel system for relevant developmental domains was applied using a publicly available annotation software. Instances of observed behaviour and failed attempts, as well as absence of responses to prompts were captured to identify opportunities across videos. Qualitative information was recorded through comments about the degree of utility of each video.

Results:

The reported age of regression across the sample spanned from 13 – 36 months. Child age in videos ranged from 0 – 40 months, with videos available before, during, and after reported regression in all participants with ages supplied. All videos in the sample contained observations relevant to the code system, with higher total and average yields in videos of play contexts and those featuring interaction with the filmer. All domains of interest were detected in the sample, however functional and fine motor skills were observed at lower frequencies. More than half of the videos in the sample allowed observations of attention skills (88%), gross motor skills (74%), social skills (66%), and speech/communication skills (62%). Play context videos and videos featuring an interaction with the filmer displayed the highest proportion of relevant observations. Qualitative analysis revealed rich information regarding target developmental domains, engagement, and curiosity in play contexts and a high degree of information in videos featuring instructions for the child from the filmer.

Conclusions:

Findings support the use of home video analysis for the early identification and clinical assessment of developmental regression. Developmental domains that may require alternate tools or specific video recorded tasks, like fine motor skills, were also identified. Video characteristic comparisons can guide video submission protocols that maximise observations, streamline analyses, and lead to standardised approaches for home video analysis. These results are consistent with past research that found home videos to be useful in detecting developmental regression and extend the potential of this tool for new research, training, and clinical purposes.

440.266 Toward New Strategies for ASD Identification in China: Early Results of Psychometric Validation of the Screening Tool for Autism in Toddlers –China (STAT-C)

W. Zheng¹, X. Xiaoling^{1,2}, P. Shum³, X. Xu³, X. Zou⁴, M. Li⁵, Y. Chen⁶, F. Jia⁷, X. Zhang⁸, H. Li⁹, Q. Cheng¹⁰, J. Lin¹¹, W. L. Stone¹², **A. Swanson¹³** and J. Zhang³, (1)The 2nd Affiliated Hospital of Kunming Medical University, Kunming, Yunnan, China, (2)Beijing Chang He Xi International Healthcare Investment Management Corporation Limited (LIH) Healthcare, Beijing, Beijing, China, (3)Children's Hospital of FuDan University, Shanghai, Shanghai, China, (4)The Third Affiliated Hospital, Sun Yat-Sen University, Guangzhou, Guangdong, China, (5)Peking University First Hospital, Beijing, Beijing, China, (6)Xi'an Children's Hospital, Xi'an, Shaanxi, China, (7)The First Bethune Hospital of Jilin University, Changchun, Jilin, China, (8)Tianjin Medical University, Tianjin, China, (9)The Children's Hospital Zhejiang University of Medicine, Hangzhou, Zhejiang, China, (10)Department of Child Health Care, Children's Hospital of Chongqing Medical University, Chongqing, China, (11)Wuhan Children's Hospital, Wuhan, Hubei, China, (12)Psychology, University of Washington, Seattle, WA, (13)Vanderbilt University Medical Center, Nashville, TN

Background: Prevalence of autism spectrum disorder (ASD) is approximately 1% among school-age children in China (Sun et al. 2019), a country with a population of 1.4 billion with 9-11 million babies born annually. While the Autism Diagnostic Observation Schedule (ADOS-2) and Autism Diagnostic Interview-Revised (ADI-R) have been the most widely used standardized tools for autism-focused assessment worldwide, they are not commonly used in China due to time requirements for administration and scoring, high cost of materials and training, and an absence of translation in simplified Chinese. In China, early identification of autism relies on clinician and caregiver completed rating scales (Chu et al. 2022) and expert understanding of DSM-5 criteria (Zhou et al. 2022). The Screening Tool for Toddlers- China (STAT-C) was translated from the original English-language version and assesses key social and communicative behaviors associated with ASD across a 20-minute interactive administration. The algorithm's cutoff score is used to evaluate likelihood for autism presence. Validation of the STAT-C is needed to support its use in China for early identification of ASD.

Objectives: Focus of this work is to determine the appropriate cutoff score for use with Chinese two-year-olds and to examine the psychometric properties of STAT-C.

Methods: The study was conducted across 10 teaching hospitals in China. The validation sample was comprised of 764 children between ages 24 and 36 months, without known genetic/metabolic differences or serious sensory/motor impairment. Providers administering the STAT-C received training and met reliability requirements with certified STAT trainers and had professional experience conducting psychological assessments. The study visit included two parts: Part 1 included STAT-C administration led by a provider certified in the STAT-C. Part 2 included a standard ASD-focused assessment using the Griffiths Mental Development Scale-Chinese (GMDS-C), M-CHAT, CARS-2 and DSM-5 criteria. Part 2 was led by a second provider blinded to results of the STAT-C. Test-retest reliability was conducted on a subset of 30 children with an average time of 17 days between administrations.

Results: Receiver operating characteristic (ROC) analysis was used to test the optimal cutoff score of STAT-C to differentiate the ASD and DD groups in the Chinese sample. Using a cutoff score of >2.0 , analyses showed a sensitivity of autism presence of .80, specificity of .83, and positive- and negative predictive value (PPV; NPV) of .89 and .73 respectively. When analyzed using a cutoff score of equal or greater to 2.0 (cutoff used in the original STAT and T-STAT), sensitivity rose to .85 and specificity decreased to .72, with PPV of .83 and NPV of .75. Test-retest reliability showed a Pearson Correlation Coefficient of 0.77.

Conclusions: Early analyses suggest that the STAT-C possesses acceptable psychometric properties and that 2.0 serves as an appropriate cutoff score to mark likelihood of autism presence. The STAT-C may be a viable option for Chinese providers seeking a standardized instrument to aid in time-sensitive early identification of ASD. Future work will further examine the validation sample and evaluate feedback from Chinese providers on collective perspective of the use of the STAT-C within clinical practice.

**440.267** Towards Promoting Therapeutic Conversation with Autistic Adolescents through Interacting with Automatic and Teleoperated Virtual Robots

Y. Yoshikawa¹, H. Kumazaki², K. Sakai³, S. Mitsuno³, M. Ban³, H. Mahzoon³ and H. Ishiguro⁴, (1)Graduate School of Engineering Science, Osaka University, Toyonaka, JAPAN, (2)Department of Neuropsychiatry, Graduate school of Biomedical Sciences, Nagasaki University, Hirokazu Kumazaki, Nagasaki, Japan, (3)Osaka University, Osaka, NA, Japan, (4)Graduate School of Engineering Science, Osaka University, Toyonaka, Japan

Background: Humanoid robots have gained recognition for their potential to support individuals with autism spectrum disorder (ASD) by providing emotional stability and reducing hesitation in social interactions (Warren et al., 2015; Kumazaki et al., 2018). Recent advances involve two virtual humanoid robots generated through computer graphics (CG), teleoperated by individuals with ASD, which facilitate one-to-one communication training (Kumazaki et al., 2022). In human-robot interaction (HRI) research, it has also been suggested that controlling two robots, one as proxy of a user and the other as a supportive side participant, can help the user self-support their dialogue (Nozawa et al., 2024).

Objectives: This report reviews the author's developments in both physical and virtual robots and discusses the challenges of combining robotic virtual conferencing and automatic dialogue systems to create a more supportive dialogue space.

Methods: The below four systems were developed and reviewed its effects: i) A virtual robotic conferencing system was developed, allowing users to communicate using 3D CG avatars of humanoid robots as their proxies (Yoshikawa et al., 2023). ii) The system was updated with more human-like avatars, aimed at university counseling, where the counselee could select preferred avatars for both him/herself and the counselor. iii) A telecommunication system was created with two physical robot avatars, enabling an operator to use one as a proxy and the other as a supportive side-participant (Nozawa et al., 2024). iv) A chatbot system was developed within popular Japanese messaging apps, providing users with opportunities for casual conversation and encouraging self-disclosure over time.

Results: (i) The virtual conferencing system was implemented in a group-based online training program for individuals with ASD in mock job interviews, improving both verbal and non-verbal communication skills. ii) A user study comparing student counseling scenarios found that the avatar-based system outperformed Zoom in certain aspects, especially in terms of ease of self-disclosure. iii) In an experimental conversation scenario involving rude questions, the dual-robot system helped reduce the operator's discomfort, demonstrating its potential to mitigate stressful social interactions. iv) A user study on the chatbot system showed that gradually deepening conversations over several days decrease reactance to being asked for self-disclosure, indicating the effectiveness of prolonged interaction.

Conclusions: The results from i) and ii) highlight the potential of virtual robots to foster more effective therapeutic conversations between individuals with ASD and their therapists. However, these technologies alone may not be sufficient for the deep self-disclosure required for intensive therapy. The findings from iii) suggest that incorporating a supportive agent in the virtual robot system could enhance the user's conversational experience. The success of iv) suggests that automatic agents collecting disclosures from users and assisting in virtual counseling sessions could be developed. Together, these results indicate a promising direction for creating multi-person dialogue spaces, where parts of virtual robots act as automatic, supportive side participants, ultimately enabling more effective small-group therapeutic sessions for individuals with ASD.

440.268 Toy Selection in the Brief Observation of Symptoms of Autism (BOSA): Parental Choices and Associations with Functional Play and Imagination Scores

K. Michener¹, F. Shic¹, K. J. Dommer², S. Corrigan², E. Olson³, J. Skytta⁴, D. Christakis⁵, S. J. Webb⁵ and A. Ajwani⁶, (1)Center for Child Health, Behavior and Development, Seattle Children's Research Institute, Seattle, WA, (2)Seattle Children's Hospital and Research Institute, Seattle, WA, (3)University of Washington, Seattle, WA, (4)University of Washington School of Medicine, Seattle, WA, (5)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (6)Seattle Children's Hospital, Seattle, WA

Background: Brief Observation of Symptoms of Autism (BOSA) is a brief, direct assessment of autism symptoms by clinicians or parents (Dow et al., 2021). Scoring considers creative use of toys, yet toy selection varies based on clinician/parent preference. How toy selections impact scores are unknown.

Objectives: Determine whether 1) toy selection (TS) correlates to BOSA scoring of C1: Functional Play with Objects and C2: Imagination/Creativity; and 2) ASD versus non-ASD groups differ on TS, BOSA C1, and BOSA C2.

Methods: Toddlers at 24-months-old (n=148) and 36-months-old (n=152) participating in a longitudinal, prospective study of ASD (including low-birthweight infants, with an ASD-sibling, or without known factors increasing autism likelihood) were classified as ASD (n=40), neurotypical (NT; n=112), or with non-ASD atypical development (ATYP; n=36). Our team classified BOSA toy options as having a creativity score of 1 (creative play more likely) or 0 (functional play more likely) and summed each parent-child dyad's selection of up to 6 toys (TS score: range 0-5) (Table 1). We used linear mixed models to assess the impact of TS and age on C1 and C2, allowing for repeat measures. We then modeled effects of diagnosis and age on TS, BOSA C1, and BOSA C2 (Table 2). Pairwise comparisons were conducted to evaluate group differences.

Results: ANOVA of Model 1 revealed a main effect of TS (higher TS led to lower BOSA C1 scores, $p < .001$) and a marginally significant interaction (negative relationship of TS to BOSA C1 stronger at 24-months, $p = .051$). ANOVA of Model 2 revealed a main effect of TS (higher TS led to lower BOSA C2 scores, $p < .001$) and no significant interaction. ANOVA of Model 3 showed main effects of diagnosis (ASD significantly lower TS than ATP and NT, $p < .05$) and age (significantly lower scores at 24-months, $p < .001$) but no significant interaction. ANOVA of Model 4 showed main effects of age (24-months significantly higher C1 score, $p < .001$), diagnosis (ASD significantly higher C1 score than ATP and NT, $p < .001$), and an interaction (such that NT children were the only ones who exhibited no significant age effect between visits, $p > .05$). ANOVA of Model 5 showed main effects of diagnosis (ASD significantly higher than ATP and NT) and age (24-months significantly higher than 36-mo) and a significant interaction (ASD significantly higher than ATYP and NT at 24-months but not significantly different from ATYP at 36-months, and NT significantly lower than ATP at 36-months).

Conclusions: Results show toddlers with access to creative toys have lower (better) BOSA C1 and C2 scores, especially at 24 months. Parents of ASD children selected fewer creative toys compared to neurotypical and atypical peers even at 24 months (typically before diagnostic status was ascertained). This difference lessened by 36 months, suggesting that toy selection may be less critical for older children. Despite equal access to creative toys at 36 months, ASD children still exhibited lower scores than neurotypical peers, in line with expectations that creative toys may not foster imaginative play for ASD toddlers as effectively as for their neurotypical counterparts.

440.269 A Comparison of Diagnostic Outcomes of Autism between DSM-5 and ICD-10 in Very Young Children

H. M. Register¹, H. S. Cheng², D. A. Berger³, D. L. Robins⁴ and A. T. Wiecekowsky¹, (1)Drexel University, Philadelphia, PA, (2)A.J. Drexel Autism Institute, A. J. Drexel Autism Institute, Philadelphia, PA, (3)Psychological Sciences, University of Connecticut, Storrs, CT, (4)A.J. Drexel Autism Institute, Drexel University, Philadelphia, PA

Background:

In anticipation of and shortly following the publication of the American Psychiatric Association's (APA) most recent edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-5; APA, 2013), concerns were raised over the sensitivity of the new criteria for autism diagnosis, specifically regarding young children (Barton et al., 2013; King et al., 2014; Kulage et al., 2014). Comparing prospective application of the DSM-5 to alternate diagnostic criteria, such as the International Classification of Diseases – 10th Revision (ICD-10), may allow us to better understand how diagnostic criteria identify autism in young children.

Objectives:

We aim to examine differences in DSM-5 and the ICD-10 classification of autism and related diagnoses in young children by evaluating participant characteristics and autism severity scores when DSM-5 and ICD-10 disagreement occurs.

Methods:

Data was analyzed for 353 children (239 males) aged 12-60 months ($M=20.97$, $SD=6.62$) from a larger study investigating autism screening in young children. As part of a comprehensive autism evaluation, children were administered the Autism Diagnostic Observation Schedule–2 (ADOS-2; Lord, 2012) which generates Calibrated Severity Scores (CSS) that indicate intensity of autistic characteristics, in addition to assessments of cognitive ability and parent report of adaptive functioning, autism symptoms, developmental history, and family history. Diagnostic labels of Childhood Autism, Atypical Autism, and Asperger's from the ICD-10, and the diagnostic label of Autism Spectrum Disorder from the DSM-5 were considered indicative of autism, whereas all other diagnostic labels were considered to be non-autism conditions.

Results:

McNemar's test revealed significant proportional differences ($p<.001$) between ICD-10 and DSM-5 agreement of autism ($n=108$, 30.6% of cases), ICD-10-only indication of autism ($n=12$, 3.4%), DSM-5-only indication of autism ($n=0$, 0%), and ICD-10 and DSM-5 agreement of non-autism ($n=233$, 66%). In all cases, when disagreement occurred between ICD-10 and DSM-5, ICD-10 criteria indicated autism (atypical autism, $n=7$; childhood autism, $n=5$) and DSM-5 criteria did not indicate autism.

Participant characteristics for agreement and disagreement of both criteria are located in Table 1. For individuals with ICD-10 and DSM-5 disagreement on indication of autism, 91.7% ($n=11$) received the ADOS Toddler Module. In addition, for those in the Disagree group, the median total CSS score was 6 ($M=6.45$, $SD=1.63$), indicative of autism and significantly different from groups with agreement on autism and with disagreement on autism ($p<.001$).

Conclusions:

The ICD-10 and the DSM-5 were concordant in classifying most children with autism or non-autism. However, a small number of participants did not meet DSM-5 autism criteria but did meet ICD-10 criteria, with no cases showing the reverse, suggesting 'narrower' criteria in the DSM-5 compared to the ICD-10, particularly for very young children. This study has implications for prior rates of autism diagnoses and contributes to a larger conversation regarding guidelines for autism diagnosis. This topic is especially timely as researchers and practitioners call for strategies to improve early diagnosis of autism in order to support autistic children's access to autism-specific early intervention.

440.270 Use of the Autism Behavior Inventory Among Students with Autism Spectrum Disorder: Findings from a Longitudinal Cohort Study

B. Hossain^{1,2}, M. G. McDONALD¹, W. O'Keefe¹, F. Widjaja², S. Bent², C. Beavis¹, D. Sheerin¹ and R. Hendren², (1)Oak Hill School, San Anselmo, CA, (2)Psychiatry, University of California San Francisco, San Francisco, CA

Background: Due to the limitations of existing scales to measure change in core symptoms of autism spectrum disorder (ASD), the novel measure of Autism Behavior Inventory (ABI) was recently developed (in 2017) both in full (ABI-F) and short (ABI-S) forms to assess change in core and associated ASD symptoms in children and adults with ASD. Developed as a caregiver-based assessment for clinical trials and practice, to our knowledge, the ABI has not previously been used in the context of specialized ASD schools nor educational interventions where short-term changes in ASD symptoms are important but difficult to measure. Therefore, we introduced the short form of the survey to an existing cohort study measuring ASD outcomes at a specialized ASD school.

Objectives: To measure any significant change in the average parent and teacher-reported ABI-S scores over time for children, adolescents, and adults with ASD.

Methods: This one-year longitudinal cohort study included 24 participants (aged 10-21 years) with ASD from a specialized school and was part of an existing cohort study that was already in effect at the school for five years when the ABI-S was introduced. Evaluations of ABI-S were completed by parents and teachers every 3 months. Repeated measures analysis using mixed-effects models was used to determine significant changes in the mean ABI-S scores across the timepoints. Parent and teacher-reported measures were analyzed separately and the time a participant had been in the broader cohort study was adjusted for.

Results: The mean age for the participants at baseline was 17.1 ± 3.2 years, with males comprising of 92% of the population. On average, there were statistically significant decreases (indicating improvement in symptoms) in the mean parent-reported ABI-S scores over time for all participants with ASD at the school ($b=-0.92$, $p=0.04$). Compared to baseline, parent-reported ABI-S score decreased by 3.6 points after 5 survey timepoints, which corresponds to approximately 1.25 years ($p=0.053$). The average teacher-reported ABI-S scores did not change over time ($p=0.5$).

Conclusions: The improvement in parent-reported ABI-S scores but not in teacher-reported scores is an interesting finding. One possible explanation is that when reporting change, teachers may have viewed autism-associated behaviors through a more precise lens and may have compared them to other students in the classroom, resulting in moderate ratings. From the parents' perspective, the specialized learning environment in the school may have benefited the students, which in turn could have contributed to a less stressful and challenging environment at home and led to better ratings of autism-associated behaviors. Nevertheless, this observed difference in parent ratings (but not teacher ratings) in a relatively short time span suggests ABI-S to be a good caregiver-based assessment that is perhaps more suited to clinical trials (indeed the purpose for which it was developed) rather than for school environments, where change may be more slow and therefore more difficult or elusive to measure. Future studies should have longer term follow-up and larger sample sizes. They could also focus on determining more precise measures of change in outcomes in specialized schools for ASD.

440.271 A Brief Observation to Screen for Autism in Toddlers Based on Socio-Communicative Skills*F. Journal, Department of Psychiatry, University of Geneva, Geneva, Geneva, Switzerland*

Background: Prevalence of Autism Spectrum Disorder (ASD) is estimated at 1 in 36 children in USA. Despite the need to provide diagnoses as early as possible to promote good development of children through appropriate interventions, waiting times before obtaining a diagnosis are long. In this regard, effective and easy-to-administer screening tools in primary care settings are essential, enabling pediatricians to identify children displaying features of ASD earlier, facilitating access to diagnostic and interventions services. Early social skills are pivotal in cognitive and developmental outcomes in early ASD and are the primary target of many early intervention models improving long-term cognitive functioning. The Early Social Communication Scales (ESCS) directly measures early milestones in social and communication development that are part of routine pediatric examination.

Objectives: This study explores fine-grained measures of early socio-communicative behaviors as potential markers for ASD using the Early Social Communication Scales (ESCS) on children under 3 years of age. The aim is to create a tool that is readable and easy to implement in a consultation, based on machine learning techniques.

Methods: This retrospective study analyzed data from 113 children with ASD and 59 with typical development (TD), aged 2.23 (SD=0.51).

Twenty-three ESCS variables were used to predict ASD diagnosis and cognitive developmental patterns. The C5.0 decision tree algorithm was used to classify ASD versus TD. K-fold cross-validation, permutation testing, and undersampling were used for model validation.

Results: The decision tree for ASD diagnosis versus TD achieved 94.77% accuracy, 96.46% sensitivity and 91.52% specificity. Nine ESCS variables were significant in distinguishing ASD from TD. Two variables were found to classify ASD from TD children with good specificity: whether the child initiates ball passes (ISI Initiates Turn Taking) and uses pointing to request objects or actions (IBR Points) but identifying only half the ASD children in our sample. A second group of variables, related to joint attention (IJA Alternates, ISI Initiates Song/Tickle, IJA Eye contact, IJA Points and RJA Following proximal points) improved the model's specificity, achieving over 90% accuracy in classifying TD children. Lastly, response to social interaction behaviors (RSI appeal and RSI Response to invitation) enhance the model's sensitivity.

Conclusions: We provide a promising tool focusing on early socio-communicative behaviors to guide pediatricians through autism screening.

Based only on 9 behaviors to be assessed, the model created is easy for pediatricians to incorporate into their routine, making it easier for them to refer children to specialist services if necessary.

**440.272** Using Low-Level Movement Dynamics during Drawing and Handwriting Tasks to Estimate Nonverbal Cognitive Ability in Minimally Verbal Autism

T. Quattieri¹, J. Williamson², S. C. Yuditskaya³, C. Jafari³, P. Hickey Townsend⁴, M. Pecukonis⁵, L. Sarnie⁶, N. Kosmyna⁷, N. Protyasha⁷, C. J. McDougale⁸, P. Maes⁷, M. Mody⁸ and L. Nowinski⁸, (1)Lincoln Laboratory, MIT Lincoln Laboratory, Lexington, MA, (2)MIT Lincoln Laboratory, Lexington, MA, (3)Lincoln Laboratory, Massachusetts Institute of Technology, Lexington, MA, (4)Psychiatry, Massachusetts General Hospital, Boston, MA, (5)Department of Psychological and Brain Sciences, Smith College, Boston, MA, (6)Lurie Center for Autism, Massachusetts General Hospital, Lexington, MA, (7)Media Lab, Massachusetts Institute of Technology, Cambridge, MA, (8)Athinoula A. Martinos Center for Biomedical Imaging, Charlestown, MA

Background: Difficulty in drawing/writing often reflects fine motor dysfunction in autism spectrum disorder (ASD) associated with cognitive deficits (Green et al, 2016). Given the challenges conducting cognitive assessments in the minimally verbal (MV) ASD population, we developed a method for estimating cognitive ability from movement dynamics in hand drawing and writing tasks, based on the hypothesis that complexity of movement dynamics is an indicator of nonverbal cognitive functioning in MV ASD.

Objectives: Use movement complexity features from shape drawing and handwriting tasks to estimate nonverbal cognitive ability in a population of MV ASD adults.

Methods: Data from 20 MV ASD participants (age 19-32; 12M, 8F) and 18 neurotypical controls (age 19-32; 10M, 9F) were analyzed. MV status was determination as: 1) non-verbal/non-speaking; 2) producing <30 words spontaneously during language sample; and/or 3) Expressive Vocabulary Test (EVT-3) scores ≤1st percentile. Tasks were performed on a Surface Tablet. Drawings consisted of the first 17 shapes from the Beery-Buktenica Test of Visual-Motor Integration 6th Edition (VMI-6), and handwriting consisted of 7 animal words. Time series x,y acceleration values were extracted and segmented into multiple 200ms frames, from which complexity feature vectors were extracted (Talkar et al, 2024; Williamson et al, 2021). Summary statistics of drawing and handwriting were computed by averaging feature vectors across all drawing and handwriting frames per participant. Nonverbal IQ (NVIQ) raw scores, assessed using the Stanford-Binet Intelligence Scales, 5th Edition, Abbreviated IQ, were used as the primary measure of nonverbal cognitive ability, with VMI-6 raw scores from a paper-and-pencil version of the assessment as a secondary measure. Linear regression was used to estimate NVIQ from summary statistics using leave-one-out cross-validation over the pooled data set of 38 participants. Prior to linear regression, principal component (PC) analysis was used to obtain reduced dimensionality, with the number of PCs selected to explain 99% of the variance. Regression modeling was done using three feature sets: 1) shape drawing (4 PCs); 2) handwriting (4 PCs); 3) shape drawing and handwriting (8 PCs). This was done to investigate the utility and complementarity of the motor tasks for estimating nonverbal cognitive ability.

Results: Within-group Pearson correlations of predicted versus measured NVIQ were computed for the ASD and control groups. Statistically significant correlations were not found for features sets (1) or (2). However, feature set (3) resulted in strong, significant correlations of $r=0.58$ ($p=0.015$) and $r=0.62$ ($p=.006$) for the ASD and control groups, respectively. In addition, by summing z-scored NVIQ and VMI-6 into a single outcome measure, stronger correlations were obtained of $r=0.61$ ($p=.004$) and $r=0.62$ ($p=.006$) for ASDs and controls, respectively (Figure 1).

Conclusions: A method was developed for estimating nonverbal cognitive ability in MV ASD adults and controls, based on local-time analysis of acceleration complexity in shape drawing and handwriting tasks. The analysis did not require holistic measurements of drawing and writing outputs or qualitative judgments. It relied only on local-time acceleration dynamics. This method may enable an easy and automated assessment tool for nonverbal cognitive ability in both MV ASD and neurotypical adults.

440.273 Using the Brief Observation of Autism Symptoms (BOSA) to Evaluate Autism Symptoms - Results from the Autism Biomarkers Consortium for Clinical Trials (ABC-CT)

C. DiStefano¹, **M. Sabatos-DeVito²**, **G. Hellemann³**, **S. Faja⁴** and **J. McPartland⁵**, (1)Children's Hospital Los Angeles, Los Angeles, CA, (2)Department of Psychiatry and Behavioral Sciences, Duke University, Durham, NC, (3)UCLA, Los Angeles, CA, (4)Boston Children's Hospital Laboratories of Cognitive Neuroscience, Brookline, MA, (5)Yale Child Study Center, Yale Child Study Center, New Haven, CT

Background:

During the COVID-19 pandemic, social distancing requirements forced research and clinical groups to use novel methods for evaluating autism symptoms. As Autism Diagnostic Observation Schedule (ADOS-2) scores are considered invalid if administered while wearing personal-protective equipment, alternate measures were often utilized. The Brief Observation of Symptoms of Autism (BOSA) is an assessment that provides a standardized, naturalistic social context via a series of parent-child activities and observed by the clinician remotely (Dow et al., 2021). Observed behaviors are interpreted within the framework of ADOS-2 codes, allowing for consistent measurement of autism symptoms. Using a validation sample of 307 participants, BOSA diagnostic score cutoffs were determined, which yielded sensitivity and specificity rates similar to the ADOS-2 (Dow et al., 2021). Replication in new samples is crucial to inform the interpretation of this novel but widely-used measure. The longitudinal follow-up phase of the Autism Biomarkers Consortium for Clinical Trials (ABC-CT) provided an ideal opportunity to examine the performance of the BOSA in a large sample of well-characterized children with autism along with a neurotypical comparison group.

Objectives:

1. Evaluate the sensitivity and specificity of BOSA diagnostic categorization compared with clinical best estimate DSM-5 diagnosis and standardized diagnostic assessment (Childhood Autism Rating Scale-2 [CARS-2]).
2. Examine the association between BOSA category and clinical characteristics (verbal/non-verbal cognition, internalizing/externalizing behavior).

Methods:

The ABC-CT enrolled children with autism or neurotypical development across five sites (McPartland et al., 2020). See table 1 for sample characterization. The first three study timepoints (prior to the COVID-19 pandemic) included direct assessment of autism symptoms (ADOS-2) alongside other clinical and biomarker measures. A fourth longitudinal timepoint (T4) occurred during the COVID-19 pandemic (1-5 years after initial study participation), during which participants completed the BOSA. The CARS-2 was completed based on the totality of parent report and direct assessment/observational information at T4. Sensitivity and specificity were evaluated by comparing the BOSA diagnostic categorization to DSM-5 diagnosis confirmed at the earlier study timepoints and T4 CARS-2 categorization. *ANOVAs* were used to compare clinical characteristics between BOSA diagnostic groups.

Results:

BOSA categorization yielded high sensitivity (86-100%) and specificity (79%-96%) with reference to DSM-5 diagnosis, consistent with the Dow, et al. (2021) validation sample (Table 2). With reference to CARS-2 categorization, sensitivity was high (87%-100%) and specificity was moderate-high (61%-92%). BOSA scores were independent of verbal and non-verbal IQ score but showed strong associations with internalizing and externalizing behavior as measured with the BASC ($p < .001$).

Conclusions:

While our sensitivity and specificity may have been increased due to the fact that our sample had already undergone research diagnosis confirmation, it is nonetheless encouraging that we replicated the initial BOSA validation results and BOSA diagnostic categories were unrelated to verbal or non-verbal cognition. Further research is needed to examine the association between BOSA category and internalizing/externalizing behavior, and to determine whether "false positives" in the neurotypical group may be due in part to the presence of mental health concerns (e.g. anxiety, depression) that may have newly manifest as participants aged into adolescence between study timepoints.

**440.275** Virtual Autism Assessment Measure for Underserved Communities

N. Benrey Grinberg¹, **M. Tafolla Magana²**, **J. E. Lerner³**, **P. Maes⁴**, **N. Schisterman⁵**, **N. E. Rosen²** and **C. Lord⁵**, (1)Psychiatry, UCLA Semel Institute for Neuroscience and Human Behavior, Los Angeles, CA, (2)University of California, Los Angeles, Los Angeles, CA, (3)UCLA Semel Institute for Neuroscience and Human Behavior, UCLA Lord Research Lab, Los Angeles, CA, (4)Department of Psychological and Brain Sciences, Boston University, Boston, MA, (5)UCLA Semel Institute for Neuroscience and Human Behavior, Los Angeles, CA

Background: Telehealth assessment for autism could facilitate early identification and intervention, especially within underserved communities as they face increased barriers to assessment and care (Maenner et al., 2020; Shenouda et al., 2022). Preliminary data suggests that the Brief Observation of Symptoms of Autism (BOSA) is a promising virtual autism screener that has good convergence validity with the Autism Diagnostic Observation Schedule (ADOS-2). In a recent study, BOSA sensitivity and specificity ranged from .86-.98 and .7-1.0, respectively (Dow et al., 2022). The BOSA consists of a 12-to-14-minute video recording of a natural social interaction between the individual and examiner. The recording is then rated by a clinician trained in the ADOS-2 (Dow et al., 2022; Stroupková et al., 2024).

Objectives: The purpose of the study was to evaluate the psychometric properties of the BOSA with a Spanish-speaking sample.

Methods: Spanish BOSA recordings were collected from 70 Hispanic American individuals living in Southern California, ages ranging from 18-months to 45-years of age. As part of a larger study, participants were also assessed with a caregiver developmental interview and through direct observation from an ADOS-2 administration. From this sample, preliminary analyses were run for 34 BOSA recordings collected from 16 minimally verbal (12 ASD, 5 females) and 17 verbally fluent individuals (14 ASD, 5 females). A Receiver operator characteristic (ROC) curve was computed for the BOSA algorithm total to determine how well the measure differentiates between ASD and nonspectrum groups. Interrater reliability was examined for 10% of these videos (as done by Dow et al., 2022).

Results: The area under the curve was .73 (95% CI [.54, .93]) and significant ($p = .02$), indicating acceptable discrimination between groups. At the optimal threshold, the sensitivity was 0.72, while the specificity was .56. Interrater reliability was assessed using Cohen's Kappa, values ranged from 0.41 to 0.81, indicating fair to strong agreement between raters. Average Kappa across all coding sessions was 0.65.

Conclusions: While preliminary, the BOSA holds clinical promise in increasing accessibility to autism assessment as it can be delivered by several people (e.g., teacher, caregiver, or paraprofessional) across different settings. This flexibility promotes early identification and intervention, particularly in underserved communities that encounter greater obstacles to obtaining timely evaluations and care (Maenner et al., 2020; Shenouda et al., 2022). Of note, given its specificity, the BOSA works well as a screener but not as a diagnostic measure. Currently, the BOSA is also limited by the requirement that its rating be done by an ADOS-2 trained clinician. Replication of analyses with our entire sample will be done by the time of presentation.

440.276 Shape Drawing As a Potential Screening Technique for Children with Autism Spectrum Disorder

H. Kumazaki¹, Y. Ohmoto², K. Tazoe³, H. Shimizu⁴, ユ, テシマ⁵, K. Terada⁵ and R. Iwanaga⁶, (1)Department of Neuropsychiatry, Graduate school of Biomedical Sciences, Nagasaki University, Hirokazu Kumazaki, Nagasaki, Japan, (2)Shizuoka University, Hamamatsu, Shizuoka, Japan, (3)Department of Neuropsychiatry, Nagasaki University, School of Medicine, Nagasaki, Nagasaki, Japan, (4)Department of Neuropsychiatry, Nagasaki University Hospital, Nagasaki, Nagasaki, Japan, (5)Gifu University, Gifu, Gifu, Japan, (6)Graduate School of Biomedical Sciences, Nagasaki University, Nagasaki, Japan

Background:

Autism spectrum disorder (ASD) is often associated with early developmental delays in fine motor skills. They often show deficits in writing and drawing, which are important skills for their social adaptability. ASD is often associated with early developmental delays in fine motor skills. Machine learning technologies have rapidly developed in recent years. Among these, neural network technology has had a significant impact in various fields, such as movie recognition. Given that machine learning can be a powerful technique for predictive models learning from movement data, it is possible to objectively evaluate the drawing process and product characteristics using movies and machine learning. We developed a new approach to ASD screening based on the task of drawing an equilateral triangle and its evaluation using machine learning. Furthermore, to deepen our interpretation of the results obtained from drawing triangles, and considering the difficulties in executive function and specificity in visual working memory in children with ASD, we proposed the idea of assessing the drawing of inverted equilateral triangles, squares, and suns. In this study, we conducted an experiment in which almost all eligible residents (approximately 99%) in a chosen city could participate.

Objectives:

The objective of this study was to assess the effectiveness of evaluating drawings of an equilateral triangle, an inverted equilateral triangle, a square, and a sun using machine learning for ASD screening.

Methods:

Forty-three males and 36 females participated in the study. The participants were asked to draw each shape in the following order: an equilateral triangle, an inverted equilateral triangle, a square, and a sun. The model for classifying whether participants were suspected of having ASD was developed using a support vector machine (SVM) algorithm with a radial basis function kernel, utilizing 16 explanatory variables. A 16-inch LCD pen tablet was used to acquire data on hand-finger fine motor activity while the participants were drawing each shape. To estimate eye movements while drawing each shape, facial images were acquired using a webcam placed on top of an LCD pen tablet. From these data, we identified the explanatory variables used to model the SVM.

Results:

For each shape, a model of SVM could be created with an accuracy, sensitivity, and specificity all above 80%. Furthermore, combining four classification models yielded a greater accuracy and specificity (above 90%) than individual classifications. There were significant relationships between the probability output of the SVM classification model and total SRS score.

Conclusions:

These results demonstrate the effectiveness of assessing shape characteristics using machine learning for ASD screening. Future studies with a wider variety of shapes are warranted to further establish the potential efficacy of using drawing skills to screen for ASD.

440.277 Intervention Using Android Robot for Individuals with Autism Spectrum Disorders

H. Kumazaki, Department of Neuropsychiatry, Graduate school of Biomedical Sciences, Nagasaki University, Hirokazu Kumazaki, Nagasaki, Japan

Background: Self-disclosure is the process by which people reveal personal information about themselves to others and is important in all types and stages of social relationships. Reciprocity via effective self-disclosure can lead to positive outcomes in initial interactions and promote further disclosure and relationship building. Individuals with ASD sometimes hesitate to disclose information to others due to challenges in understanding such interchanges or recognizing the potential value in relational reciprocity, as well as differences in social motivation. An android robot (Figure 1) is a humanoid robot with an appearance and movements resembling those of an actual human. It can exhibit a variety of facial expressions during speech and provide subtle nonverbal cues. It is very similar to human but, since it is a robot, it is still much simpler than humans. There is increasing anecdotal evidence for the fact that individuals with ASD may have unique opportunities to use android robots to assist them. Given the affinity between android robot and individuals with ASD, there is a possibility that interview by android robots in place of human interviewers can result in a higher degree of task engagement for individuals with ASD by reducing their social anxiety and helping their imagination and creativity. Given these factors, it is possible that interactions with android robots are linked to promoting self-disclosure by these individuals.

Objectives: The objective of this study was to investigate whether interview by android robot can prompt self-disclosure for individuals with ASD.

Methods: 21 young adults with ASD (Male: 17. Female 4: 21.3 ± 5.1) participated in the study. We compared the difference in disclosure statements and subjective emotion in interview setting by an android robot and a human interviewer. In addition, we assessed the subjective emotions in interview setting. Our quantitative data suggested that interview by android robot promoted more self-disclosure, especially about the negative topic compared to interview by a human interviewer. In addition, the level of participant embarrassment in response to addressing by the android robot seemed to be lower compared to that in the human interviewer condition.

Results: All participants completed the trial procedures without technological challenges or distress that could lead to session termination. Our quantitative data suggested that interview by android robot promoted more self-disclosure, especially about the negative topic compared to interview by a human interviewer and that written on test paper. In addition, the level of participant embarrassment in response to addressing by the android robot seemed to be lower compared to that in the human interviewer condition.

Conclusions: In the assessment and support for individuals with ASD, eliciting self-disclosure is a pressing issue. It is hoped that the appropriate use of robots will lead to a better understanding and support for their application.

440.278 The Psychometric Qualities of the a-Sleep

R. T. Nauta¹, M. L. Bezemer² and E. M. Blijd-Hoogewys³, (1)INTER-PSY, Groningen, Groningen, Netherlands, (2)INTER-PSY, Groningen, Netherlands, (3)Psychiatrie Noord, Groningen, Netherlands

Background:

Sleep disturbances are common among adults with ASD, affecting 50-80% (Carmassi et al., 2019). These issues worsen autistic behaviors, increase anxiety, and contribute to emotional and behavioral difficulties. Sleep problems are the strongest predictor of lower quality of life in individuals with ASD (Deserno et al., 2019). The A-Sleep questionnaire (80 items) was designed to assess sleep problems specific to adults with ASD, based on literature and input from ASD professionals and individuals with ASD.

Objectives:

To evaluate the psychometric properties of the A-Sleep questionnaire.

Methods:

Retrospective data were collected from an ASD diagnostic process at a mental health institution. Self-report questionnaires used included the A-Sleep, BRIEF-A (for divergent validity), HSDQ (for convergent validity), M-ASD (for construct validity), and AQ-10 (to screen for ASD traits in the control group).

The study involved 177 adults divided into three groups: a clinical group ($n = 122$), consisting of those diagnosed with ASD ($n = 68$) and those without ASD ($n = 54$), and a control group ($n = 55$) recruited from the general population via social media. Control group exclusion criteria included self-reported ASD or an AQ-10 score above 5.

Reliability was assessed with Cronbach's alpha, and test-retest reliability was evaluated with Pearson's correlation. Convergent and divergent validity were also measured using Pearson's correlation, and group differences in A-Sleep scores were analyzed using one-way ANOVA. Factor analysis was used to refine the questionnaire.

Results:

The A-Sleep demonstrated excellent internal consistency (Cronbach's $\alpha = .914$) and strong test-retest reliability ($r = .89$, $n = 45$, $p < .001$).

Construct validity was supported by a moderate correlation with the M-ASD ($r = .48$, 95% BHI = .33-.60). Significant differences in A-Sleep scores were found between groups, with the ASD group reporting the highest sleep problems, followed by the non-ASD clinical group and the control group (ANOVA, $p < .001$, $\eta^2 = .282$).

Strong convergent validity was observed with a high correlation to the HSDQ ($r = .88$, 95% BHI = .83-.92), and weaker correlations with the BRIEF-A scales supported divergent validity. Factor analysis in the clinical group ($n = 99$) explained 45% of the variance, refining the A-Sleep into a 30-item version, the A-Sleep-R. The four identified factors were: insomnia (8 items, $\alpha = .835$), late sleeping (6 items, $\alpha = .829$), sleep quantity and consequences (10 items, $\alpha = .839$), and sleep-related anxiety (6 items, $\alpha = .844$).

Conclusions:

The A-Sleep is a reliable and valid self-report tool for assessing sleep problems in adults with ASD, with excellent internal consistency, strong test-retest reliability, and solid convergent and divergent validity. It effectively differentiated clinical and control groups, and the factor analysis led to the development of a more efficient 30-item version, the A-Sleep-R. This refined tool is suitable for use in both research and clinical practice to assess sleep disturbances in adults with ASD.

440.279 Psychometric Properties of the M-ASD Questionnaire

H. Sluis¹, M. L. Bezemer² and E. M. Blijd-Hoogewys³, (1)INTER-PSY, Groningen, Netherlands, (2)Psychiatrie Noord, Groningen, Netherlands

Background:

Autism spectrum disorder (ASD) in adults, particularly in females, is often under-recognized due to subtler manifestations, such as less pronounced social-communication difficulties and repetitive behaviors (APA, 2022; Hull et al., 2020). Timely identification of ASD can lead to improved long-term outcomes, prevention of secondary issues, reduced family stress, and lower societal costs (Garcia-Primo et al., 2014). The M-ASD questionnaire, a Dutch 50-item screening tool, was developed to better capture these more elusive presentations of ASD (Grondhuis et al., 2020).

Objectives:

To validate the M-ASD questionnaire in both a clinical setting and a control group.

Methods:

Retrospective diagnostic data were analyzed from 1260 adults suspected of having ASD who were referred to a general mental healthcare institution. Participants underwent comprehensive ASD assessments, which included the M-ASD, AQ-50, and BRIEF-A screening questionnaires. Of these, 63% received an ASD diagnosis (62% women). A subgroup of 39 participants was retested with the M-ASD within 2–8 weeks. Additionally, 181 adults from the general population (84% women) completed the M-ASD and AQ-10. Internal consistency of the M-ASD was evaluated using Cronbach's α , while construct validity was assessed via Pearson's r and T-tests. Criterion validity was tested using ROC analysis (sensitivity, specificity, PPV, NPV), and test-retest reliability was determined by Pearson's r .

Results:

The M-ASD showed excellent internal consistency (Cronbach's $\alpha = .955$) and strong test-retest reliability ($r = .924$, 95% CI [.859, .960]). Convergent validity was supported by a significant correlation with AQ-50 ($r = .760$, $p < .001$, 95% CI [.736, .782]), while divergent validity was indicated by weaker correlations with the BRIEF-A subscales Organization of Materials ($r = .194$, $p < .001$, 95% CI [.135, .252]) and Task Monitor ($r = .282$, $p < .001$, 95% CI [.225, .337]). The M-ASD effectively distinguished between ASD, non-ASD, and control groups (large to very large effect sizes). In the clinical ASD vs. non-ASD comparison, the M-ASD achieved 59% sensitivity, 79% specificity, 83% PPV, and 52% NPV (AUC = .734, 95% CI [.709, .758], $J = .3775$). When comparing clinical ASD with the control group, sensitivity was 93%, specificity 100%, PPV 100%, and NPV 75% (AUC = .989, 95% CI [.980, .994], $J = .9249$).

Conclusions:

The M-ASD demonstrated robust psychometric properties, including excellent internal consistency, test-retest reliability, and strong validity measures. However, the tool missed 48% of ASD classifications in the clinical group, underscoring the need for comprehensive diagnostic approaches beyond a single questionnaire. The relatively higher age and greater proportion of women in the control group may have impacted results. Overall, the Dutch M-ASD is a valuable screening tool for ASD with tailored cut-offs for clinical and general population use.

440.280 Validation of the TSC-Associated Neuropsychiatric Disorders Self-Report Quantified Checklist (TAND-SQ)

N. Chambers¹, T. M. Heunis², L. De Waele³, E. Campbell¹, L. Schlebusch¹, A. C. Jansen¹ and P. J. de Vries¹, (1)Centre for Autism Research in Africa, Division for Child and Adolescent Psychiatry, University of Cape Town, Cape Town, South Africa, (2)Vrije Universiteit Brussel, Brussel, Capital Region, Belgium, (3)Department of Paediatric Neurology, University Hospitals Leuven, Leuven, Flemish Brabant, Belgium, (4)Mental Health and Wellbeing Group, Vrije Universiteit Brussel, Brussels, Belgium

Background: Tuberous Sclerosis Complex (TSC) is a rare genetic condition with high rates of associated neuropsychiatric disorders (TAND), including autism. A self-report quantified checklist for TAND (TAND-SQ), was recently developed. It includes 33 items making up seven natural TAND clusters (including an autism-like cluster). Each item is rated as having ever been present to generate cluster scores (CS), and given a severity rating (over the last month) to generate cluster severity scores (CSS) and a total TAND severity score (TTSS).

Objectives: This study aimed to validate the CS, CSS and TTSS of the TAND-SQ.

Methods: We used a descriptive group design and two convenience samples with existing relevant independent clinical data from the TSC Alliance Natural History Database (NHD) in the USA ($n=69$), with documented clinical diagnoses (including autism), and from the Developmental Synaptopathies Consortium Rare Diseases Clinical Research Network (RDCRN) study based at the Boston and Cincinnati Children's Hospitals ($n=23$). The RDCRN group had a range of widely-used standardised, behavioural measures and systematic autism diagnostic evaluations. We used Cronbach's alpha (α) to assess the reliability of the items within each cluster, and Spearman's correlations (ρ) to examine relationships between TAND-SQ scores, diagnoses and behavioural measures.

Results: We found acceptable internal consistency for the CS ($\alpha = .67-.89$) and CSS ($\alpha = .76-.95$), for all but the eat/sleep cluster. Most CS and all CSS were significantly correlated to corresponding clinical diagnoses reported in the TAND-SQ, with strong positive relationships observed for the autism-like CS and CSS and a diagnosis of autism ($\rho = 0.75$, $p < .001$ for both scores). The TTSS was significantly correlated to a global self-rating of TAND burden reported in question 10 of the TAND-SQ ($\rho = 0.75$, $p < .001$). In the RDCRN cohort, we found significant correlations between the CS, CSS, and TTSS and scores on a range of relevant standardised behavioural measures. The autism-like cluster CS and CSS were significantly correlated with measures of autism symptoms on the ADOS-2 ($\rho = 0.55$, $p < .033$ and $\rho = 0.58$, $p < .024$ respectively) and the Social Responsiveness Scale Social Communication Index ($\rho = 0.62$, $p = .007$ and $\rho = 0.66$, $p = .009$ respectively). The TTSS was significantly correlated with the Vineland-3 Adaptive Behavior Composite ($\rho = -0.75$, $p < .001$) and the Child Behavior Checklist ($\rho = 0.71$; $p = .001$). The autism-like CS was significantly associated with clinical autism diagnoses reported in the NHD cohort ($\rho = .64$, $p < .001$) and with systematic expert research diagnoses in the RDCRN cohort ($\rho = .48$, $p = .019$).

Conclusions: Findings support the internal consistency and convergent validity of the CS, CSS and TTSS of the TAND-SQ, including the autism-like cluster. Results suggest that the TAND cluster scores may be useful for guiding clinical decision making and care for individuals with TSC. For patients with high symptom burden, CSS might help families prioritise further evaluations for TAND. For patients with low symptom burden, endorsing any item should still prompt further referrals. Findings support further research of the TAND-SQ as a measure of natural TAND trajectories over time and as a possible behavioural outcome measure for TAND interventions.

Poster Session**441 - Digital Health Research or Technology Demonstration II**

May 3rd, 2025, 12:30 PM - 1:30 PM - Hall 4A

441.281 A Mobile-Health Project to Reduce the Tand Identification and Treatment Gap (TANDem) - Feasibility and Acceptability of the Tand Toolkit App

T. Heunis¹, N. Chambers², L. De Waele³, E. Campbell³, L. Schlebusch², A. C. Jansen^{1,4,5} and P. J. de Vries², (1)Mental Health and Wellbeing Group, Vrije Universiteit Brussel, Brussels, Belgium, (2)Centre for Autism Research in Africa, Division for Child and Adolescent Psychiatry, University of Cape Town, Cape Town, South Africa, (3)Department of Paediatric Neurology, University Hospitals Leuven, Leuven, Flemish Brabant, Belgium, (4)Department of Translational Neurosciences, University of Antwerp, Antwerp, Belgium, (5)Department of Pediatrics Koningin Mathilde Moederen Kindcentrum, Antwerp University Hospital, Antwerp, Belgium

Background: Tuberous Sclerosis Complex (TSC) is a rare genetic condition with high rates of TSC-associated neuropsychiatric disorders (TAND), including autism. TAND significantly impact the mental health of individuals with TSC and their caregivers, yet are often not identified or managed. The TANDem project was developed in partnership with families to reduce the TAND identification and treatment gap through a technological solution. The project aims included 1) the development and validation of a self-report quantified TAND Checklist (TAND-SQ) built into a mobile application (app), and 2) generation of consensus clinical recommendations for the identification and treatment of TAND, to be incorporated as a TAND toolkit in the app.

Objectives: The focus of this study was to evaluate the feasibility and acceptability of the TAND Toolkit App to TSC stakeholders.

Methods: The mobile app and the TAND toolkit were initially developed separately. In a formative phase, the app and the toolkit were evaluated individually by multiple stakeholder groups using rapid user acceptance evaluation feedback and revision loops. The app was evaluated by the TAND consortium (n=11), and caregivers and individuals with TSC from Boston Children's Hospital and Cincinnati Children's Hospital (n=23) using an in-app feedback form. The TAND toolkit was evaluated by members of the TAND consortium (n=19), and caregivers and individuals with TSC from the TSC Alliance and TSC International (n=11+6) via an electronic toolkit feedback form. Members of TSCi (n=33) also participated in an in-person focus group. The app and toolkit were then integrated into the TAND Toolkit App and evaluated in a summative phase by a group of Belgian caregivers and individuals with TSC recruited through the Belgian TSC support organisation (be-TSC) using an app feedback form (n=10), toolkit feedback form (n=20), and online focus group (n=3).

Results: The formative evaluation phase yielded a wealth of suggestions for changes that were then incorporated into subsequent rounds of reviews. Pooling the quantitative feedback from both the formative and summative phases, for the app (n=44) 91% of users tested the app on a smartphone (66% iOS users) and 9% a tablet/iPad. The majority (91%) rated the language in the app easy to understand, liked the app user interface, and found the steps for progressing through the app logical, with an overall app rating of 91%. For the toolkit (n=56), most participants rated the information for each TAND cluster as 'helpful' or 'very helpful': autism-like = 91%, dysregulated = 88%, eat/sleep = 89%, mood/anxiety = 89%, neuropsychological = 89%, overactive/impulsive = 93%, scholastic = 84%, and psychosocial = 86%, with an overall acceptability rating of 86% for the toolkit. The majority of Belgian families (75%) gave the integrated TAND Toolkit App a 4- or 5-star rating. Qualitative feedback highlighted the need for multilingual functionality and for flexibility to use the app on a mobile device or a computer.

Conclusions: The TAND Toolkit App is a feasible and acceptable mobile-health information app for families and individuals with TSC. Some additional features may make it more feasible for global use.

441.282 Acceptability and Feasibility of a Digital Remote Measurement System for Autism and Co-Occurring Conditions

I. Yorke¹, A. Roy Choudhury², B. Oakley³, P. Conde², Y. Ranjan², H. Sankesara², Z. Rashid², N. Cummins², A. Folarin², R. Dobson², E. Loth¹, J. K. Buitelaar⁴, D. Murphy⁵ and E. Simonoff⁶, (1)Child and Adolescent Psychiatry, King's College London, London, England, United Kingdom, (2)Department of Biostatistics & Health Informatics, Institute of Psychiatry, Psychology & Neuroscience, King's College London, London, England, United Kingdom, (3)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (4)Department of Forensic and Neurodevelopmental Sciences, Flat 2, 116, South Hill Park, London, London, United Kingdom, (5)Department of Cognitive Neuroscience, Donders Institute for Brain, Cognition and Behaviour, Radboud University Nijmegen Medical Center, Nijmegen, NETHERLANDS, (6)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, UNITED KINGDOM, (7)Institute of Psychiatry, Psychology and Neuroscience, Institute of Psychiatry, London, United Kingdom

Background:

Advances in treatment development for issues affecting the everyday lives of autistic people (e.g., mental health and sleep problems) are hampered by the limitations of conventional outcome measures (e.g., potential for bias in patient-reported outcomes). Digital remote monitoring technology (RMT) offers opportunity for low-burden collection of subjective and objective data during everyday life. However, applicability of such technology in autism research depends on its acceptability to autistic participants, and the feasibility of implementation in clinical research.

Objectives:

We aimed to develop a novel RMT system to collect data on autistic traits, sleep, mood, and attention, and to evaluate its acceptability and feasibility among autistic and non-autistic smartphone users.

Methods:

We invited autistic and non-autistic participants in the Longitudinal European Autism Project (aged 12 and older; independent Android smartphone users) to enrol in a 28-day “Mobile Measures Month”. Our system (using the RADAR-base mobile health research platform; Ranjan et al., 2019) involved wearing a Fitbit Inspire 2 device and downloading several smartphone applications. Two applications enabled active daily reporting (e.g., on sleep quality, mood, and attention). A third application collected data from smartphone sensors (e.g., app usage, call and messaging logs, and location) passively. At the end of the month, participants completed the System Usability Scale (SUS; Brooke, 1996) to indicate the overall usability of the system. Total SUS scores have a possible range of 0-100. Scores exceeding 70 are considered to indicate acceptable usability, above 75 indicate good, and above 85 indicate excellent usability. Data acquisition for this study is complete and data analysis is underway.

Results:

Of 82 LEAP participants screened for eligibility, 41 (48.7%) were eligible, with most ineligible participants being iPhone users (n=34). Of those eligible, 32 (78%) consented and nine (22%) declined, with reasons including data privacy concerns (n=1) and anticipated daily reporting burden (n=3). Including 18 additional participants following an alternative recruitment path, 47 (34 autistic) participants enrolled and 46 (97.9%) continued participation in at least one component throughout the 28 days (see Figure 1). Preliminary analyses show that of a possible 28 sleep quality reports requiring daily completion, participants completed an average of 21.9 (standard deviation 7.79; range 2-28). Mean SUS for autistic participants and 81.1 (SD 11.6; range 62.5-95.0) for comparison participants. The difference between groups was not significant ($t=-1.7$; $df=32$; $p=.099$). Adherence to wearing the Fitbit was variable (see Figure 2) and patterns will be explored further. Availability of passive smartphone data, and associations of acceptability and adherence data with participant characteristics will be explored.

Conclusions:

Most eligible participants consented to and completed the study, and usability ratings were favourable. Compatibility of smartphone applications across operating systems was a considerable barrier to feasibility; however, preliminary findings show this application of RMT to be largely acceptable among the autistic smartphone users in this study. Further analysis will yield insight into participant characteristics that may affect acceptability, laying important groundwork for future studies using RMT in autistic populations.

441.283 An Exploratory Study of Cardiac Synchrony and Joint Engagement in Parent-Child Dyads of Autistic and Neurotypical Children

N. Yamane¹, **H. Lansberry²** and **M. S. Goodwin¹**, (1)Northeastern University, Boston, MA, (2)Chicago College of Osteopathic Medicine, Downers Grove, IL

Background: Research on dyadic physiological synchrony in children with autism spectrum disorder (ASD) compared to neurotypical children has yielded mixed results, generally indicating reduced or atypical synchrony in ASD. Understanding these patterns has important implications for identifying biomarkers and developing social interventions. Further research can clarify how physiological processes contribute to synchrony and how synchrony patterns vary across contexts.

Objectives: We aimed to understand the role of heart rate variability (HRV) as a putative physiological mechanism underlying parent-child joint engagement (JE) by: 1) Assessing whether parent-child dyads with and without ASD differ in trend and concurrent HRV synchrony; 2) Investigating whether trend and concurrent HRV synchrony predict JE during play.

Methods: We obtained behavioral and cardiac data from video and ambulatory electrocardiograph (ECG) recordings in 11 parent-child dyads with ($n=5$; M[SD]: 4.1[1.2 years) and without ASD ($n=6$; 3.3[1.0 years) while engaged in a 15-minute dyadic play task in the enTRAIN study. The enTRAIN study assessed interpersonal physiological dynamics through semi-structured socioemotional regulation tasks and parent-report questionnaires. Each dyad received the same set of toys and was instructed to play together as they would at home, while parent and child ECGs were recorded simultaneously with the chest-worn Actiwave Cardio (CamNtech). ECG data were pre-processed into interbeat intervals to extract the HRV root mean square of successive differences (RMSSD). We then quantified trend and concurrent HRV synchrony as low- (LF) and high-frequency (HF) wavelet coherence of parent and child RMSSD, respectively. Dyadic proximity was calculated from video using three-dimensional pose estimation with popular deep learning models. Supported and Coordinated JE events were independently annotated in Datavyu by blinded, reliable raters (90% agreement, Gwet's $AC_1=.88$) according to Bakeman and Adamson's (1984) State-Based Joint Engagement scheme. To assess differences in trend/LF and concurrent/HF HRV synchrony between dyads with and without ASD, we used linear mixed-effects models (LMMs), accounting for repeated HRV synchrony measures within each dyad. To examine whether parent-child HRV synchrony predicts JE, we used Bayesian mixed-effects multinomial logistic regression models (MEMLR) with four Markov chains and 2000 iterations, normal priors for fixed effects, and Cauchy priors for random effect standard deviations.

Results: Our LMMs revealed no effect of ASD diagnostic status on either trend ($\beta=.01$, $p=.78$) or concurrent ($\beta=.02$, $p=.24$) HRV synchrony. Similarly, MEMLR models showed no effect of ASD diagnostic status on Supported or Coordinated JE outcomes. However, a greater HRV synchrony was associated with a reduced likelihood of Supported JE ($OR=.60$) and an increased likelihood of Coordinated JE ($OR=5.04$). Greater concurrent HRV coherence was also associated with a reduced likelihood of Supported JE ($OR=.47$) but not linked to Coordinated JE. Across all models, reduced dyadic proximity was associated with increased likelihoods of both Supported and Coordinated JE.

Conclusions: Autistic and neurotypical toddlers did not differ in cardiac synchrony with their parents; however, there is limited statistical power in our small sample size. Across groups, closer physical proximity and HRV synchrony are associated with JE, highlighting the potential clinical significance of HRV synchrony as a dyadic physiological marker of relational engagement.

441.284 Digitalising Care Pathways in LMIC: Implementing a Web-Based Tool in the Autism-Care Pathway in Sri Lanka

V. S. Thebuwana¹, D. Jangra², R. Roy³, D. V. Vipulaguna⁴, A. Hewamalage⁵ and B. Fernando⁶, (1)Sri Lanka College of Paediatricians, Colombo, Western, Sri Lanka, (2)Sangath, New Delhi, Delhi, India, (3)COMPASS, Sangath India, New Delhi, Delhi, India, (4)Ministry of Health, Sri Lanka, Colombo, Western, Sri Lanka, (5)Namaste Sri Lanka, Colombo, Western, Sri Lanka, (6)Sri Lanka College of Paediatricians, Colombo, Western, Sri Lanka

Background: Transitioning towards web-based data collection and database creation can help improve service delivery by addressing communication and coordination issues commonly seen in the fragmented care pathways in Lower and Middle income countries (LMIC). The NAMASTE (Neurodevelopment and Autism in South Asia: Treatment and Evidence) project is working to facilitate early detection of autism and NDD in Sri Lanka, India and Nepal. A web-based tool is used in this project to digitalise the autism care pathway, from identifying children with a high likelihood of autism, to the referral process and follow-up. Recognising the challenges of implementing digitalised care pathways in LMIC, NAMASTE took an iterative approach to the process of developing and implementing the tools, digitalising the referral pathway and data storage, in Sri Lanka.

Objectives: This paper aims to 1) describe the iterative process of developing web-based data collection tools and an implementation protocol, and 2) explore the facilitators and barriers related to digitalising care pathways in an LMIC setting.

Methods: Key stakeholder interviews, and initial focus group discussions (FGDs) among the implementation team and health ministry officials assessed current procedures and necessary modifications to set up a digitalised care pathway. Once the first version of the tools and the pathway were set up and a pilot carried out, we ran a second round of FGDs involving end users: 16 Medical Officers of Health (MOHs) and 48 Public Health Midwives (PHMs), to assess barriers and facilitators to implementation.

Results: Following discussions with the officials, we identified that the process unfolded in two phases. The Setting Up Phase involves 1) Comprehensive review of methods and tools for data collection and storage 2) Needs assessment of resources and infrastructure – physical and digital, skills, personnel 3) Obtaining approvals – regulatory, software web tools 4) Developing web-based tools, 5) Training and facilitating implementation of the web-based tools among MOHs and PHMs. In the second, Implementation Phase, the end-users 1) implement detection tools, 2) collect and transmit data using survey links, 3) receive feedback on next steps from the web-based tool based on an inbuilt triaging mechanism, 4) convey findings to caregivers, 5) refer relevant children for consultant diagnosis. The in-built triaging mechanism also informed end users which of the two caregiver training packages was suitable for each parent and where they consented, passed on their details to NAMASTE. The facilitators and barriers of the process of transitioning into digitalised care pathways were as follows: behavioural - limited data literacy, resistance to change; organisational - lack of skilled personnel and financial constraints; and technical - weak digital infrastructure, lack of interoperability. **Conclusions:** The initial identification and referral steps and part of the support pathway (support packages for caregivers) were effectively digitalised. Inter-operability with the management care data systems, once identified children are referred for consultant care, remains a challenge.

441.285 Engaging the Brain with "CICADAS": A Novel Neuroplasticity-Based Social Cognitive Training Application for Autistic Teens

S. Jacob¹, A. Tseng², A. Yang³, B. Biagianti³ and H. Lee⁴, (1)UCLA, Los Angeles, CA, (2)University of Minnesota - Twin Cities, Minneapolis, MN, (3)formerly at Posit Science, Milan, Milano, Italy, (4)Posit Science, San Francisco, CA

Background: During adolescence, neural networks subserving socioemotional and cognitive processing undergo dynamic, adaptive changes in response to increasingly complex socially-demanding environments.¹ For autistic youth who struggle with social communication and interaction, restricted interests, repetitive behaviors, and atypical responses to sensory stimuli,² the critical teenage neurodevelopment period can be particularly challenging. Further, avoidance of discomfiting social stimuli and contexts may preclude experience-dependent acquisition of key functional skill-sets. Yet, despite the increasing global prevalence of autism spectrum disorder (ASD), evidence-based interventions designed to improve outcomes in autistic adolescents are still lacking.³ In recent years, implementations of computerized, adaptive brain-based targeted cognitive-training (TCT) programs have improved general cognitive deficits in neuropsychiatry (e.g., schizophrenia, depression, ADHD).⁴ Thus, leveraging our pilot data testing TCT program in autistic adolescents and young adults⁵ and prior findings from patients with psychosis,⁶ we developed CICADAS (Care Improving Cognition for ADolescents on the Autism Spectrum), a digital application designed to prime the brain to engage in flexible, adaptive long-term socioemotional learning using closed-loop technology. For example, increasing auditory processing speed through TCT may strengthen receptive language capacities.

Objectives: We aimed to evaluate the CICADAS app as a stand-alone intervention or in conjunction with remotely delivered PEERS (Program for the Education and Enrichment of Relationship Skills), one of the few evidence-based social skills programs available for autistic teens.^{7,8} We hypothesized that using the CICADAS app would prime individuals to engage more efficaciously with social cognitive experiences and training.

Methods: We recruited N=62 (11-18yrs; 41M;17F;4NB) participants with confirmed ASD from PEERS clinics for a three-arm, active-controlled, randomized crossover trial (Groups: CICADAS, PEERS+CICADAS, PEERS+Active-Control; AC). Performance, adherence, and engagement metrics for TCT tasks were used to evaluate feasibility and acceptability of the mobile app. Adolescent self-report and parent-report outcome assessments were administered at Pre-Intervention, Post-Intervention, and 16-week Follow-Up sessions with measures including standardized, validated questionnaires of social, behavioral, and cognitive function. We applied linear mixed models to evaluate efficacy of CICADAS as a stand-alone intervention or as an augmentation to PEERS.

Results: Demonstrating feasibility, 80.0% of participants completed immediate post-training assessments and 73.3% of participants completed 16-week follow-up assessments. Significant effects of GROUP, TIME, and GROUPxTIME interactions were found on several measures collected over three time-points. For example we found significant effects of time on the Pediatric Quality of Life Inventory Total Scale ($F = 6.758, p = .002$) with the PEERS+CICADAS group showing improvements on the composite measure of Psychosocial Health ($F = 7.029, p = .001$) greater than the CICADAS only ($F = 2.150, p = .122$) and PEERS+AC ($F = 1.872, p = .160$) groups. Repeated measures of the Social Responsiveness Scale, 2nd Edition also showed significant effects of TIME ($F = 10.989, p = .000$); notably, only the PEERS+CICADAS group demonstrated significant improvement across all three time-points ($F = 3.786, p = .026$) on the Social Cognition subscale.

Conclusions: Our findings demonstrate that CICADAS is not only feasible, deliverable, and beneficial as a stand-alone program, but engaging in the adaptive CICADAS app (versus static AC) conferred an additional advantage to autistic teens who participate in the established PEERS program.

441.286 Factors Influencing Data Completion and Quality in a Remote Autism Screening Study

J. Howard^{1,2}, **S. Chung**^{1,2}, **M. Keller**^{1,2}, **S. Sipe**^{1,2}, **C. H. Stoute**^{1,2}, **O. K. Wilson**^{1,2}, **J. Yang**^{1,2}, **L. Driggers-Jones**^{1,2}, **B. Eichner**³, **B. A. Goldstein**⁴, **J. Green**^{1,2}, **P. R. Krishnappa Babu**⁵, **A. Reed**⁴, **M. Spanos**^{1,2}, **G. Sapiro**⁵ and **G. Dawson**^{2,6}, (1)Department of Psychiatry and Behavioral Sciences, Duke University Medical Center, Durham, NC, (2)Duke Center for Autism and Brain Development, Duke University, Durham, NC, (3)Department of Pediatrics, Duke University, Durham, NC, (4)Department of Biostatistics & Bioinformatics, Duke University, Durham, NC, (5)Department of Electrical and Computer Engineering, Duke University, Durham, NC, (6)Department of Psychiatry and Behavioral Sciences, Duke University, Durham, NC

Background:

The COVID-19 pandemic promptly necessitated remote measures in research. Despite returning to in-person activities, hybrid and remote opportunities remain priorities for researchers and participants. This highlights the need for effective participant instruction in studies using remote methods. While the effectiveness of asynchronous vs. synchronous classroom instruction has been explored, a gap remains in comparing remote instruction modalities in research.

This study aims to assess factors influencing data acquisition in a remote study evaluating the accuracy of a digital autism screening application (*SenseToKnow* iPad/iPhone mobile app). The relationship between caregiver demographic background and preference for asynchronous vs. synchronous instruction was investigated, as was the relationship between instruction type preference and instruction completion and app attempt/completion.

Objectives:

- 1) Determine whether caregiver demographic characteristics, including primary language, race/ethnicity, age, and education level, are associated with instruction type preference, app attempt, and app completion.
- 2) Determine whether caregiver instruction completion, app attempt, or app completion differ based on instruction type preference (YouTube vs. Zoom).

Methods:

Participants (n=1,342) were caregivers of children, aged 6-36 months, recruited through primary care practices, Children's Developmental Services Agency, and the broader community.

Asynchronous instructions involved a 5-minute YouTube video; synchronous instructions involved a 15–30-minute Zoom meeting. An app attempt was defined as ≥ 1 of 9 app videos completed; app completion was defined as ≥ 5 of 9 app videos completed. Primary language was the language in which consent was provided for study entry (English/Spanish).

We evaluated caregiver demographic differences with standardized mean differences (SMD); we fit logistic regressions to determine whether app instruction completion, app attempt, or app completion differed by instruction type preference, when controlling for demographics (SMD >0.1).

Results:

Race/ethnicity (SMD=0.60), primary language (SMD=0.25), and education level (SMD=0.47) differed between participants who chose YouTube vs. Zoom for receiving app instructions.

Race/ethnicity (SMD=0.39), education level (SMD=0.44), and age (SMD=0.19) differed between those who attempted the app vs. those who did not.

Race/ethnicity (SMD=0.40), education level (SMD=0.47), and age (SMD=0.17) differed between those who completed the app vs. those who did not.

Participants who chose Zoom for receiving app instructions were significantly less likely to complete app instructions vs. those choosing YouTube (odds ratio (OR)=0.65, 95% confidence interval (CI)[0.46, 0.90]).

There was no significant difference in rates of attempting or completing the app when comparing those who chose Zoom vs. YouTube for receiving app instructions (attempting OR=0.91, 95%CI[0.66, 1.25]); (completing OR=0.93, 95%CI[0.67, 1.28]).

Conclusions:

Findings reveal that preferences regarding receipt of study instructions differ by demographic group (see Table 1). Results underscore the importance of synchronous instruction, as Spanish-speaking participants were more likely to choose Zoom compared to English speakers, emphasizing the need for multilingual staff to ensure equitable participation. However, asynchronous instruction (e.g., YouTube) proved valuable, given lower completion rates for those who chose Zoom. Future analyses, to be presented at the conference, will consider the relationship between preferred instruction type and quality of data collected.

441.287 Haptikart: An Engaging Videogame Reveals Elevated Proprioceptive Vs. Visual Bias in Individuals with Autism Spectrum Disorder

D. E. Lidstone¹, M. Singhal², L. J. Wang³, J. D. Brown⁴ and S. H. Mostofsky⁵, (1)Kinesiology, Penn State Harrisburg, Middletown, PA, (2)Department of Otolaryngology-Head & Neck Surgery, University of Pittsburgh, Pittsburgh, PA, (3)Electrical Engineering and Computer Science Department, University of Michigan, Ann Arbor, MI, (4)Department of Mechanical Engineering, Johns Hopkins University, Baltimore, MD, (5)Center for Neurodevelopmental and Imaging Research, Kennedy Krieger Institute, Baltimore, MD

Background: The integration of visual and proprioceptive input is key to learning actions like social gestures, tool use, and motor skills. Understanding how visual vs. proprioceptive input is weighted helps us better comprehend child development patterns. Research suggests children with autism spectrum disorder (ASD) rely heavily on proprioceptive input, which causes challenges in visual-motor integration (VMI). For instance, children with ASD struggle with tasks such as catching balls, tracking moving objects, and imitating motor actions. Traditional methods for quantifying sensory-motor bias are cumbersome and limited in clinical use. To address this, we developed “HaptiKart,” an engaging video game that uses a force-feedback steering wheel to explore differences in proprioceptive and visual bias in children with ASD compared to typically developing (TD) peers.

Objectives: This study aimed to: (1) explore the impact of ASD on perceptual bias (proprioceptive vs. visual), (2) examine the influence of age and age-by-(autism) diagnosis interactions on perceptual bias, and (3) investigate relationships between perceptual bias and ASD severity, ADHD symptoms, and intellectual ability.

Methods: Eighty-one participants (33 with ASD and 48 TD), aged 8 to 31 years, played “HaptiKart,” a driving game using a force-feedback steering wheel to offer “steering assist.” Participants were group-matched by age and sex. The task involved steering a car along a track at a constant speed, using both visual feedback from the monitor and proprioceptive feedback from the steering wheel (**Fig. 1A-B**). After a familiarization period, participants completed two conditions (each lasting ~2 minutes) in a counterbalanced order: (1) non-delayed visual feedback with a 300-ms delay in proprioceptive feedback (V+DP) and (2) 250-ms delayed visual feedback with non-delayed proprioceptive feedback (DV+P). A one-minute washout block with non-delayed visual and proprioceptive feedback separated the conditions. Bias scores were calculated by subtracting performance in the DV+P condition from the V+DP condition (bias score = V+DP – DV+P), with positive scores indicating proprioceptive bias and negative scores indicating visual bias. We used ANCOVA to analyze how diagnosis and age impacted bias scores, controlling for sex, and explored associations between bias and autism severity (ADOS-2 and SRS-2 scores), ADHD symptoms (Conners4 scores), and IQ (GAI).

Results: Consistent with our hypothesis, the ASD group showed a significantly higher proprioceptive bias compared to the TD group (ASD>TD; $p = 0.002$) (**Fig. 1C**). Across all participants, there was a trend toward decreasing proprioceptive bias with age ($p = 0.06$), but no significant diagnosis-by-age interaction ($p = 0.68$). Higher proprioceptive bias was associated with greater autism severity (ADOS-CS: $r = 0.48$, $p = 0.035$; SRS-2: $r = 0.52$, $p < 0.001$) and lower IQ ($r = 0.54$, $p < 0.001$), but not with ADHD symptoms ($r = 0.17$, $p = 0.38$).

Conclusions: Our novel driving videogame, HaptiKart, revealed individuals with ASD show an increased reliance on proprioception, correlating with autism severity and lower IQ. HaptiKart offers a brief, engaging and scalable approach for assessing autism-associated differences in sensory-motor bias and could thereby serve as a digital biomarker to monitor autism symptoms and guide future interventions.

441.288 Preliminary Results of a Randomized Controlled Trial on the Use of Intransitive Gestures in a Sample of Italian Preschool Children with Autism Spectrum Disorder

S. Annunziata¹, E. Santini², M. Brivio², G. Fassina³, L. Santos^{4,5}, E. Ambrosini², A. Pedrocchi³ and A. Cavallini², (1)IRCCS Don Carlo Gnocchi Foundation, Milan, Milan, Italy, (2)IRCCS Fondazione Don Carlo Gnocchi ONLUS, Milan, Milan, Italy, (3)Department of Electronics, Information and Bioengineering, Politecnico di Milano, Milan, Milan, Italy, (4)Department of Electronics, Information and Bioengineering, Politecnico di Milano, Milan, Italy, (5)Institute for Systems and Robotics, Instituto Superior Técnico, University of Lisbon, Lisbon, Lisbon, Portugal

Background: The importance of early intervention in Autism Spectrum Disorders (ASD) has been widely demonstrated, and developmental trajectories in ASD highlight the importance of nonverbal communication, such as intransitive gesture production, as a possible positive prognostic factor for language development.

The use of technological tools in ASD therapy has also become increasingly important due to the increased engagement and responsiveness in ASD to technological objects, such as robots.

We therefore developed a training protocol using the humanoid robot NAO, called IOGIOCO (Interactive mirroring Games wIth sOCial rObot), based on the use of intransitive gestures embedded in naturalistic dialogues, stimulating a triadic interaction between child, robot and therapist. The protocol included different complexity levels, from mirroring tasks to spontaneous interactions. We previously tested the protocol on 10 ASD children aged 2–6 years in a pilot study finding promising results[1].

Objectives: The main aim is to test the effectiveness of the IOGIOCO protocol, by analyzing the preliminary results of the first group of subjects included in a crossover Randomized Controlled Trial. (Ethics Committee approval ID: 07_29/03/2023).

Methods: We aim to enroll 20 preschool children with an ASD diagnosis according to DSM-5 criteria (confirmed by ADOS-2). We will test them at T0 and randomly assign them to two groups, G1 and G2, according to a cross-over design. After T0 assessment, G1 will undergo a 12-weekly-session training with the social robot NAO, while G2 will continue the therapy as usual. After a second assessment of the entire cohort at T1 (after 12 sessions) G1 will be included in a follow-up group, while the G2 will undergo the social robot intervention. Finally, all participants will be assessed at T2, i.e. 12 weeks after T1. ABAS II and MacArthur-Bates number of gestures will be administered at the three-time points, while Griffiths-III will enrich T0 assessment. Finally, we will administer a satisfaction questionnaire to parents on 11 questions on a Likert scale (1,Not-at-all satisfied- 5,Extremely satisfied).

Results: Up to now, 11 subjects (mean age 50 months, SD 13, F:M=3:7, General Quotient(GQ) at Griffiths-III=45) have completed the intervention protocol (Experimental Group, EG), and 7 (mean age, 51 months, S.D. 13, F:M=3:4,GQ=39) have concluded the control period (Control Group,CG). A Mann-Whitney U test did not highlight significant differences between the two groups for General Quotients at Griffiths III ($p=0.68$) and age ($p=0.79$).

We used Mann-Whitney test to compare the variations from T0 to T1 of the experimental and the control groups respectively, and we found significative differences in Social Domain ($p < 0.01$) and in Practical Domain ($p=0.04$) of ABAS-II questionnaire (Figure). The results of the satisfaction questionnaire indicate a high level of satisfaction with the training program (mean: 3,9;SD 0,7).

Conclusions: Preliminary results show a significant improvement in the intervention group compared to the control group in two subdomains of the ABAS-II. These data need to be confirmed by a larger sample, but they suggest an impact of the social robot intervention on ASD children's adaptive skills compared to therapy as usual.

441.289 Towards Objective Social Behavior Analysis: A Multi-View Digital Solution for Direct Eye Contact Detection during Naturalistic Free Play Assessments

C. Sun¹, A. McEwan², R. Thapa³ and A. J. Guastella¹, (1)Faculty of Medicine and Health, University of Sydney, Sydney, NSW, Australia, (2)School of Biomedical Engineering, The University of Sydney, Darlingtown, NSW, Australia, (3)Brain and Mind Centre, Children's Hospital Westmead Clinical School, Faculty of Medicine and Health, University of Sydney, Sydney, NSW, Australia

Background:

Individuals with autism spectrum disorders (ASD) are often reluctant to make direct eye contact with their social partners during naturalistic social interactions. This is one of the central behavioral markers in assessing the effectiveness of social functioning during free play. Existing gold-standard clinical diagnostic tools often introduce subjective biases and rely heavily on clinicians' decisions. Accurate identification and objective assessment of social behaviors, such as direct eye contact, remain challenging. This is particularly true in naturalistic, free play settings. There remains a critical need to identify direct eye contact in naturalistic settings to mimic real-world social interactions and assist in the assessment of social functioning.

Objectives:

This study aimed to develop a deep learning-based framework for detecting direct eye contact between children and assessors in social interaction sessions during free play. The reliability of the framework was compared with expert-annotated direct eye contact behaviors observed during the sessions.

Methods:

We developed a multi-view social behavior detection framework that analyzes spatial and temporal features of direct eye contact behaviors between child participants and assessors in 5-minute free play sessions. This study involved video footage from 136 children aged 3 to 12 years, comprising 103 children with ASD diagnosis and 33 typically developing children. The proposed framework was trained with sparsely sampled true color spatial images, and optical flow images representing the moving patterns of direct eye contact behaviors between the child and assessor. Video footage collected from multiple views was fed into the trained deep learning model, providing an average consensus of the detected social behavior. The children's caregivers were allowed to sit in the assessment room during the free play session to create a familiar environment for the child participant.

Results:

The proposed framework demonstrated highly competitive performance in identifying direct eye contact behaviors in free play compared to manual subjective coding. The inter-rater reliability kappa value for expert annotations was 0.812 (SD: 0.179). Our proposed framework achieved F1 scores of 85.42% and 90.04% in single-view predictions for the "eye contact" and "no eye contact" segments, respectively. In multi-view prediction, the F1 scores significantly improved to 91.96% and 94.48%.

Conclusions:

The results highlight the effectiveness of digital methods for objectively analyzing social behaviors during social functioning assessments through multi-view approaches. Significant improvements in F1 scores and the robustness of the proposed framework were observed in detecting direct eye contact behavior during free play, even when multiple individuals were present. These findings demonstrate the scalability potential of our proposed framework for implementation in clinical settings. The high degree of agreement between the deep learning model predictions and manual coding by trained experts suggests that social behaviors among multiple people can be quantified, indicating that digital translation of such tools has the potential to be integrated into standardized clinical practice.

441.290 Using AI Facial Expression Analysis Software to Assess Negative Affect in Autistic Children

R. Beaumont¹, H. Walker², A. Willis³ and K. Sofronoff⁴, (1)Weill Cornell Medicine, New York, NY, (2)Minds and Hearts, Brisbane, QLD, Australia, (3)Children's Health Queensland Hospital, South Brisbane, QLD, Australia, (4)School of Psychology, University of Queensland, Brisbane, Australia

Background: Emotion regulation difficulties often contribute to impairments in social, emotional and academic functioning in autistic children. Traditional assessment tools, such as parent-report and teacher-report questionnaires and observational assessments are time-consuming, expensive and prone to bias. Advances in technology, such as facial expression analysis software, hold promise in offering efficient and objective approaches to assessing emotion regulation in naturalistic environments.

Objectives: This study examined the feasibility and accuracy of iMotions' AFFDEX SDK 5.1 facial expression analysis technology in coding negative expressed affect in autistic children. This software was chosen as it has been used in past research studies with autistic children (e.g. Ahn et al., 2024; Alarifi et al., 2023). This is the first study to independently validate the software with autistic youth.

Methods: Participants included 50 autistic children aged seven to 12 years (44 males, 6 females) with cognitive abilities within the average range. This was a fully remote study, with participants recruited from three Australian states.

Parents set-up their children at a computer with a webcam in their home to play a frustrating video game 'Space is 'Key'. Children joined a videoconference with the assessor who observed them playing the video game remotely for five minutes. For a final two minutes, children were encouraged to do an activity of their choice, to help them to calm down before the assessor logged off. Assessment sessions were videorecorded and later coded by two independent human raters for negative expressed affect from facial expression and iMotions' AFFDEX SDK 5.1 facial expression analysis software.

Results: The average percentage of codable video clip intervals was 90% for Rater 1, 89% for Rater 2 and 79% for the iMotions software. The main factors contributing to intervals not being coded were children moving 'offscreen' or their webcam image being too pixelated to code. Visible signs of negative expressed affect through facial expression were coded 33.05% of the time by Rater 1 (SD=31.14), 32.75% of the time by Rater 2 (SD=31.55) and 3.42% of the time by the AFFDEX AI algorithm (SD=5.55). Correlational analyses indicated a strong correlation between the negative affect ratings of the two human raters ($r=.99$, $p<.001$), and weak and non-significant correlations between the human raters and AI algorithm ($r_s<.18$, $p_s>.23$). Examination of the signal data from AFFDEX SDK 5.1, synched with participants' video footage, suggested that the software lacked sensitivity in capturing subtle signs of negative affect (e.g. sad or staring eyes), and interpreted anxious or frustrated facial grimacing as positive affect (smiling).

Conclusions: Facial expression analysis software holds promise as an objective, efficient and cost-effective measure of emotion regulation in autistic children in both clinical and research contexts. This study assessed the feasibility and accuracy of iMotions' AFFDEX SDK 5.1 facial expression analysis software in coding negative expressed affect in autistic children while playing a frustrating video game. Results suggested that the AI algorithm lacks sensitivity and validity in assessing autistic children. This study highlights the importance of independent validation of technological innovations for different subpopulations, including autistic youth.

441.291 Wearable Devices Demonstrate the Relationship between Sleep Problems and the Severity of Autism Symptoms

M. Hacohen¹ and **I. Dinstein²**, (1)Ben Gurion University of the Negev, Israel, Be'er Sheva, Israel, (2)Cognitive and Brain Sciences Department, Ben Gurion University, Beer-Sheva, Israel

Background: Sleep disturbances are of high interest in autism research given their reported high prevalence and deleterious impact. Previous autism sleep studies have mostly used subjective parent questionnaires and reported that autistic children with more severe sleep problems also exhibit more severe core symptoms, aberrant behaviors, and sensory sensitivities. However, studies using objective sleep measures from actigraphy, and polysomnography (PSG) recordings of autistic individuals have rarely assessed these relationships. Here we explored the Simons Sleep Project (SSP) data, a new open-science resource with multi-night data from multiple wearable and nearable devices to assess such relationships.

Objectives: To extract objective sleep measures from multiple wearable devices including actigraphy and ambulatory EEG and determine their relationship with the severity of core autism and co-occurring symptoms.

Methods: The SSP contains data from 102 families who reported having one autistic child and one non-autistic sibling, both 10-17 years old. Parents completed multiple questionnaires and received a Dreem3 EEG headband (Beacon Biosignals Inc.), EmbracePlus smartwatch (Empatica Inc.), and Withings Sleep mat (Withings Inc.). Simultaneous data was collected from all devices along with a sleep diary for 2-3 weeks from each child, yielding a final dataset of 1772 nights with successful simultaneous data from all three devices. We used automated sleep scoring by EmbracePlus and Withings to classify sleep/wake epochs and the POPS algorithm (LUNA software) to classify sleep/wake epochs in the raw EEG data. We then computed sleep onset, final awakening, wake after sleep onset (WASO), total Sleep Time (TST), sleep onset latency (SOL), and sleep regularity index (SRI) from the three devices. We computed Pearson Correlation Coefficients between each of sleep measures and parent reported scores from the Vineland (adaptive behaviors), Child Sleep Habits Questionnaire (CSHQ, sleep disturbances), Aberrant Behaviors Checklist (ABC), Social Responsiveness Scale (SRS, core autism symptoms), and Sensory Profile (SP, sensory problems).

Results:

In line with previous literature, we found that parent-reported sleep disturbances (CSHQ) were positively correlated with the severity of parent-reported core symptoms (SRS scores), sensory problems (Sensory profile) and aberrant behaviors (ABC scores) ($r > 0.3$, $p < 0.001$) and negatively correlated with Vineland scores ($r = -0.38$, $p < 0.001$). Similar, weaker relationships were apparent between SOL and the same behavioral measures. Vineland scores were negatively correlated with SOL (actigraphy: $r = -0.19$, $p = 0.007$; EEG: $r = -0.19$, $p = 0.006$) while sensory avoiding scores from the Sensory Profile were positively correlated with SOL (actigraphy: $r = 0.27$, $p < 0.001$; EEG: $r = 0.24$, $p < 0.001$) as were SRS total scores (actigraphy: $r = 0.24$, $p < 0.001$; EEG: $r = 0.18$, $p = 0.01$) and ABC hyperactivity scores (actigraphy: $r = 0.26$, $p < 0.001$; EEG: $r = 0.31$, $p < 0.001$). In contrast, WASO, TST, and SRI measures were not significantly correlated with any of the symptom scores. Similar results were found when examining the entire sample (autism and siblings) or each subgroup separately.

Conclusions: These findings suggest that SOL, whether measured with actigraphy or EEG, is an objective sleep measure of particular interest that quantifies a specific sleep disturbance with potential impact on the severity of multiple symptom domains. It suggests a specific target for intervention that could potentially have cascading effects on the severity of multiple symptom domains.

Poster Session

442 - Social Cognition and Social Behavior II

May 3rd, 2025, 12:30 PM - 1:30 PM - Hall 4A

442.292 The Relationship between Social Motor Synchrony and Self-Rated Rapport in Autistic, Non-Autistic and Mixed Dyads

T. N. Efthimiou¹, S. J. Foster², C. Wilks³, M. Dodd⁴, S. Fletcher-Watson⁵, M. Lages⁶, D. Ropar⁷, N. J. Sasson⁸ and C. J. Crompton⁹, (1)University of Edinburgh, Edinburgh, United Kingdom, (2)Psychology, University of Texas at Dallas, Richardson, TX, (3)University of Edinburgh, Edinburgh, United Kingdom, (4)Nottingham Trent University, Nottingham, United Kingdom, (5)Salvesen Mindroom Research Centre, University of Edinburgh, Edinburgh, United Kingdom, (6)School of Psychology and Neuroscience, University of Glasgow, Glasgow, United Kingdom, (7)University of Nottingham, Nottingham, UNITED KINGDOM, (8)University of Texas at Dallas, Richardson, TX, (9)Centre for Clinical Brain Sciences, University of Edinburgh, Edinburgh, UNITED KINGDOM

Background: Social Motor Synchrony (SMS) during social interactions is associated with increased interpersonal rapport—a sense of friendly connection characterised by mutual understanding and ease of communication—in non-autistic populations. Previous research suggests that autistic people exhibit lower SMS during social interactions with both autistic and non-autistic partners (Georgescu et al. 2020). However, it remains unclear whether this impacts autistic experiences of rapport, as the relative importance of synchrony in social communication strategies may differ between autistic and non-autistic populations.

Objectives: This study had three aims: first, to replicate and extend previous findings of reduced SMS in dyads involving at least one autistic person; second, to examine the relationship between SMS and interpersonal rapport within autistic ($n = 12$), non-autistic ($n = 17$), and mixed dyads ($n = 14$; total N participants = 86); and third, to assess the reliance on SMS for achieving rapport among autistic and non-autistic participants. By investigating these dynamics, we aimed to provide insights into the role of synchrony in social interactions across different neurotypes.

Methods: Participants engaged in a 5-minute unstructured conversation with an unacquainted partner. These interactions were video-recorded and analysed using Motion Energy Analysis (MEA; Ramseyer, 2020), a method that quantifies movement by detecting changes in video frames over time. MEA generates time-series data, which are sequences representing each participant's movement intensity at successive time points throughout the conversation. SMS was computed by calculating the cross-correlation between the two participants' time-series data. This cross-correlation assesses the degree to which participants' movements are temporally aligned, providing a quantitative measure of SMS.

Results: Contrary to previous findings, we did not observe reduced SMS in autistic-matched and mixed dyads compared to non-autistic dyads ($F(2, 40) = 0.09, p = .913, \eta^2 = .005, 95\% \text{ CI } [0.00, 1.00]$). For all three neurotypes, Frequentist (all $ps > .05$) and Bayesian (all 95% credible intervals included zero) analyses did not support the notion that SMS significantly predicts rapport. However, we found that SMS has a stronger positive effect on rapport in non-autistic dyads compared to autistic dyads ($Mdiff = 4.14, SE = 1.90, t(39) = 2.176, p = .036, \text{ CI } [0.29, 7.98]$; Fig 1). Indeed, our participant-level analysis indicated that non-autistic participants require a higher ratio of SMS to rapport compared to autistic participants ($M = 0.65, SD = .21, t(84) = 2.04, p = .022, d = .45, \text{BF}_{10} = 1.3$; Fig 2). This suggests that non-autistic individuals have a higher threshold, requiring more SMS to achieve high levels of rapport.

Conclusions: These findings indicate that SMS does not differ significantly across neurotypes in short conversational tasks. However, non-autistic people appear to rely more on SMS to build rapport, whereas autistic people may utilise different strategies for establishing interpersonal connections. These findings highlight the need to consider neurodiversity in social interaction research, promoting improved communication and mutual understanding across different neurotypes. Recognising that the mechanisms contributing to rapport may differ between autistic and non-autistic people can better support mutual understanding across diverse social contexts.

442.293 Information Transfer and Self-Assessment of Solutions within and between Autistic and Non-Autistic Adults.

C. Wilks¹, S. J. Foster², M. Dodd³, S. Fletcher-Watson¹, M. Lages⁴, D. Ropar⁵, N. J. Sasson⁷ and C. J. Crompton⁸, (1)University of Edinburgh, Edinburgh, United Kingdom, (2)Psychology, University of Texas at Dallas, Richardson, TX, (3)Nottingham Trent University, Nottingham, United Kingdom, (4)Salvesen Mindroom Research Centre, University of Edinburgh, Edinburgh, United Kingdom, (5)School of Psychology and Neuroscience, University of Glasgow, Glasgow, United Kingdom, (6)University of Nottingham, Nottingham, UNITED KINGDOM, (7)University of Texas at Dallas, Richardson, TX, (8)Centre for Clinical Brain Sciences, University of Edinburgh, Edinburgh, UNITED KINGDOM

Background: Previous research (Crompton et al., 2020) found that chains of autistic people transmitted information as effectively as chains of non-autistic people. However, when autistic and non-autistic people interacted with each other in mixed-neurotype chains, information sharing deteriorated and less information was transmitted. These findings challenge clinical (American Psychiatric Association, 2013) and social cognitive characterizations of autistic individuals as uniformly deficient in social communication (Kapp, 2019) and suggest information transfer in autism is contextually-dependent.

Objectives: The current study tested whether Crompton et al.'s (2020) findings generalised to a larger, multi-site sample using a task requiring the transmission of primarily visual information as opposed to verbal. We also examined how accurately participants self-assessed performance, as self-assessment accuracy has been shown to predict functional outcomes better than objective performance (Gould et al., 2015; Silberstein et al., 2018) and may be reduced for autistic people (DeBrabander et al., 2021). Moreover, our data provided a unique opportunity to examine self-assessment accuracy in autistic and non-autistic people interacting in real-time, a skill that may be important for changing one's behaviour during social situations like interviews and meetings.

Methods: 310 adults (154 autistic) were allocated to one of three "diffusion chain" conditions consisting of six participants each: (i) autistic, (ii) non-autistic, or (iii) mixed autistic and non-autistic. The first participant (Participant 1) in each chain watched a video of an experimenter creating a specific shape from a puzzle toy that could be manipulated into a wide range of shapes. Participant 1 was told to show Participant 2 how to make a dog, who showed Participant 3, and so on until the end of the chain (Participant 6). Accuracy (Objective Performance) was scored as the number of puzzle pieces in the correct location; self-assessment was measured on a 100-point scale and the accuracy of this self-assessment was calculated by comparing it to Objective Performance.

Results: All analyses were pre-registered. There was no difference in the amount of information transmitted between autistic and non-autistic chains ($\beta = 6.74, SE = 9.16, t(51.7) = 0.74, p = 0.47$); however, mixed chains also transmitted a comparable amount of information to autistic ($\beta = -7.38, SE = 9.15, t(51.4) = -0.81, p = 0.42$) and non-autistic ($\beta = -0.64, SE = 9.15, t(51.4) = -0.07, p = 0.95$) chains (Figure 1; left panel). Participants in autistic and non-autistic chains also did not differ in the accuracy of their self-assessment ratings ($\beta = 6.48, SE = 10.36, t(52.3) = 0.63, p = 0.53$), and mixed chains did not differ from autistic ($\beta = -5.34, SE = 10.34, t(51.8) = -0.52, p = 0.61$) or non-autistic ($\beta = 1.14, SE = 10.31, t(51.3) = 0.11, p = 0.91$) chains (Figure 1; right panel).

Conclusions: Both autistic and non-autistic participants shared information with others and evaluated their performance similarly. This supports Crompton et al. (2020), showing that the result generalises to the transmission of different types of information and was not an artefact of their language-based task. However, the predicted breakdown in information sharing in the mixed chains did not occur. It is possible that a mismatch in autistic and non-autistic language use/communication style impacted information transmission in the previous study but not in our less-verbal (visuospatial) task, and/or that the increased heterogeneity of our sample overshadowed any effect of neurotype.

442.294 Imitation Types in Relation to Language Skills in Young Autistic Children

H. Van de Vyver¹, P. Warreyn¹, E. Demurie¹, M. Kissine², I. Noens³, L. van Esch³, M. Weyland⁴ and H. Roeyers¹, (1)Department of Experimental-Clinical and Health Psychology, Ghent University, Ghent, Belgium, (2)ACTE — Center of research in Linguistics — ULB Neuroscience, Université libre de Bruxelles, Brussels, Belgium, (3)Parenting and Special Education Research Unit, Faculty of Educational Sciences, KU Leuven, Leuven, Belgium, (4)ACTE — Center of research in Linguistics — ULB Neuroscience Institute, Université libre de Bruxelles, Brussels, Belgium

Background:

Language abilities are highly heterogeneous in autistic children, ranging from being minimally verbal to verbally fluent (Bacon et al., 2019). Previous studies have found that imitation abilities are positively related to (expressive) language abilities in autistic children (e.g., Pecukonis et al., 2019). However, imitation has often been measured via one total score, while it includes imitation of actions with objects (i.e., procedural imitation), actions without objects (i.e., gestural imitation) and imitation of spoken words (i.e., verbal imitation). Moreover, imitation can take place either in a structured context (i.e., elicited imitation) or a social-interactive context (i.e., spontaneous imitation; Ingersoll & Meyer, 2011).

Objectives:

This study examines the association between structured gestural, verbal and procedural imitation, as well as spontaneous procedural imitation, and the concurrent receptive and expressive language abilities in young autistic children.

Methods:

110 autistic children aged between two and six years ($M = 4.40$) were assessed in a mobile research van. Imitation abilities were assessed using: the Preschool Imitation and Praxis Scale as a measure for structured gestural and procedural imitation, a structured verbal imitation paradigm, and the object scale of the Unstructured Imitation Assessment for spontaneous procedural imitation. Language abilities were assessed using the Bayley Scales of Infant Development (BSID-III) for younger or less verbal children and the Clinical Evaluation of Language Fundamentals (CELF-P-2) for older children. The Snijders-Oomen Non-verbal Intelligence test (SON-R 2-8) was used to assess nonverbal cognitive abilities (NVIQ).

Results:

Bivariate correlation analyses revealed significant Spearman correlations ($p < .001$) between all imitation types, language and NVIQ. Regression analyses were conducted with imitation types as predictors of receptive and expressive language age equivalents divided by age, controlled for NVIQ, age, testing site and socio-economic status (i.e., degree of the mother). The model with only control variables had an R^2 of .57 and .54 for receptive and expressive language respectively. Imitation abilities were added stepwise to these models. For receptive language, adding structured procedural, verbal and spontaneous imitation provided the best fit ($R^2 = .75$), accounting for .14, .02 and .02 in explained variance respectively. For expressive language, the best fit was found when structured verbal, procedural and spontaneous imitation were added ($R^2 = .77$), accounting for .20, .01 and .02 respectively. Structured procedural ($p < .001$; $p = .002$) and verbal imitation ($p < .001$) were positively associated with receptive and expressive language abilities, while spontaneous procedural imitation was negatively associated ($p = .004$; $p = .02$). In a separate model, gestural imitation was positively associated to both language abilities ($p < .001$) but it did not have added value in the explained variance.

Conclusions:

Imitation abilities seem to be associated with concurrent receptive and expressive language abilities, even when controlling for NVIQ, suggesting a unique contribution of imitation abilities. Procedural imitation explained most variance for receptive language, while verbal imitation did so for expressive language, suggesting different associations for both language abilities. Gestural imitation did not have added value. Contrary to our expectations, spontaneous imitation was negatively associated to both language abilities.

442.295 Impact of Discrepancies between Parents and Adolescents Perceptions of Empathy and Social Anxiety in Self-Concept Among Autistic Adolescents

T. M. Anderson¹, C. T. Moody², Y. Bolourian¹, G. Sotomayor³ and E. A. Laugeson¹, (1)UCLA Semel Institute for Neuroscience and Human Behavior, UCLA PEERS® Clinic, Los Angeles, CA, (2)UCLA Semel Institute for Neuroscience and Human Behavior, University of California Los Angeles, Los Angeles, CA, (3)Semel Institute for Neuroscience and Human Behavior, University of California Los Angeles, Los Angeles, CA

Background: Discrepancies between adolescent and parent reports on adolescents' social functioning are common in research and clinical settings (De Los Reyes & Ohannessian, 2016). Literature suggests these reporter discrepancies may be clinically informative, with difference scores between mothers' and their children's reports of internalizing disorders being associated with youth's negative self-concept (Castagna et al., 2021), and positive parent-child relationships relating to higher self-esteem and reduced reporter discrepancies on internalizing symptoms (Treutler & Epkins, 2003). Though less well-studied in autistic populations, there is evidence that parent- and youth-informant discrepancies show consistent patterns of autistic youth reporting more positive social functioning than parents do (Lerner et al., 2012). However, it is unclear if and how such discrepancies related to autistic youth self-concept have emerged in the typically developing literature. This is especially relevant to autistic populations, who have lower self-esteem than the general population (Nguyen et al., 2020; McCauley et al., 2019), placing them at higher risk for negative mental and physical health outcomes (Trzesniewski et al., 2006).

Objectives: This study aimed to examine the relationship between discrepancies in self-and-parent-reported measures of adolescent social anxiety and empathy, and how these discrepancies impact autistic adolescents' self-concept.

Methods: Participants included 138 autistic adolescents between 10-18 years old (73.9% male, $Mage=14.07$; $SD=1.94$) and their parents who attended the UCLA PEERS® for Adolescents program. The *Social Anxiety Scale* (SAS; La Greca & Lopez, 1998) and *Empathy Quotient* (EQ; Auyeung et al., 2012), both parent- and adolescent-reported, were used to assess adolescent social anxiety and empathy skills, respectively. Adolescent self-concept was measured via self-report on the *Piers-Harris Self-Concept Scale* (PH2; Piers & Herzberg, 2002). Discrepancies were calculated as the difference between self and parent reports, with positive scores indicating that adolescents reported higher levels of traits than their parents, and negative scores indicating the reverse. A multiple regression analysis was performed to examine reporter discrepancies on measures of social anxiety and empathy as predictors of adolescents' self-esteem.

Results: Regression analysis indicated that reporter discrepancies on both the EQ and SAS significantly predicted the PH2. Specifically, a higher EQ discrepancy, where adolescents reported higher empathy than parents, was associated with higher self-esteem ($B=0.136$, $p=.033$), indicating that a strong self-perception of empathy may enhance their overall self-worth. Conversely, a negative relationship was found between parents and adolescents' perceptions of social anxiety ($B=-0.180$, $p=.001$). When parents rated their adolescents' social anxiety higher than their adolescents did via self-report, the adolescents tended to have lower self-esteem. Overall, the model accounted for 12.5% of the variance in adolescent self-esteem, $F(2,130)=10.42$, $p<.001$.

Conclusions: Overall, these findings suggest that the alignment between parent and adolescent perceptions significantly influences autistic adolescents' self-esteem. It is possible that reporter discrepancies may be reflective of broader family processes and that congruence in perceptions may foster a positive self-image among autistic adolescents. Future research should examine potential moderators of self and parent-report discrepancies and their impact on adolescent functioning.

442.296 Individual and Environmental Correlates of Attachment Security in Autistic Children

W. Trottier-Dumont¹, C. Cyr², K. Dubois-Comtois³ and E. L. Bussières⁴, (1)University of Quebec at Trois-Rivières, Trois-Rivières, QC, Canada, (2)Psychology, Université du Québec à Montréal, Montréal, QC, Canada, (3)Psychology, Université du Québec à Trois-Rivières, Trois-Rivières, QC, Canada, (4)Psychology, Université du Québec à Trois-Rivières, Trois-Rivières, QC, Canada

Background: The ability of autistic children to form secure attachment relationships has been documented in several studies (Rutgers et al., 2004, for a meta-analysis). More recently, the role of sensitive parenting in the development of attachment security in autistic children has been highlighted in a meta-analysis showing an effect size of $r = .47$ (Cossette-Côté et al., 2022). However, this meta-analysis could not examine the moderating role of children's neurodevelopmental characteristics, such as severity of autistic characteristics (SAC) and developmental level (DL). Some authors have suggested that higher SAC and low DL may be associated with increased attachment insecurity (Teague et al., 2017).

Objectives: This study aims to examine the association between parental sensitivity (PS) and attachment security in autistic children; it also aims at examining whether children's SAC and DL moderate this association.

Methods: The sample comprises 41 mothers and their autistic children aged between 2 and 6 years old recruited during the COVID-19 pandemic. A 10-minute free play/snack time parent-child interaction was filmed at home by videoconference. PS was assessed with the parent-child interaction coding system for preschool and school-age children (Moss et al., 1996). Child attachment security was coded using a short 25-item version of the Attachment Behaviors Q-Set (AQS; Waters, 1995). SAC and DL were, respectively, assessed with the Childhood Autism Rating Scale 2nd Ed. interview (CARS-II; Schopler et al., 2010) and the Ages and Stages Questionnaires socioemotional 1st Ed. (ASQ-SE; Squires et al., 2011). Coders were blind to other measures' scores and showed good to excellent inter-rater reliability (PS: $r_{icc} = .86$; attachment security: $r_{icc} = .80$; SAC: $r_{icc} = .92$).

Results: Medium associations were found between attachment and sensitivity and between DL and SAC (see Table 1). Two hierarchical regressions tested the moderating roles of children's neurodevelopmental characteristics between parental sensitivity and child attachment security. Results showed non-significant main effects of PS, DL, and SAC. The interaction term of PS X SAC (see Table 2, Model 1) was significant, $b = -.105$, indicating that the association between PS and attachment security is only significant for children with a low SAC ($t = 3.02$, $p = .01$). The interaction term of PS X DL (see Table 2, Model 2) was not significant, $b = -.006$.

Conclusions: Findings are consistent with the Cossette-Côté et al. (2022) meta-analysis, showing an association between PS and child attachment security in autistic children. However, this association is observed only for autistic children with a lower SAC. Findings also indicate that DL is not associated with attachment security in autistic children. This highlights the need to consider children's severity of autistic characteristics in parent-child relationship assessments and intervention with autistic children. However, the current study is based on a small sample, thus the results should be interpreted cautiously, and future studies could benefit from larger samples and longitudinal designs.

442.297 Influence of Cross-Modal Processing on the Facial Trustworthiness Judgments of Individuals with Autism Spectrum Disorder

E. Vaucheret¹, M. Leist², M. Rios Pistoia³, G. Medina⁴, M. Gutierrez⁵, R. Ortola Martinez⁶ and B. Rodrigues⁷, Hospital Italiano de Buenos Aires, Buenos Aires, Buenos Aires, Argentina

Background:

People make trustworthiness judgments by briefly exposing themselves to faces, affecting social interactions. People with ASD have difficulty reading social information from faces. A characteristic not studied in individuals with ASD is the role of cross-modal processing in the perception of trust.

Objectives:

This study aimed to examine this influence on the facial trustworthiness judgments of children with ASD.

Methods:

Eighty participants were divided into two groups: Control Group ($n=40$) made up of neurotypical individuals aged 11.2 years, and ASD Group ($n=40$) made up of individuals with ASD aged 10.3 years ($CIT=89.2$). Cross-modal processing was studied using the Bouba-Kiki effect.

Participants observed 20 faces, 10 round and 10 angular. The angular ones were associated with "names-Kiki", the round ones were associated with "names-Bouba". Cross combinations of names and faces were included. Each participant answered if they "would lend their toy to the model in the photo that was called..."

Results:

The ASD Group showed greater perception of trust ($M=13.1$) compared to the Control Group ($M=10.5, p=0.02; d=0.5$), and had greater cross-modal engagement ($p=0.002$). Cross-modal processing positively influenced the trustworthiness judgments of the Control Group ($M=11.25$), compared to the ASD Group ($M=10.4; p=0.03; d=0.47$). The Control Group was 5.5 times more likely to trust faces influenced by cross-modal processing compared to the ASD Group, who did it 7.7 times less in relation to this effect ($p=0.008$).

Conclusions:

Children with ASD tend to have a higher perception of trust. However, they are not influenced by cross-modal processing regarding facial trustworthiness judgments, which reveals a different modulation when making these types of decisions.

442.298 Emotion Expression Differences in Autistic and Typically Developing Young Children in Response to Social and Nonsocial Play-Based Tasks: A Feasibility Study

E. Paolizzi¹, H. M. Register², V. Colantuono³, H. Ayaz⁴, G. Vivanti⁵, D. L. Robins⁶ and A. T. Wiecekowsk⁶, (1)A.J. Drexel Autism Institute, Drexel University, Philadelphia, PA, Philadelphia, PA, (2)Drexel University, Philadelphia, PA, (3)A.J. Drexel Autism Institute, Philadelphia, PA, (4)School of Biomedical Engineering Science and Health Systems, Drexel University, Philadelphia, PA, (5)A.J. Drexel Autism Institute, AJ Drexel Autism Institute, Philadelphia, PA, (6)A.J. Drexel Autism Institute, Drexel University, Philadelphia, PA

Background:

Research suggests that autistic individuals present with differences in emotion expressivity in comparison to typically developing (TD) individuals (Loveland, 2005), which might contribute to lower success in social interactions (Brewer et al., 2016). Further, autistic children seem to present differences in emotional physiological responses in relation to tasks' sociality, presenting normative patterns in non-social tasks (Nuske et al., 2013). Current literature has yet to define dimensional differences in emotional presentation, as well as whether expressivity differences are modulated by social and non-social nature of situations

Objectives:

This study aims to explore differences in facial emotion expressivity between TD and autistic young children during active engagement in social and non-social emotion-eliciting play-based tasks, and to investigate the feasibility of eliciting emotion expression through play-based tasks.

Methods:

The study included 21 autistic ($M=42.33$ months, $SD=11.16$) and 22 TD ($M=43.55$ months, $SD=10.92$) young children. Participants were administered a set of probes modified from the Laboratory Temperament Assessment Battery (Lab-TAB) Locomotor Version (Macari et al., 2018) to assess emotional response in emotionally valenced tasks designed to elicit joy and frustration.

Each task was presented twice in separate conditions: a social condition, where the examiner interacted with the child using exaggerated vocal inflection and facial expressions, and a non-social condition, where the examiner maintained a neutral vocal inflection and facial expression, and minimally interacted with the child.

Lab-TAB sessions were video-recorded and facial emotional expressivity was double coded offline by two researchers blinded to grouping and condition. Discrepancies were resolved by P.I. (1) Peak Intensity of emotion, (2) Frequency of Peak, (3) Gestalt Intensity, and (4) Frequency of Gestalt, were analyzed (see Table 1 for scoring criteria).

Results:

General Linear Models (GLM) were fitted to predict the four parameters, considering diagnosis (ASD/TD), condition (Social/Non-social Task), and Emotion elicited by each task (Joy/Frustration). Models were significant and Emotion was found to be the only significant predictor (Peak intensity: $F(7,172)=21.83, p<.001, \eta^2=0.48$; Frequency of Peak: $F(7,172)=4.06, p<.001, \eta^2=0.15$; Gestalt Intensity: $F(7,172)=7.75, p<.001, \eta^2=0.25$; Gestalt Frequency: $F(7,172)=9.70, p<.001, \eta^2=0.29$).

GLMs that then separately explored emotional valence indicated that social nature of the task ($p=.003, \eta^2=0.10$) and group designation ($p=.006, \eta^2=0.09$) were significantly related to Frequency of Gestalt in joy ($F(3,85)=0.001, p=.001, \eta^2=0.18$), with autistic children expressing joy less frequently than TD and both groups expressing joy more frequently in social tasks versus non-social. Whereas no significant GLMs were found for other behavioral codes (all $ps>.05$).

Conclusions:

The tasks were effective in eliciting the target emotions, although no significant differences were found between social and non-social conditions. when considering emotions altogether. The observed differences in the Frequency of Gestalt in joy suggest that the social nature of tasks may influence the expression of positively-valenced emotion. Future studies should investigate this finding further with a more robust sample size.

442.299 Interpersonal Brain Synchrony in Mother-Child Social Interactions in Autistic and Non-Autistic Children: An fNIRS Hyperscanning Study

E. J. Choi¹, K. Stubbs¹, **L. Moradkhani¹**, Y. Li¹, A. Reid¹, D. Nouri¹, L. Shea¹, M. E. Wienberg¹, B. Stojanoski², E. Duerden¹ and R. A. Stevenson¹,
(1)University of Western Ontario, London, ON, Canada, (2)Ontario Tech University, London, ON, Canada

Background: Autistic children often face challenges in forming secure attachment relationships with their caregivers. Previous research, however, has shown that the sequelae of attachment security in autistic children may be similar to typically developing (TD) children, with around half of autistic children being classified as securely attached. Interpersonal synchrony reflects important aspects of real-time social relationships, encompassing not only behaviours and affective states but also biological neural rhythm, which can provide valuable insights into attachment relationships between autistic children and their primary caregivers.

Objectives: This study compared neural synchrony between mother-child dyads in school-aged children with autism and typically developing children to explore how attachment security modulates neural synchrony in both groups.

Methods: Functional near-infrared spectroscopy (fNIRS) was used to measure neural synchrony between mother-child dyads during puzzle play in the bilateral prefrontal cortices (PFC) and temporoparietal junction (TPJ). Both mother and child reported on their attachment relationship after the brain scan session. To date, 27 mother-child dyads (6 Autism, 21 TD, Mean age= 10.22±1.63 years, 44.4% male) have completed the sessions (Target: 30 for each group). In the puzzle task, the mother and child played with puzzles either independently (individual condition) or together (cooperation condition) (Figure 1A). The wavelet transform coherence (WTC) was used to estimate interpersonal neural synchrony in each dyad.

Results: In both groups and both conditions, high WTC indicated strong pairwise cohesion across most channels. A mixed effect model and subsequent contrast revealed significant differences in WTC between the Cooperation and Individual puzzle play conditions. Specifically, differences were observed strong cohesion between TPG to PFC while cooperating in the Autism group, while strong cohesion between TPG while playing individually in the TD group (Figure 1). Although the group differences were only trending towards significance due to a small sample size in one group, the TD group demonstrated a tendency of greater cohesion in mother-child dyads relative to the Autistic group. Additionally, widespread correlations between neural synchrony and attachment security were observed in the TD group (Figure 2, left). Correlations between neural synchrony and attachment security in the ASD are depicted in Figure 2, right panel, though interpretations should be tempered due to the current sample size.

Conclusions: Our preliminary analyses demonstrated that mother-TD dyads showed greater neural synchrony during cooperative puzzle play than mother-ASD dyads. The associations between neural synchrony and attachment security suggest that the relationship between mother-child attachment styles and mother-child interpersonal neural synchrony may differ across diagnosis status.

**442.300** Interpersonal Distance As Social Consequences in Adults with Typical Development with Varying Autism Spectrum Quotient: A Gaze-Contingent Study

C. An¹ and S. Matsuda², (1)Comprehensive Human Sciences, University of Tsukuba, Tsukuba, Ibaraki, Japan, (2)University of Tsukuba, Tsukuba, Ibaraki, Japan

Background:

Interpersonal distance is an important component of complex social interactions. Proper regulation of interpersonal distance can foster effective communication, while violations may lead to discomfort or perceived intrusions. However, research on individuals with Autism Spectrum Disorder (ASD) and interpersonal distance has produced conflicting results. Clinical studies suggest that individuals with ASD violate the social distance of others. In contrast, some experimental studies found that individuals with ASD maintain a greater interpersonal distance. These discrepancies may arise from variations in experimental design. Some studies treat changes in distance as an antecedent stimulus and others as a consequence of participants' behavior. Additionally, face-to-face experimental settings may be experienced differently by typically developing individuals and ASD.

To address these inconsistencies, this study manipulated the 3-term contingency, static face (antecedent stimulus) - gaze (behavior) - approach or recede (consequence). The study will explore participants' automatic, unconscious responses to social stimuli through gaze-contingent to gain a more nuanced understanding of how interpersonal distance is regulated.

Objectives:

To examine the effects of approaching or receding stimuli as social consequences on value learning and contingency processes in individuals with varying Autism Spectrum Quotient (AQ) scores.

Methods:

The experiment will involve 80 typically developing college students. The eye-tracking task will be implemented on the Tobii Pro X3-120. Face stimuli will be sourced from the 'AIST Facial Expression Database'.

During the baseline phase, participants will freely observe two pairs of static faces. In the training phase, viewing one face (high value) will trigger approach (recede) animation, while viewing the other face (low value) will result in no change. In the final test phase, participants will again freely view the two static faces (Figure 1).

The independent variables in the experiment were the condition- the face movement direction (approach, recede) and value (high value, low value).

The dependent variables were the mean dwell time, the proportion of high-value preference, saccadic reaction time, and AQ Score. These dependent variables will be derived from eye movement data, including metrics such as fixation duration and saccadic latency.

Results:

Data is currently collected from 49 participants. After the completion of data collection, the following analyses will be conducted:

Preliminary Analyses:

1. Investigate the relationship between gender and the condition (approach, recede).
2. Analyze the relationship between mean dwell time and condition during the baseline phase.
3. Examine the relationship between SRT and condition during the training phase.

Statistical Analyses:

1. Correlate the high-value (HV) preference proportion with the experimental procedure (baseline, test).
2. Correlate AQ scores (total score and subitems) with changes in HV preference proportion.
3. Correlate AQ scores (total score and subitems) with SRT.

Conclusions:

If participants consistently prefer the high-value face that triggers distance changes, this could suggest that value learning, based on social consequences, influences comfort with interpersonal distance. If significant correlations between AQ scores and the high-value preference proportion or SRT, it suggests that autism spectrum traits influence implicit social preferences, such as comfort with interpersonal distance or responsiveness to social cues.

**442.301 Interpersonal Dynamics in Autism: Insights from Vitality Forms**

J. Li¹, Q. Xie², X. Wang² and Z. Wang³, (1)School of Psychology, South China Normal University, Guangzhou, Guangdong, China, (2)Key Laboratory of Brain, Cognition and Education Sciences, Ministry of Education; Institute for Brain Research and Rehabilitation, and Guangdong Key Laboratory of Mental Health and Cognitive Science, South China Normal University, Guangzhou, Guangdong, China, (3)Key Laboratory for Quality of Life and Psychological Assessment and Intervention, Research Center for Quality of Life and Applied Psychology, School of Humanities and Management, Guangdong Medical University, Dongguan, Guangdong, China

Background:

Children with autism spectrum disorder (ASD) often face challenges in establishing effective interactions with others, with social difficulties being a core issue affecting their social adaptation. Interpersonal interactions are inherently bidirectional; thus, exploring the social cognitive deficits of children with ASD solely from their perspective does not capture the full narrative of their social challenges. Vitality forms express the subject's attitude toward others and serves as the foundation for social interaction. While previous research has identified obstacles in ASD individuals' recognition of others' vitality forms, the bidirectional nature of social interactions regarding vitality forms in ASD has not been adequately investigated.

Objectives:

This study aims to examine the ability of different groups including parents and autistic adults to recognize vitality forms in ASD, gaining a comprehensive understanding of ASD vitality forms from the perspective of social interaction's bidirectionality.

Methods:

A total of 80 participants were recruited, divided into four groups: (1) ASD parents group (AP, $n=18$, $\text{age}=38.28\pm1.64$), (2) TD parents group (TP, $n=16$, $\text{age}=37.87\pm1.25$), (3) High Autistic Traits group (HAT) ($n=24$, $\text{age}=22.08\pm2.47$), and (4) Low Autistic Traits group (LAT) ($n=22$, $\text{age}=21.82\pm2.46$). Participants completed two experimental tasks: determining whether the action goals of children (ASD vs. TD) were consistent (Aim Task: ASD condition vs. TD condition) and assessing whether the vitality forms of actions by children (ASD vs. TD) were consistent (Vitality Form Task, VF: ASD condition vs. TD condition), using sensitivity indices d' and reaction times as dependent variables.

Results:

Both the AP and TP groups demonstrated significantly higher accuracy in recognizing TD children's videos compared to ASD children's videos ($F_{(1,32)} = 8.23$, $p = 0.01$, $\eta^2 = 0.21$). In the HAT group, accuracy in the AIM task was higher than in the VF task ($F_{(1,23)} = 8.10$, $p = 0.01$, $\eta^2 = 0.26$), and accuracy for recognizing TD children's videos was significantly greater than for ASD children's videos ($F_{(1,23)} = 18.059$, $p < 0.001$, $\eta^2 = 0.44$). The LAT group also showed significantly higher accuracy in recognizing TD children's videos compared to ASD children's videos ($F_{(1,21)} = 7.68$, $p = 0.01$, $\eta^2 = 0.27$).

Conclusions:

Our findings indicate that different groups perform better in recognizing the behaviors of typically developing children, while they encounter significant difficulties in identifying the behaviors of children with ASD. This discrepancy may reflect the unique characteristics of behavioral expression in individuals with ASD. Our study indicates that even parents of children with autism do not show heightened sensitivity to ASD actions, which is consistent with previous studies that showed they could not identify cry from autistic children. The high autistic traits group also face challenges in understanding vitality forms, potentially due to exhibiting behaviors and cognitive characteristics associated with ASD. Our findings are expected to enhance the understanding of the bidirectional challenges faced by individuals with ASD and their neurotypical counterparts during interactions.

442.302 Interplay of Social Anxiety and Autistic Traits: Attention to the Eyes in Autistic and Neurotypical Children

X. Su¹, W. Ni², X. Li³ and L. Yi^{2,4}, (1)School of Psychological and Cognitive Sciences & Beijing Key Laboratory of Behavior and Mental Health, Peking University, Beijing, China, (2)School of Psychological and Cognitive Sciences & Key Laboratory of Behavior and Mental Health, Peking University, Beijing, China, (3)Peking University Sixth Hospital, National Clinical Research Center for Mental Disorders, Beijing, China, (4)PKU-IDG/McGovern Institute for Brain Research, Peking University, Beijing, China

Background: Autistic individuals often exhibit reduced attention to the eyes with others. Individuals with social anxiety may also show avoidance of attention to the eyes, but other research reported heightened alertness and delayed disengagement in individuals with social anxiety. While many autistic individuals experience high levels of social anxiety, the interrelationships between social anxiety and autistic traits regarding attention to the eyes remain unclear. Specifically, it is unknown whether social anxiety manifests differently in attention to the eyes among autistic individuals compared to neurotypical (NT) individuals.

Objectives: This study employed an eye-tracking paradigm to investigate attention to the eyes in autistic and NT children, aiming to explore how autistic traits and social anxiety interactively modulate the attentional process to the eyes.

Methods: Forty-five autistic children (mean age = 12.31 years, $SD = 2.16$) and 42 NT children (mean age = 12.02 years, $SD = 1.70$) participated in the study. All participants completed the Social Anxiety Scale (SAS; La Greca et al., 1988), while their parents completed the Autism Spectrum Quotient—Adolescent's Version (AQ; Baron-Cohen et al., 2006). We used a Tobii Pro Fusion eye tracker to capture participants' eye movements during a gender judgment task, consisting of 60 trials. Each trial began with participants focusing on the center of the screen, followed by the presentation of a face from the Tsinghua Facial Expression Database for 3 seconds, after which they determined the face's gender. The participants' first fixation was directed to either the eyes (eye-cuing condition) or the mouth (mouth-cuing condition). We calculated the latency to disengage from the eyes after initial fixations to eyes and the latency to shift from the mouth to the eye region following initial fixations to mouth. Additionally, we assessed the eye-looking proportion. Statistical analyses were performed using linear mixed models (LMMs).

Results: When we categorized NT and autistic children based on the cutoff of SAS into high ($SAS \geq 8$) and low social anxiety ($SAS < 8$) groups, we found that autistic children with high social anxiety took longer to shift from mouth to eyes and showed a lower eye-looking proportion than the other three groups in the mouth-cueing condition ($ps < .05$; Figure 1). Subsequently, we conducted LMMs among all participants to examine the impact of AQ and SAS on these indices. We identified an interactive effect of autistic traits and social anxiety on eye-looking proportion in the mouth-cueing condition ($p = .029$) and the time taken to shift from mouth to eye ($p = .066$). Further, we divided participants into two groups based on mean AQ (73). In the high AQ group ($AQ \geq 73$), higher levels of social anxiety were associated with a reduced proportion of eye-looking in the mouth-cueing condition and a prolonged gaze shift from the mouth to the eyes ($ps < .05$; Figure 2).

Conclusions: This study suggests that eye avoidance is evident only when both high levels of autistic traits and social anxiety coexist. Autistic children with elevated social anxiety are more likely to exhibit eye avoidance compared to neurotypical children with similar levels of social anxiety.

442.304 Joint Attention and IQ Among Autistic Children: Links across Development

A. Dakopoulos¹, O. J. Sargent², B. Heath³, S. J. Rogers⁴, M. Solomon⁵, D. G. Amaral³, P. Mundy⁴ and C. W. Nordahl³, (1)Department of Psychiatry and Behavioral Sciences, MIND Institute, UC Davis Medical Center, Sacramento, CA, (2)The University of Wisconsin-Madison, Madison, WI, (3)Department of Psychiatry and Behavioral Sciences, UC Davis MIND Institute, Sacramento, CA, (4)Department of Psychiatry and Behavioral Sciences, University California Davis, Sacramento, CA, (5)Peter Mundy, Davis, CA

Background: Research and theory suggests that an early disturbance of joint attention, and the related understanding of referential communication may contribute to differences in the development of IQ among autistic people. Between six- and twelve-months of life children incrementally develop the ability to use shifts of gaze direction, pointing and showing bids for joint attention in order to follow and initiate episodes of intentional reference in interaction with caregivers. Differences in the development of initiations and responses to bids for joint attention are an early symptom of autism that is associated with differences in social cognitive development, learning and language acquisition. Recent research also suggests joint attention symptoms may be a significant correlate of IQ differences in autism across ages. This study was designed to examine that hypothesis.

Objectives: 1) to examine concurrent and longitudinal associations between joint attention and IQ across childhood in a large sample of autistic children with and without intellectual disability; and 2) examine whether sex moderates the association between joint attention and intelligence in autism.

Methods: Longitudinal data was collected in 314 autistic children from 2-13 years of age at Visit 1 ($n = 196/118$ (m/f), $m_{age} = 3.01$ years), Visit 2 ($n = 86/53$ (m/f), $m_{age} = 5.64$ years), and Visit 3 ($n = 91/29$ (m/f), $m_{age} = 11.42$ years). Diagnoses of autism were established at Visit 1 by licensed clinical psychologists using ADOS and ADI-R, and all children were reassessed at Visits 2 and 3. Joint attention scores at Visits 1, 2, and 3 were derived from ADOS-2 items, an approach that has been utilized by others and whose factor structure was established and independently replicated. The Mullen Scales of Early Learning (MSEL) was used at Visit 1 to obtain a developmental quotient (DQ), and the Differential Ability Scales-II (DAS-II) was used to measure IQ at Visit 2 and 3.

Results: Children's joint attention skills were strongly related to their concurrent IQ scores at Visit 1 ($r(312) = .61, p < .001$), Visit 2 ($r(137) = .78, p < .001$), and Visit 3 ($r(118) = .65, p < .001$). Associations between joint attention and IQ were significantly stronger than other measures of autism symptom severity (e.g., ADOS severity scores, p 's $< .001$). Longitudinal path analyses indicated that joint attention development from Visit 1 to 3 significantly mediated IQ development across that same time period ($p = .023$). Finally, a differential relation between joint attention development from Visit 1 to 2 was found for girls compared to boys, with autistic girls demonstrating a stronger association between joint attention development and IQ outcome at Visit 3 compared to boys ($F(1,66) = 6.55, p = .012$).

Conclusions: Results of the present study indicate that joint attention in early and middle childhood is concurrently related to IQ in autistic children, and that joint attention development predicts IQ outcomes in later childhood. There is also evidence that joint attention may develop differentially for autistic boys compared to girls from age 2 to 13 years.

**442.305** Less Face Engagement, More Object Focus, and Greater Pupil Constriction Associated with Autistic Traits in Nonautistic Preschoolers

C. E. Brittenham¹ and J. B. Wagner², (1)Departments of Pediatrics & Neuroscience, Albert Einstein College of Medicine, Bronx, NY, (2)Department of Psychology, College of Staten Island, CUNY, Staten Island, NY

Background: Autistic children often show reduced social attention and increased interest in non-social stimuli (Pierce et al., 2011). Eye-tracking studies reveal attentional differences in autism when processing faces and objects, especially when presented in direct competition (Unruh et al., 2016). Additionally, greater pupil constriction during visual scanning in autistic children as compared to their nonautistic peers suggests distinct visual processing strategies in autism (Anderson et al., 2006).

Objectives: This study asks whether patterns of visual attention and scanning observed in autistic children are also evident in nonautistic children with higher levels of autistic traits.

Methods: Nonautistic preschool-aged children ($N = 52$, $M_{age} = 49.25$ months, $SD = 11$) viewed images displaying arrays of five items (face, bird, car, phone, scrambled face, see Elsabbagh et al., 2013) while an SMI RED 120Hz eye-tracker recorded gaze and pupil responses. Eight different arrays were presented, each for 12 seconds. Caregivers completed the Social Responsiveness Scale, Second Edition (SRS-2, Constantino & Gruber, 2012), assessing autism-related characteristics. Participants were grouped into low or high traits groups following a median split of SRS-2 total scores. Eye-tracking analyses examined 1) face engagement as attention to faces relative to all items and 2) object engagement as attention to objects (average for phone and car) relative to all items. Face and object engagement were calculated for both total time and number of fixations. Additionally, pupil size change was calculated (stimulus minus pre-stimulus).

Results: Linear mixed models (LMM) with category (face, objects) and group (low, high) revealed significant category x group interactions for total time ($F(1,104) = 13.83, p < .001$, see Figure 1A) and fixation ($F(1,104) = 12.28, p < .001$). Follow-ups showed that as compared to the low traits group, the high traits group exhibited less face engagement for total time and fixations ($ts > 2.5, ps < .02$) and more object engagement for total time and fixations ($ts > 2.2, ps < .03$). Within groups, only the low group showed greater face than object engagement for both total time and fixations ($ts > 4.0, ps < .001$). Across the full sample, face engagement was negatively correlated with SRS-2 scores ($rs > -.32, ps < .02$), while object engagement was positively correlated with SRS-2 scores ($rs > .28, ps < .02$; see Figure 1B). For pupil analysis, the high traits group showed greater constriction relative to baseline during visual scanning than the low traits group, $t(50) = 2.24, p = .030$, and overall, pupil change was negatively correlated with SRS-2 scores, $r(50) = -.315, p = .024$ (see Figure 2).

Conclusions: The current study found less face engagement and more object focus in a sample of nonautistic children with higher levels of autistic traits, extending past findings with autistic children (Unruh et al., 2016). Additionally, greater pupil constriction from baseline observed in the high traits group suggests that altered visual processing strategies could reflect variation in autistic traits more broadly (Anderson et al., 2006). These findings underscore the high potential of visual attention and scanning to offer insights into the broader continuum of autistic traits.

442.306 Live Social Interaction Joint-Attention Task for Autistic Adolescents

S. Muhammad¹, M. Arrington², H. M. Mattern³ and S. Scherf⁴, (1)*The Pennsylvania State University, State College, PA*, (2)*UC - Davis, Davis, CA*, (3)*Developmental Psychology, Penn State University, University Park, PA*, (4)*Pennsylvania State University, University Park, PA*

Background:

Eye gaze cues (e.g., holding and shifting gaze) provide important non-verbal communicative signals that organize social interactions. Autistic individuals have difficulties understanding eye gaze cues, which was originally observed in infants during episodes of joint attention (i.e., shared attention to objects with other people (Mundy, 1994). Importantly, these difficulties persist beyond infancy into adolescence and adulthood (Riby et al, 2013; Whyte & Scherf, 2017; Griffin & Scherf, 2020). A concern about much of this work is that it uses paradigms that do not involve social partners, which may alter the way gaze shifts are perceived and understood (Laskowitz et al, 2020).

Objectives:

Here, we present a new task that evaluates sensitivity to perceiving, understanding, and using eye gaze cues in the context of a live social interaction. It was developed as part of a battery of tasks to evaluate the effectiveness of a psychosocial serious game intervention to improve sensitivity to eye gaze cues in autistic adolescents (Scherf et al, 2018).

Methods:

The task is a live joint attention task that is age-appropriate for adolescents. A researcher sits directly across a small table from the participant and leads the social interaction. On each trial, the researcher places two objects on the table (e.g., two cups), verbally describes a context in which they like to use cups (e.g., drinking coffee in my office), executes a shift of gaze while saying, "that one is my favorite," and asks the participant to pick up the favorite object and place it in front of them. The task was executed with different sets of objects before and after the intervention. Both accuracy and visual attention were measured.

Results:

42 autistic adolescents were randomized to either the intervention or placebo control groups for a randomized controlled trial. At baseline assessment, participants in both groups completed the live joint attention task significantly above chance levels (Control $M = .75$ ($SD = .24$), Intervention $M = .68$ ($SD = .29$)). However, the distribution of scores indicated both ceiling and floor effects. Full scale IQ was positively associated with performance, $r(40) = 0.44$, $p = .002$. Overtime, these scores were most stable in the control group ($ICC = 0.65$, 95% CI 0.12 – 0.86) and more variable in the intervention group ($ICC = 0.45$, 95% CI -0.30 – 0.77).

Conclusions:

The results suggest that many autistic adolescents were able to perceive and understand the eye gaze cues in the live joint attention task. Increasing the difficulty of the task may be necessary to avoid ceiling effects, particularly for individuals who also have particularly high IQ. This is the first iteration of a task to help fine-tune our understanding of autistic adolescents' ability to use eye-gaze cues in live social interactions.

442.307 Non-Autistic College Students' Responses to the Social Behavior of a Fictional Autistic Peer

A. M. Birnschein¹, R. L. Harmon² and T. S. Tomeny², (1)*Psychology, The University of Alabama, Tuscaloosa, AL*, (2)*Psychology, The University of Alabama, Tuscaloosa, AL*

Background: Autistic college students commonly experience strained social relationships with non-autistic peers (e.g., Locke et al., 2010). This is often attributed to the autistic individual's social skills differences, which are central to a diagnosis of autism (American Psychiatric Association, 2022). Yet, how non-autistic peers receive and respond to autistic individuals is also predictive of social interaction outcomes (e.g., Sasson et al., 2017). Many researchers have studied non-autistic people's responses to autistic peers (e.g., White et al., 2019), but to our knowledge, no existing study has evaluated potential mediating effects of involved constructs.

Objectives: The present study investigated the relations between non-autistic college students' perceptions of a hypothetical autistic individual and the non-autistic peers' affective responses, attitudinal responses, and willingness to engage socially with that hypothetical peer.

Methods: 469 non-autistic college students enrolled in an introductory psychology course independently reviewed a written vignette (adapted from Underhill et al., 2019) depicting a scenario in which they were in the same college course as a classmate who demonstrated characteristics of autism. Non-autistic participants then responded to questions assessing their in-the-moment affect responses, beliefs about, and attitudes and behavioral intentions toward the hypothetical vignette character. Additionally, they completed measures assessing their previous experiences with autistic people, their social desirability, and their demographic information. We hypothesized that the relation between predictor variables: non-autistic peers' quality of previous contact, perceptions of the hypothetical peer's control over their behavior, and perceptions of the hypothetical peers' responsibility for their behavior and criterion variables: attitudes about autism and willingness to engage with autistic individuals, would be mediated by the peers' affective responses to autistic individuals.

Results: Results indicated that positive affect mediated the relations between quality of previous contact and positive attitudes and willingness to engage, whereas there was no association between perceived controllability or perceived responsibility and positive affect, positive attitudes, or willingness to engage (Figure 1).

Conclusions: These results demonstrate that having more positive previous experiences with autistic individuals and more positive in-the-moment affective responses toward an autistic individual are associated with more positive non-autistic peer perceptions and behavioral intentions. Thus, future interventions aiming to improve interactions between autistic and non-autistic people may benefit from facilitating positive interactions between the social partners to improve the likelihood that non-autistic people will be willing to have positive perspectives of, and more likely to engage with, autistic peers. Continuing to investigate the mechanisms facilitating or hindering non-autistic engagement with autistic peers can shift the onus from autistic individuals to both social partners. Such intervention work should align with neurodiversity perspectives promoting understanding and acceptance of the social presentations of autistic people.

**442.308 Patterns of Social Difficulties and Anxiety in Autism**

G. L. Simmons¹, K. Iheoma¹, J. Reaven², K. Pickard³ and L. G. Klinger¹, (1)*TEACCH Autism Program; Psychiatry, UNC TEACCH Autism Program, Chapel Hill, NC*, (2)*Psychiatry, University of Colorado Anschutz Medical Campus, Aurora, CO*, (3)*Emory University School of Medicine, Marcus Autism Center, Atlanta, GA*

Background: Autistic youth present with diagnostic difficulties navigating social interactions and maintaining relationships¹. Additionally, as many as 40% of autistic youth may exhibit clinically significant anxiety². Importantly, parents and youth frequently do not agree on measurements of internalizing symptoms in youth, and inclusion of multiple reporters is critical³. In non-autistic youth, anxiety is understood to derive, in part, from difficulties with social/emotional reciprocity and parent-reported social difficulties⁴. Research examining this model in autistic youth is inconsistent: self-reported peer victimization is associated with self-reported anxiety symptoms in autistic youth⁵, though self-reported social difficulties alone do not account for the development of parent-reported social anxiety⁶. Parent-reported anxiety predicts the development of peer relationships⁷ and autistic traits⁸, though research does not support the inverse model⁹. The proposed study incorporates caregiver-, self- and teacher-reports to examine the impact of social difficulties on anxiety in autistic youth.

Objectives:

1. Examine association between social difficulties and anxiety, controlling for social cognitive differences, in single informant (caregiver) model
2. Explore interrater agreement on anxiety and social difficulties in autistic youth
3. Examine association between social difficulties and anxiety across informant ratings of anxiety

Methods: Autistic youth ages 8 -15 ($n = 67$) and caregivers were recruited as part of an ongoing multi-site, randomized clinical trial. Youth (age $M=10.89$, $SD=1.55$) were predominantly male assigned at birth (70.1%), White/Caucasian (79.1%), with average cognitive ability (WASI-II FSIQ: $M=103.04$, $SD=17.98$) Measures included SRS-2⁹ (Social Cognition subscale); Strengths and Difficulties Questionnaire¹⁰ (SDQ-Caregiver; SDQ-Teacher); Screen for Child Related Anxiety Disorders¹¹ (SCARED-Caregiver; SCARED-Self); and School Anxiety Scale¹² (SAS-Teacher); collected at a single timepoint.

Results:

Regarding Aim 1, caregiver ratings were examined with six partial correlations^a controlling for social cognitive difficulties (SRS-2): social difficulties were significantly related to all SCARED domains (Table 1).

Regarding Aim 2, Wilcoxon signed-rank tests indicated no significant differences between standardized (z -score) caregiver/child/teacher-reported total anxiety or social anxiety (SCARED, SAS; $p>.05$). Paired-samples t -test indicated no difference between caregiver/teacher reported SDQ-Peer Problems ($p=.112$).

Regarding Aim 3, ten partial correlations^a were conducted between caregiver/teacher-reported SDQ-Peer Problems and caregiver/self/teacher-reported Total Anxiety and Social Anxiety, controlling for social cognitive difficulties (SRS-2). Nonsignificant weak correlations were noted between caregiver-reported SDQ-Peer Problems and SAS-Teacher Total Anxiety ($r = -.25$, $p=.225$), as well as with SCARED-Self Social Anxiety ($r = -.25$, $p=.225$). Overall, SDQ-Peer Problems were not significantly related to reported anxiety across informants (remaining partial $r < .20$, $p > .05$).

Conclusions: Findings contribute to our understanding of social difficulties and anxiety in autism. Within caregiver ratings, social difficulties are related to anxiety even when controlling for social cognitive differences associated with an autism diagnosis. Further, while no differences were found between reporters, social difficulties were not related to anxiety across reporters. Lack of agreement across raters reflects prior work examining social difficulties and teacher-reported anxiety in non-autistic youth¹², and underscores the importance of including multiple informants in clinical research. Overall results demonstrate value of work targeting social difficulties (i.e., social skill interventions), particularly those which support youths' self-directed social development, which may impact overall mental health.

442.309 Predicting Vocalizations during Peer Social Contact for Children with ASD in Inclusive Preschool Classrooms
M. Drye, L. Estrada, L. Vitale, L. K. Perry and D. S. Messinger, Department of Psychology, University of Miami, Coral Gables, FL

Background: Children with ASD commonly exhibit challenges with language and social interaction. Prior research has indicated reduced vocalization rates during classroom social contact among children with ASD. However, it is unknown whether these difficulties are influenced by overall vocalization rate, overall social contact with peers, or both. Understanding the social experiences of children in inclusive preschool classrooms with objective measures may shed light on how such differences emerge.

Objectives: Explore predictors of preschoolers' frequency of vocalizations per minute in social contact, including overall proportion of classroom time in social contact and overall vocalization frequency per minute of classroom time, among children with ASD, developmental disabilities (DD), and typical development (TD).

Methods: Participants were 108 3-5-year-old preschoolers (35 ASD, 38 DD, 35 TD) in 12 inclusive classrooms. Approximately monthly, children wore vests with Ultra-Wideband Radio Frequency Identification (RFID) tags to record their movement and a LENA audio recorder to record their vocalizations during the school day ($M=123$ minutes per observation). Child position/orientation was used to identify moments of social contact with peers (within 2 meters and approximately face-to-face). Vocalizations lasted ≥ 50 milliseconds and ended if interrupted by silence or noise lasting ≥ 300 milliseconds. Multilevel models (observations nested in children nested in classrooms) predicted vocalization frequency during social contact from log-transformed, child-centered proportion of classroom time in social contact and child-centered overall vocalization frequency with interaction terms quantifying how these associations varied by group (ASD, DD, TD).

Results: Children with TD vocalized in social contact at a mean rate of 3.25 vocalizations per minute. Controlling for other predictors, neither autistic children nor children with DD significantly differed from the TD group in their mean vocalization frequency in social contact ($p_{ASD} = .086$; $p_{DD} = .386$; $\alpha = 0.01$). Greater time spent in social contact was associated with increased vocalization frequency for children with TD ($p < .001$), but interaction effects indicated that this relationship was weaker for autistic children ($p = .003$) and children with DD ($p = .002$) than children with TD. Greater overall vocalization frequency in class was associated with increased vocalization frequency for children with TD ($p < .001$), and interaction effects indicated that this association was also positive for the ASD and the DD groups ($p_{ASD} = .049$; $p_{DD} = .513$; **Table 1 & Figure 1**).

Conclusions: Controlling for the influence of overall social contact and vocalization frequency, no differences were observed in the vocalization rate in social contact between children with ASD and other children. Children with TD who spent more time in social contact tended to vocalize more often during social contact, yet this association was nearly absent for children with ASD and DD. In contrast, children with ASD, DD, and TD all showed positive associations between their overall classroom and social contact vocalization frequencies. Time spent in social contact with peers appears to have less influence on how frequently children with ASD and DD vocalize in social contact, highlighting the need for interventions targeting the communicative quality of social interactions for neurodivergent children.

442.311 A Qualitative Exploration of the Range of Coping Strategies Used to Compensate/Camouflage in Social Situations: A Framework Analysis with Data from 342 Autistic and Non-Autistic Adults in Hong Kong

Q. K. Y. Siu^{1,2}, F. Happe³, E. Loth⁴ and K. K. M. Shum¹, (1)Department of Psychology, University of Hong Kong, Hong Kong, Hong Kong, (2)Social, Genetic and Developmental Psychiatry Centre, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (3)Social, Genetic and Developmental Psychiatry Centre, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, UNITED KINGDOM, (4)Department of Forensic and Neurodevelopmental Sciences, Flat 2, 116, South Hill Park, London, London, United Kingdom

Background: Current conceptualisations of the coping strategies used to compensate for social difficulties or increase social acceptance in autism stem from Western research (Hull et al., 2017; Livingston et al., 2019). However, social conventions (e.g., expectations of socially acceptable behaviours) and socialisation goals are culture-dependent, and potentially shape differences in the development and use of social coping strategies. Taking a broader sociocultural perspective, growing research in the East has centred on masking and camouflaging, here referred to as shallow compensation. There remains a lack of exploratory qualitative research using open-ended questions to investigate a wider range of social coping strategies (i.e., more flexible and proactive strategies than just shallow compensation) beyond Western contexts.

Objectives: This qualitative study aimed to broadly explore various strategies used by autistic and non-autistic adults in Hong Kong to cope in social situations, ranging from behavioural and cognitive to environmental-mediated processes.

Methods: We extended Livingston et al.'s (2019) methodology to a Hong Kong convenience sample. Participants were 69 autistic adults, 50 self-identifying autistic adults (who did not have a formal diagnosis), and 223 non-autistic adults aged 18 to 72 years ($M = 26.2$, $SD = 9.70$; with 62% identified as females). They completed an online survey comprising open-ended and semi-open questions on their experiences of using social coping strategies, and standardised self-report questionnaires measuring autistic traits and cultural orientations, as part of a larger cross-cultural study. Framework analysis was conducted to identify themes and subthemes that represent various social coping strategies.

Results: Five superordinate themes were identified: 1) 'regulate behaviours to meet social functions', which involves suppression and enactment of behaviours to avoid social faux pas and/or display social interest; 2) 'information-seeking for social reasoning', which includes both explicit (e.g., asking directly) and implicit (e.g., observing for verbal and non-verbal cues) sources of information to reason about others' inner states via non-social cognitive means; 3) 'cognitive reappraisal' ('a mental game'), such as adjusting expectations and applying self-compassionate thinking in social situations; 4) 'remove interpersonal stressors' through full/partial absence from a social situation; and 5) 'seek person-environment fit' through attempts to select or create an optimal environment and play to one's strengths in a setting, to promote positive social experiences. All themes and subthemes were shared between autistic and non-autistic people, and largely mapped to the strategy repertoire reported by Livingston et al. (2019). We additionally found cognitive reappraisal to be a novel group of strategies that is conceptually distinct from other strategies identified in previous Western findings. More specific cultural variations in the 'how-to' (e.g., more indirect ways for applying a strategy), rather than 'what kinds' of strategies, were observed within subthemes.

Conclusions: This is the first study to report qualitative findings on the repertoire of social coping strategies from a non-Western sample. The findings will inform a cross-culturally applicable conceptual framework for social coping strategies in autism, and our subsequent development of a new comprehensive questionnaire measure of social coping strategies.

442.312 Reappraising Social Attention Tasks in Autism Cognition Research: A Pathway to Neurodiversity-Centered Revision

M. Alexandrovsky^{1,2} and M. C. Lai², (1)Department of Psychology, University of Toronto, Toronto, ON, Canada, (2)Campbell Family Mental Health Research Institute, Centre for Addiction and Mental Health, Toronto, ON, Canada

Background: Cognitive differences are central to autism. While prevailing theories, such as those regarding social attention, often frame autistic individuals as deficient, there is a growing reflection on whether this is an equitable and accurate understanding of autistic cognition. Importantly, experimental tasks were infrequently designed by or with autistic individuals and did not adequately consider their unique needs and perspectives. Consequently, these tasks may fall short of capturing both the weaknesses and strengths of autistic cognition. For example, evidence for diminished attention to the eyes and social stimuli in autistic individuals is inconsistent, and stimuli are usually passively viewed and not entirely ecologically valid.

Objectives: We approach this issue of inequitable autism cognition research by systemically and critically reviewing prevailing cognitive experimental tasks used in autism research. This first report focuses on critically reappraising experimental tasks pertaining to social attention by identifying inequities in the tasks and exploring their impact on autistic individuals and our understanding of autism.

Methods: We conducted an integrative umbrella review in PsychInfo, MedLine, Embase, Cochrane Database of Systematic Reviews, and Web of Science Core Collection (see PRISMA flowchart, Fig. 1) to identify prominent experimental paradigms. An autistic researcher (the first author) reappraised the paradigms via engagement with other autistics in a modified Delphi process, targeting (1) barriers to expected interaction with stimuli and discomfort during measurement; (2) ecological validity using the Multidimensional Assessment of Research in Context (MARC) Tool; (3) potential misinterpretation of instructions by participants and of behavioral findings by researchers; and (4) autistic research priorities.

Results: After screening, 12755 task mentions in the included reviews were extracted, of which 774 were related to social attention. Most such studies used eye-tracking methods and social stimuli (Table 1). Reappraisal from the lead autistic researcher led to concerns with (1) sensory barriers related to passive viewing of stimuli that were not considered for task execution and data analyses (e.g., screen brightness, pixilation, color contrast); (2) questionable ecological validity, further differentiating stimuli from real-life interactions (Table 1); and (3) while specific experimental instructions were rarely reported, researchers assumed that a lack of visual attention inherently entails reduced social attention. To improve ecological and interpretation validity, experiments need to go beyond passive viewing by integrating attention tracking in naturalistic, accessible interactions. Moreover, research must incorporate non-visual modalities, as autistic individuals can be socially engaged without looking at a social target. These results, research priorities, and potential task revisions will be further shaped by the ongoing Delphi process with an autistic focus group. Full results will be presented at the conference.

Conclusions: Through engagement with other autistic people in a critical Delphi process, critiques of social attention tasks in autism research are being enhanced and revisions proposed. For example, research in verbally-communicative populations could incorporate qualitative reports in addition to eye tracking measures, in sensory-friendly real-time interaction. Ultimately, this study strives to contribute to the wellbeing of autistic individuals and the community by reshaping the landscape of autism cognition research to authentically reflect the lived experiences of autistic individuals.

442.313 Relations between Social Camouflaging and Self-Assessment Accuracy in Cognitive and Social Cognitive Domains

X. Shannon and K. R. Warnell, *Department of Psychology, Texas State University, San Marcos, TX*

Background: Despite extensive research on social cognition in autism, few studies have examined alignment between assessments of one's own social skills and external measures of social ability (i.e., self-assessment accuracy; Harvey & Pinkham, 2015). Prior research on self-assessment accuracy in autism has found evidence for both overestimation and underestimation of social cognitive ability (DeBrabander et al., 2021). Variability in social camouflaging, or the employment of strategies to mask autistic behaviors (Hull et al., 2017), may explain these heterogeneous findings and influence links between misestimation and well-being. Camouflaging, autistic-like traits, and mental health are related in the general population (O'Loghlen et al., 2024), but no studies have examined how camouflaging influences self-assessment accuracy.

Objectives: We examined how variability in camouflaging impacted the relation between actual and self-assessed performance on cognitive and social cognitive tasks.

Methods: U.S. adults from the general population ($N=202$; average age 39.73y; 83 male, 114 female, 5 non-binary) completed an online survey. Participants completed a face-based social cognitive task (Reading the Mind in the Eyes; Baron-Cohen et al., 2001a), a story-based social cognitive task (Hinting Task; Corcoran et al., 1995), and a math test as a non-social control. Additionally, participants completed measures of social camouflaging (Camouflaging Autistic Traits Questionnaire [CAT-Q]; Hull et al., 2019), autistic traits (Autism Quotient; Baron-Cohen et al., 2001b), social anxiety (Social Interaction Anxiety Scale; Mattick & Clarke, 1998), social motivation (Mind Reading Motivation; Carpenter et al., 2016), general self-monitoring (Snyder, 1986), depression (Kroenke et al., 2001), and loneliness (Hughes et al., 2004).

Results: CAT-Q scores significantly moderated the relation between actual and self-assessed performance on the face-based social cognition task, even after controlling for age, gender, autistic traits, social anxiety, social motivation, and general self-monitoring ($F(1,192)=5.69, p=.018$).

Moderating effects were strongest for the CAT-Q compensation subscale, which assesses strategies to compensate for social difficulties (e.g., practicing facial expressions). Johnson-Neyman analysis indicated two inflection points such that low compensators showed a strong positive correlation between actual and perceived ability (i.e., high self-assessment accuracy) with the correlation becoming non-significant and then negative as compensation increased. Compensation also moderated links between underestimation and mental well-being (loneliness: $F(1,196)=4.20, p=.042$; depression: $F(1,196)=2.96, p=.087$), such that greater underestimation of performance related to negative outcomes only for high compensators. These moderation effects were present even though compensation scores were not related to actual or estimated performance ($r_s < .1$). Camouflaging did not moderate relations between actual and self-assessed ability on the math test or the story-based social cognitive measure.

Conclusions: Social camouflaging impacted relations between actual and self-assessed performance on a face-based social cognitive task, but not a story-based social cognitive task or a non-social control task. For the face-based task, the ability of individuals to correctly estimate their scores was significantly diminished at higher levels of camouflaging, even though the scores themselves were not impacted. Although the current study cannot identify the mechanisms driving this moderation, future research should use more interactive measures with clinical populations to pinpoint the potentially bidirectional factors linking increased camouflaging to difficulties gauging social success.

442.314 Relationship Closeness and Loneliness: Predictors of Subjective Wellbeing in Autistic Adults

K. L. Ridgway¹, J. Walsh-Adams², C. M. Macmillan³, M. Hooley⁴, D. Hedley⁵, E. Westrupp⁶, M. A. Stokes⁴ and D. H. Demmer⁷, (1)Healthy Autistic Life Lab; School of Psychology, Deakin University - Healthy Autistic Life Lab, Melbourne, VIC, Australia, (2)Healthy Autistic Life Lab, Melbourne, VIC, Australia, (3)Murdoch Children's Research Institute, The Royal Children's Hospital, Parkville, VIC, Australia, (4)Healthy Autistic Life Lab; School of Psychology, Deakin University, Burwood, VIC, Australia, (5)Olga Tennison Autism Research Centre, La Trobe University, Melbourne, VIC, Australia, (6)School of Psychology, Deakin University, VIC, Australia, Melbourne, VIC, Australia, (7)School of Psychology, Healthy Autistic Life Lab, Deakin University, Melbourne, VIC, Australia

Background: According to the homeostatic theory of Subjective Wellbeing (SWB) an individual's SWB is maintained within a positive homeostatic set-point range (70- to 90-points on a scale of 0-100) that helps to protect against adverse mental and physical health outcomes. Homeostatic maintenance is supported by putative *buffers*, such as feeling socially connected through close relationships. Autistic individuals can have difficulty establishing close social relationships, which may increase loneliness and interfere with the homeostatic maintenance of their SWB. Given that lower SWB is found among autistic people compared to the general population, it may be useful to examine the potentially mediating role of social relationships in the SWB of autistic individuals.

Objectives: To examine the homeostatic theory of SWB in autistic adults, by exploring the effect of loneliness and relationship closeness on SWB.

Methods: We conducted a cross-sectional, quantitative study of 170 autistic adults ($M_{age}=30.59$, $SD=9.45$). Of our sample, 86 (50.6%) were assigned male at birth, 81 (47.6%) assigned female at birth, and three participants did not specify. Participants completed an online survey between December 2023 and March 2024 on measures of autistic traits (Social Responsiveness Scale Second Edition), relationship closeness (Unidimensional Relationship Closeness Sale), loneliness (UCLA 3-item), and SWB (Personal Wellbeing Index-Adult).

Results: On average, our sample of autistic adults scored low SWB ($M=48.89$, $SD=20.84$); 82.3% scored below the positive range (<70 points) with 50% scoring <50-points. A stepwise regression analysis revealed that at step one, age and assigned sex significantly predicted SWB $F(2,167) 3.58$, $p<.05$, $\eta^2=0.04$. At step two, autistic traits significantly predicted SWB, $F(3,166) 6.775$, $p<.001$, $\eta^2=0.08$. At step three, relationship closeness significantly predicted SWB, $F(4,165) = 12.42$, $p<.001$, $\eta^2=0.13$. In the fourth step, loneliness significantly predicted SWB, $F(5, 164) = 14.42$, $p<.001$, $\eta^2=0.15$. This model explained 31% of the variance in SWB ($R^2=0.31$, $p<.001$), with relationship closeness predicting ($b=.35$, $p<.001$), loneliness ($b=-.30$, $p<.001$), autistic traits ($b=-.27$, $p<.001$), and assigned sex at birth ($b=-.16$, $p<.05$).

Conclusions: Our results suggest that close relationships and loneliness are related to lower SWB in autistic adults, consistent with the homeostatic theory of SWB. Consistent with previous research, our sample of autistic adults' mean SWB score was well below the positive range expected based on adult population norms. Concerningly, our sample's very low SWB scores suggest that autistic adults are at high risk of homeostatic defeat. Our findings suggest relationship quality as an important factor in establishing and maintaining SWB among autistic adults, and we recommend that interventions target relationship support to help autistic people build and maintain strong close relationships and reduce loneliness to protect SWB.

442.315 Revisiting "Empathic Accuracy" across Autistic and Non-Autistic Adults Using a Newly Developed Cross-Neurotype Empathic Accuracy Task

W. Ai¹, **J. X. Yu¹**, M. Alexandrovsky¹, B. K. Jacob², J. Lee³, A. Li⁴, D. Ong⁵, W. A. Cunningham¹ and M. C. Lai⁶, (1)Department of Psychology, University of Toronto, Toronto, ON, Canada, (2)Department of Psychology, University of Toronto Mississauga, Mississauga, ON, Canada, (3)University of Toronto, Toronto, ON, Canada, (4)Centre for Addiction and Mental Health, Toronto, ON, Canada, (5)University of Texas at Austin, Austin, TX, (6)Campbell Family Mental Health Research Institute, Centre for Addiction and Mental Health, Toronto, ON, Canada

Background: Autistic people's social-communication difficulties have been understood through a deficit-based lens. The Double Empathy Problem (DEP) theory posits that social misunderstanding occurs bidirectionally between autistics and non-autistics. However, there lacks cognitive-level empirical examinations of DEP predictions. Cognitive empathy (i.e., inferring others' feelings) and affective empathy (i.e., experiencing others' feelings) support social-communication. It is unclear how these empathic capacities are dynamically impacted by neurotype (mis)alignment. **Objectives:** To examine how cognitive and affective empathy depend on different neurotype-pairing contexts using a revised empathic accuracy task.

Methods: We developed a cross-neurotype version of the empathic accuracy task (cnEAT). We recorded autistic and non-autistic adult narrators recounting sad and happy autobiographical events. Afterwards, the narrators viewed their videos and retrospectively rated time-series changes in their *emotional intensity* along a continuous scale from *no emotion* to *very strong emotion*.

In this pilot study, we employed a 2 (narrator neurotype: autistic vs. non-autistic) x 2 (participant/perceiver neurotype: autistic vs. non-autistic) design. The pilot sample included 60 autistic (30 men, 30 women, $M_{age}=34.9$ yrs) and 60 non-autistic (30 men, 30 women, $M_{age}=36.2$ yrs) North American adults recruited via Prolific. Each participant watched 4 emotional videos featuring 2 autistic and 2 non-autistic narrators, each narrating either a sad or happy event. Participants were blind to the video emotion labels and the narrators' neurotypes. Participants only watched narrators of the same gender. To measure cognitive empathy, while watching, participants continuously tracked the narrator's emotional intensity using the same scale the narrators used. To measure affective empathy, they reported how happy or sad each video made them feel on a 7-point Likert scale. For each video, we calculated Pearson's correlations between each participant's rating and the narrator's own (gold-standard) rating time-series. These coefficients, indexing cognitive empathy, were compared using mixed ANOVAs for happy and sad videos separately. A series of *t*-tests assessed how affective empathy differed across participant-narrator neurotype pairings.

Results: For cognitive empathy of happiness, a participant-by-narrator neurotype interaction approached significance, $F(1, 97)=3.71, p=0.057, \eta_p^2=0.04$. Pairwise comparisons revealed that non-autistic participants were less accurate when rating autistic than non-autistic narrators, $t(97)=-2.38, p=0.019$. For sadness, there was a main effect of participant neurotype, $F(1, 99)=5.92, p=0.017, \eta_p^2=0.06$. Non-autistic participants showed greater accuracy than autistic participants across sad videos, $t(99)=2.53, p=0.013$.

For affective empathy, non-autistic participants felt less happy when viewing autistic than non-autistic narrators recounting happy events, $t(118)=-5.63, p<0.001$. Within autistic participants, they felt sadder when watching autistic than non-autistic narrators recounting sad events, $t(117)=4.53, p<0.001$. Comparing between autistic and non-autistic participants viewing the autistic narrator, autistic participants felt sadder, $t(117)=2.00, p=0.048$.

Conclusions: These preliminary findings partially support the DEP theory predictions. Although non-autistic participants were more accurate in inferring sadness, they may struggle with recognizing and relating to the happiness of autistic narrators. Importantly, autistic participants interpreted the emotions of autistic and non-autistic narrators equally as accurately and related to the sadness of autistic narrators more strongly. These observations challenge longstanding assumptions of autistic "lack of empathy" and guide future research on context-dependent features of autistic social cognition.

442.316 Self-Regulation Processes Underlying Social Motivation Differences in Children with ASD: The Influence of Social Context

J. M. Keith¹ and **L. Bennetto²**, (1)Department of Psychiatry, University of Rochester Medical Center, Rochester, NY, (2)Psychology, University of Rochester, Rochester, NY

Background: Autism spectrum disorder (ASD) is a prevalent neurodevelopmental condition that includes differences in social communication and the presence of restricted, repetitive interests and behaviors. Considerable research supports the role of disrupted social motivation processes in atypical social development in ASD. Separately, research suggests that individuals with ASD experience increased stress reactivity to, and behavioral avoidance of, social stimuli, and also demonstrate pervasive deficits in self-regulation across functioning domains.

Objectives: This project makes a novel contribution to these literatures by examining the relationship between both cognitive and emotional self-regulation and social motivation in children with and without ASD (ages 5-8 years). Based on the high prevalence of sensory processing differences in ASD and the large sensory demands present in most social interactions, this study also considered the impact of sensory dysregulation in both self-regulation and social motivation. This was accomplished via two studies.

Methods: Study 1 (N=115) utilized parent report to assess these constructs in children with ASD with a range of language and academic abilities compared to an age- and gender-matched sample of typically developing children. Study 2 (N=14) assessed the feasibility of examining these same constructs directly through the use of innovative laboratory techniques. Specifically, this study examined the impact of social background noise on cognitive dysregulation and autonomic regulation, and how the effects of noise on these processes related to social motivation in a subsample of children from Study 1. Additionally, autonomic reactivity and regulation were measured within a naturalistic 360° video social environment and then related to general and task-specific measures of social motivation.

Results: Study 1 results suggest greater sensory and self-dysregulation and lower social motivation in ASD compared to controls. In addition, significant relationships were found between measures of cognitive dysregulation, emotion dysregulation, and social motivation. Importantly, cognitive dysregulation emerged as a significant mediator in the relationship between sensory dysregulation and social motivation in the ASD group. Study 2 results strongly support the feasibility of using wearable autonomic sensors and 360° video in young children with and without ASD. Additionally, measures of autonomic regulation significantly related to parent report of emotion dysregulation and sensory dysregulation, providing preliminary evidence for concurrent validity of these measurement approaches. Task-based social motivation was also significantly related to autonomic arousal during the 360° video and during the EF tasks paired with social noise.

Conclusions: Together, these studies' findings support continued investigation of these constructs in a larger laboratory-based study. This project has important etiological and intervention implications. Specifically, this work carefully investigated mechanisms in the development of social symptoms in ASD and found similar relationships across methodologies. These self-regulatory mechanisms may be important targets to investigate in intervention research and clinical practice to improve both the internal experience of individuals with ASD and their social development. Additionally, this work supports the importance of considering and adjusting sensory components of social environments to promote social engagement.

442.317 Social Anxiety and Stress Responses in Autistic Children and Adolescents: Integrating Multi-Informant and Multilevel Assessments

R. Lievore^a and **I. C. Mammarella^a**, (1)Department of Developmental and Social Psychology, University of Padua, Padova, Italy, (2)Department of Developmental and Social Psychology, University of Padova, Padova, Italy

Background: Social anxiety and social stress are common in neurodevelopmental conditions. While these aspects have been studied using various methods, no research yet integrated multi-informant assessments of social anxiety (i.e., parents, participants) and different components of social stress responses (subjective, behavioral, physiological). Moreover, comparing groups with different neurodevelopmental conditions using the same measures, allows to identify their respective strengths and weaknesses.

Objectives: The aim was to investigate social anxiety and responses to social stress in autistic children and adolescents compared to non-diagnosed (ND) peers and to another clinical comparison group, precisely Specific Learning Disorder (SLD).

Methods: Two studies were conducted. Study 1 included 280 participants aged 8 to 16 years: 60 autistic without intellectual disability (ID), 70 with SLD, and 150 ND peers matched for age, sex, and IQ. Study 2 involved 55 participants: 15 autistic without ID, 15 with SLD, and 20 ND. The sample was predominantly male. In both studies, participants performed the Trier Social Stress Test (TSST), requiring them to prepare and give a public speech to an unresponsive audience. Study 1 examined behavioral (quality of speech) and subjective (valence, arousal, perceived competence, and worries) aspects of social stress. Subjective experiences were evaluated before and after the speech using self-report measures. Study 2 expanded upon the first study by measuring physiological responses to social stress continuously through electrocardiogram. Heart rate and heart rate variability (HRV) were considered as measures of adaptive emotional regulation. Social anxiety was investigated using reports from both parents and children with different questionnaires in both studies.

Results: Regarding the various components of social stress, autistic children and those with SLD received lower scores for public speech quality (behavioral aspects) than ND individuals, $F(2, 277)=12.91, p<.001$. Concerning subjective responses, linear mixed effects models revealed a significant interaction between Time (before and after the task) and Group (autism, SLD, ND) for arousal, $F(2,277)=3.38, p=.03$, and perceived competence, $F(2,277)=3.76, p=.02$. Pairwise comparisons showed that autistic participants reported lower arousal and higher perceived competence than ND, while those with SLD reported lower perception of competence (Figure 1, panel A). As concerns autonomic responses, after controlling for gender, the interaction between Time and Group was statistically significant for heart rate, $\chi^2(df=6)=15.61, p=.02$, and for HRV index (RMSSD), $\chi^2(df=6)=13.42, p=.03$. Autistic participants exhibited decreased cardiac reactivity across the TSST compared to SLD and ND individuals (Figure 1, panel B). As for social anxiety, ANOVAs showed that parents of autistic participants and those with SLD reported higher scores in their children than parents of ND peers, $F(2, 277)=16.14, p<.001$. However, no differences emerged from participants' self-reports, $F(2, 277)=.50, p=.60$.

Conclusions: Our findings show unique response patterns within each group, confirming that the combined investigation of social anxiety and social stress responses offers valuable insights for research and clinical practice. Studying these phenomena in a multidimensional way is crucial, as discrepancies in social stress experiences and anxiety symptoms during daily life can provide useful information for treatment in autism. Indeed, tailored interventions based on individual characteristics should address socio-emotional support.

**442.319 Social and Non-Social Facets of Positive Emotionality in Neurodiverse Preschoolers**

S. Macari, A. Vernetti, E. Hong, K. K. Powell and K. Chawarska, Child Study Center, Yale University School of Medicine, New Haven, CT

Background:

Positive emotionality (PE) is thought to be diminished in children with autism, but evidence is conflicting and evidence is sparse regarding the methods and context in which it is evaluated. Considering the importance of positive emotions in social and cognitive development and overall well-being, improving our understanding of PE in autism and other neurodevelopmental conditions (NDC) and its links with core developmental characteristics has important theoretical and clinical implications.

Objectives:

To examine (1) the latent structure of PE in preschoolers with and without autism using a multi-method approach involving parent report of temperament and direct observation of behavioral and physiological emotional reactivity during induction probes and (2) the associations between components of PE and autistic traits, verbal and nonverbal cognitive abilities, and adaptive functioning.

Methods:

Participants included preschoolers with autism (ASD; $n=73$; mean age=58.11 months), neurodevelopmental conditions (NDC; including developmental delays, ADHD, anxiety, etc.; $n=48$; mean age =60.82 months), and typical development (TYP; $n=23$; mean age =63.47 months). Peak expression of PE and concomitant changes in physiological arousal (electrodermal activity, EDA) were assessed during induction tasks adapted from the Laboratory-Based Temperament Assessment Battery-Preschool (Lab-TAB). Parents completed four PA scales from the Children's Behavior Questionnaire (CBQ), which capture PE in social and non-social contexts: Approach/Positive Anticipation, Low-Intensity Pleasure, High-Intensity Pleasure, and Smiling/Laughing. Outcome measures included autistic traits (SRS-2), nonverbal IQ (MSEL/DAS), language (PLS-5), and adaptive functioning (VABS-II) in social and communication domains.

Results:

Principal component (PC) analysis of the behavioral, physiological, and parent-reported indices revealed two PCs, expression of PE in social contexts (PE-S), and in non-social contexts (PE-NS). PE-S was lower in the autism than in the TYP group ($p=.028$), but the autism and NDC groups were similar ($p=.682$). PE-NS was comparable in the autism and TYP groups ($p=.275$), but lower in the autism than in the NDC group ($p=.006$). Multiple linear regressions indicated that higher PE-S was significantly associated with lower SRS-Total scores ($\beta=-0.47, p<.001$) and higher Vineland Communication ($\beta=0.34, p<.001$) and Vineland Socialization ($\beta=0.41, p<.001$) scores. Higher PE-NS was significantly associated with higher NVIQ ($\beta=0.16, p=.05$), PLS-5 language ($\beta=0.19, p<.05$), and Vineland Socialization ($\beta=0.20, p=.014$) scores.

Conclusions:

The multimethod, multi-level approach identified social and non-social facets of positive emotion in neurodiverse preschoolers as previously demonstrated in typically developing young children. PE in social contexts tracks with lower autistic traits and higher adaptive socialization and communication skills, while PE in non-social contexts was associated with higher cognitive, language, and social skills. PE is related to important behavioral dimensions in neurodiverse preschoolers, with implications for learning, intervention, and education.

442.320 The Broader Autism Phenotype (BAP): Exploring the Relationships between Friendship Quality and BAP Traits Amongst Neurotypical College Students

S. A. Lehman¹, M. K. Guell¹, M. Berman², E. J. Adler¹ and A. V. Van Hecke¹, (1)Psychology, Marquette University, Milwaukee, WI, (2)Psychology, Marquette University, Milwaukee, WI

Background: The Broader Autism Phenotype (BAP) is a collection of sub-diagnostic autistic traits. Relatives of autistic individuals are known to score higher on measures of BAP (Sasson et al., 2013), though sub-diagnostic autism traits are also present in the general population (Constantino & Todd, 2003). Individuals with elevated BAP levels in the general population report more social difficulties, lower relationship satisfaction, lower social connectedness, higher loneliness, and greater anxious and depressive symptoms (Beffel et al., 2021; Stice & Lavner, 2019). It is important to understand what features of BAP may be driving social difficulties and relationship differences experienced by high-BAP individuals.

Objectives: The objective of the present study is to better understand which BAP characteristics drive friendship quality in non-autistic young adults.

Methods: The current sample includes 173 non-autistic students ages 18-25 ($M = 18.75$; 72.3% female) recruited through community outreach on an undergraduate college campus. Participants completed self-report measures assessing quality of friendships (FQ; Baron-Cohen & Wheelright, 2004) and characteristics associated with the BAP (BAP-Q; Hurley et al., 2007). The BAP-Q produces 3 subscales: social aloofness (i.e., a lack of interest or enjoyment in social interaction), rigid personality (i.e., little interest in or difficulty adjusting to change), and pragmatic language problems (i.e., deficits in the social aspects of language, such as with reciprocal conversation). The FQ total score and BAP-Q subscales were used in the current analyses while controlling for gender.

Results: Friendship quality was negatively associated with social aloofness ($r(173) = -0.37, p < .01$) and pragmatic language abilities ($r(173) = -0.21, p < .01$). Friendship quality was not significantly correlated with rigid personality. Multiple regression was used to predict participants' friendship quality based on their BAP subscale scores. Social aloofness significantly predicted friendship quality while controlling for gender ($\beta_1 = -0.32, t(172) = -4.13, p < .01$), whereas pragmatic language abilities ($\beta_1 = -0.04, t(172) = -0.52, p = 0.60$) and rigid personality ($\beta_1 = 0.05, t(172) = 0.62, p = 0.54$) did not. This regression model accounted for 21.7% of the variance in friendship quality ($R^2 = 0.217, F(4, 167) = 11.58, p < .01$).

Conclusions: Findings from the current study indicate that BAP traits differentially predict friendship quality in neurotypical college students; namely, more social aloofness predicts poorer friendship quality, whereas rigid personality and pragmatic language abilities do not predict friendship quality. The current research contributes to our understanding of which aspects of the BAP might be related to the increased social difficulties experienced by this population. These findings suggest that self-reported lack of interest or enjoyment in interaction with others is the driving factor in self-reported poorer friendship quality for high-BAP individuals, not features related to difficulties with change or social communication behaviors. These data may be relevant for clinicians working with high-BAP individuals who present with higher loneliness, lower social connectedness, and greater internalizing symptoms. Future research should explore the relationship between the BAP and friendship quality amongst a more diverse sample to examine whether these findings generalize to the greater BAP population.

442.321 The Detection of Disruption in Social Contingency Relates to Autistic Traits

A. Green¹, L. Byrge², E. Fox³ and D. P. Kennedy⁴, (1)Psychological and Brain Sciences, Indiana University - Bloomington, Bloomington, IN, (2)University of North Florida, Jacksonville, FL, (3)Indiana University - Bloomington, Bloomington, IN, (4)Psychological and Brain Sciences, Indiana University, Bloomington, IN

Background: A variety of social cognitive tasks have been created to characterize the social differences seen in autism spectrum disorder (ASD). These tasks typically involve static stimuli, cartoon representations, or interpretations of social statements. While these have been incredibly useful to our understanding of ASD, they frequently suffer from 2 key limitations – 1) they often lack a ground truth (thus making performance more about consensus than accuracy) and 2) the tasks often cannot be systematically and parametrically manipulated.

Objectives: We sought to overcome these limitations by designing a task to measure perceptual sensitivity to interpersonal interactions. Stimuli were constructed by recording natural dyadic conversations and then experimentally modifying the conversations by subtly shifting the timing between the videos, thus disrupting the contingent social-communicative dynamics expressed between them. We hypothesized that performance on this task would vary parametrically as a function of the amount of temporal shift (more difficult with the smallest shift), and that performance would be related to autistic traits (specifically, social aloofness).

Methods: *Stimulus Creation.* Video data was collected from pairs of strangers who participated in a ten-minute conversation. Participants were instructed to get to know each other. All conversations captured face-forward views of both interaction partners. Twenty conversations (40 individuals) were used to create 120 five-second video clips (without audio). Half of these video clips were not modified in any way (matched condition; 60 stimuli) while half were altered such that one individual in the social interaction was advanced or lagged either 1.5 seconds, 3 seconds, or 4.5 seconds ahead or behind the other individual in the interaction (20 stimuli per condition). *Task.* Twenty neurotypical participants were instructed to determine whether the timing between the interaction partners had been shifted, or not. Participants also completed the Broad Autism Phenotype Questionnaire (BAP-Q) as a measure of social aloofness. *Analyses.* D-prime (d' or sensitivity) was calculated for each of the 3 conditions (1.5s, 3s, 4.5s) as well as for overall performance (all shifted conditions compared to the matched condition).

Results: We found that, overall, people are able to discriminate between matched and shifted stimuli [$d' = 0.55$ ($SD = 0.27$); $t(19) = 8.98, p < 0.001$, one-sample t-test]. In support of our hypotheses, we found a relationship between discriminability and shift size [$d'_{1.5s} = 0.39$ (0.30), $d'_{3s} = 0.53$ (0.31), $d'_{4.5s} = 0.70$ (0.39); $F(2) = 4.32, p = 0.02$, one-way ANOVA] (Figure 1). Furthermore, overall performance on the task was significantly correlated with social traits: individuals with higher levels of aloofness performed worse on the sensitivity task [$r(19) = -0.48, p < 0.05$] (Figure 2).

Conclusions: We find that people are sensitive to temporal shifts in social contingencies in a parametric way (with increasing shifts leading to increased discriminability), and that sensitivity to these alterations relates to individual differences that track social aloofness. Data collection is ongoing and will examine performance in autistic compared to non-autistic individuals, examine how performance may relate to other measures of social cognitive ability and real-world behavioral measures (e.g., social network size), and continue to optimize the task to maximize detection of stable individual differences in the perception of social contingency.

**442.323** The Intersection of Autism and Race Influencing Social Perspectives of White Vs. Black Autistic and Neurotypical Targets

E. Gelerian¹, M. Elderkin¹, A. da Silva Frost² and A. Mosley³, (1)UC Davis, Davis, CA, (2)Northwestern University, Evanston, IL, (3)Psychology, UC Davis, Davis, CA

Background: A growing interest in taking a social model approach to autism research indicates that Autistic people are marginalized and socially stigmatized (Alkhalidi et al., 2021; Sasson et al., 2017). However, extant research has primarily focused on white autistic people, which fails to account for how individuals with intersecting subordinated identities (e.g., Black and Autistic) may be subjected to differential rates of identity devaluation and marginalization (Purdie-Vaughns & Eibach, 2008).

Objectives: In this research, we take an intersectional approach to investigate how perceivers' impressions and mental representations of autism interact with racial identities of the target. We aimed to confirm whether or not participants held stereotypic and biased beliefs about Autistic people broadly, and if these beliefs were consistent—or potentially even harsher—towards black Autistic people.

Methods: Participants were randomly assigned to one of the following between-subjects conditions: Black Autistic Person, Black Person, White Autistic Person, or White Person. They first wrote down five adjectives that spontaneously came to mind when thinking of that group, and then rated their assigned group on a number of fundamental person perception (warmth, sociability, morality, trustworthiness, honesty, competence, ability, assertiveness, dominance, masculinity, femininity) or stereotype relevant (athleticism, IQ, EQ, volatility, unpredictability, aggressiveness) traits. The five adjectives were treated as each participant's verbal character representation of their group, and were evaluated using a natural language processor (SADCAT; Nicolas et al., 2020). Participants also responded to two open-ended questions regarding how their community and personal experiences informed their impressions of autistic people.

Results: Participants largely rated black and white targets very similarly across traits and domains. However, there were differences in ratings of Autistic compared to non-Autistic targets, with Autistic people generally being rated more negatively. For example, on agentic traits, sociability, emotional intelligence, and athleticism, Autistic people were given lower ratings than non-Autistic people, and for most of these traits the neurotype difference was especially or only true for black targets. The patterns from direct ratings largely held when evaluating participants' indirect impressions by analyzing their spontaneous character profiles using NLP as well. Finally, participants' responses to the open-ended questions demonstrated an othering alongside negatively labeled characteristics, such as being "cold", "unsympathetic" and "liable for outbursts or breakdowns". Most impressions were formed indirectly based on what participants had been told by their communities or seen in media. Participants that had personal experience with Autistic people were more likely to identify redeeming characteristics such as "authenticity" and "strong moral codes".

Conclusions: Overall, though we found very little direct evidence of racial bias against black targets, there was clear and consistent evidence that participants held negative attitudes towards Autistic targets across all three measurement types. While efforts to reduce racism have been an important focus in American society for decades, the same has not been true for ableism or anti-autism bias, which seems to be reflected in our results. Furthermore, the multiply marginalized black Autistic targets did in fact elicit unique—and particularly even more negative—impressions from participants, in line with previous intersectionality research in other domains.

442.324 An Examination of Autistic Student Friendship Trajectories during and Following Participation in a School-Based Social Skills Intervention

D. M. Tagavi¹, C. Kasari² and J. Locke¹, (1)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (2)Education and Psychiatry, University of California Los Angeles, Los Angeles, CA

Background: Autistic children often experience non-reciprocal friendships, characterized by unbalanced social interactions (Kasari et al., 2011). These relationships are more common than in non-autistic peers and are linked to outcomes such as loneliness, anxiety, and depression (Mazurek, 2014). Enhancing friendship reciprocity is important for fostering social well-being and quality of life (Rotheram-Fuller et al., 2010). Peer-mediated interventions (PMIs), where neurotypical peers serve as models to facilitate social skill development, have emerged as effective strategies to foster friendship reciprocity (Carter, 2021). Schools are ideal settings for implementing PMIs, as they offer structured environments with ample opportunities for social interaction.

Objectives: This study examined changes in friendship reciprocity between autistic students and their neurotypical peer models during a targeted social skills intervention. Specifically, we investigated how autistic students' friendship endorsements of peer models and peer models' friendship endorsements of autistic students changed over the course of a peer-mediated intervention and at a 12-week follow-up. Additionally, we explored how friendship reciprocity between autistic students and their neurotypical peers evolved during and after intervention.

Methods: Participants included 39 autistic students (ages 6-11) and 107 neurotypical peer models. All participants were part of a larger RCT of a peer-mediated social skills intervention (Kasari et al., 2012). The intervention involved training neurotypical peers to facilitate social interactions with autistic students. Autistic students and peers were asked to identify individuals they enjoy spending time with (friends) and those they prefer not to spend time with (non-friends) on a friendship survey. Responses were coded to determine friendship reciprocity. We examined four types of relationships, which have been shown to impact outcomes for autistic individuals: 1) Equally Reciprocal Friendships; 2) Reciprocal Friendships; 3) Autistic Student non-endorsed (i.e., autistic student rated peer as a friend and peer did not rate them); and 4) Autistic Student non-liked (i.e., autistic student rated peer as a friend and peer rated them as non-liked). Logistic multilevel models were used to assess changes in friendship endorsements and reciprocity over time.

Results: Autistic students demonstrated significant increases in friendship endorsements during intervention, with increases in the number of friends they endorsed and a decrease in number of outward non-liked endorsements. However, these increases were not sustained at follow-up, with endorsements returning to near-baseline levels. Neurotypical peers showed significant increases in their friendship endorsements of autistic students during intervention, with gains also diminishing at follow-up. Regarding friendship reciprocity, significant improvements were observed during intervention, with more reciprocal friendships forming between autistic students and their peers. These reciprocal friendship ratings declined following intervention. Significant changes were not observed for the other three types of reciprocal relationships.

Conclusions: PMIs are effective in promoting friendship reciprocity and increasing social inclusion for autistic students. However, the observed decline in social gains post-intervention indicates that continued supports may need to be in place. Future research should explore long-term interventions or follow-up booster sessions to maintain gains in friendship reciprocity. Additionally, embedding PMIs into the routine school day and training school staff to support positive peer interactions may help sustain progress.

442.325 The Role of Age in Social Camouflaging in Autism: A Meta-Analytic Review

J. Applewhite¹, H. Adams¹ and A. Jack², (1)Psychology, George Mason University, Fairfax, VA, (2)George Mason University, Fairfax, VA

Background: Autism is diagnosed more frequently and earlier in males versus females. Social camouflaging, or the hiding, masking, or suppression of autistic traits, has been theorized to contribute to these diagnostic discrepancies. Existing studies have primarily examined how gender may relate to camouflaging, with varying results. Few have directly analyzed age-related differences in camouflaging behaviors. However, age could be a crucial factor to understanding individual differences in camouflaging and how these may impact diagnostic timing. We hypothesized that the relationship between age and camouflaging will be stronger for autistic females across all age groups.

Objectives: This meta-analysis investigates the relationship between age and camouflaging in autism. We aimed to determine if gender moderated the relationship between age and camouflaging.

Methods: We followed the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) for reporting our meta-analysis findings. To be included in the analysis, studies must have : reported the correlation analysis or correlation table for the relationship between age and camouflaging, included autistic individuals, with a focus on autistic individuals in mixed-neurotype samples; and used either a discrepancy, observational or self-reported method of measuring camouflaging. The literature search, conducted between February and March 2024, involved two coders searching PubMed and APA PsycInfo using the terms: *autis* or ASD or Autistic or Autism spectrum disorder AND age or child* OR children or adolescents or adults AND Camouflaging or Masking OR Impression management OR Compensation*. 68 articles were screened with 13 deemed suitable for further analysis. Age was coded as a continuous variable (using mean and standard deviation), while gender was coded as a categorical variable and recorded as a percentage. A random effects meta-analysis calculated the average effect, and a mixed effects meta-analysis examined the moderating effect of gender. Effect sizes were regressed on gender in a restricted maximum likelihood meta-regression.

Results: There was a small negative effect of age on camouflaging (pooled $r = -0.040$; 95% CI = $-0.122, -0.042$; range = -0.22 to 0.19). There was high heterogeneity between effect sizes ($I^2 = 85.96\%$, $<.001$, $QE = 84.29$, $p <.001$). Egger's test and visual inspection of the funnel plot indicated no publication bias ($z = 0.32$, $p = 0.748$). Moderator analysis showed that gender (%female; $B = .002$, $SE = .002$, $p = .255$) did not have a significant moderating effect.

Conclusions: Meta-analysis of the extant literature suggests that age has a small negative effect on camouflaging, such that camouflaging behaviors decreased with age. This corroborates work suggesting that autistic children/teenagers camouflage more than older or autistic adults. Contrary to our hypothesis and previous theory, no significant moderating effects of gender was observed. This may be due to the disproportionate sampling of females in the studies or a lack of younger age groups in the data (see Table 1). From a developmental perspective, these findings are relevant to autistic youth as they may be prone to experience later-life outcomes due to early camouflaging behavior and these results should inform how clinicians provide support and resources.

442.326 The Role of Anxiety in Predicting Visual Attention to Faces Among Autistic Children: Results from the Autism Biomarkers Consortium for Clinical Trials (ABC-CT)

C. Carrow¹, A. Naples¹, K. Chawarska², G. Dawson³, S. Faja⁴, S. Jeste⁵, N. Kleinbans⁶, J. Dziura⁷, S. J. Webb⁸, C. Sugar⁹, F. Shic¹⁰ and J. McPartland¹¹. (1)Yale Child Study Center, Yale University School of Medicine, New Haven, CT, (2)Child Study Center, Yale University School of Medicine, New Haven, CT, (3)Department of Psychiatry and Behavioral Sciences, Duke University, Durham, NC, (4)Boston Children's Hospital, Harvard, Boston, MA, (5)Children's Hospital Los Angeles, Los Angeles, CA, (6)University of Washington, Seattle, WA, (7)Yale University, New Haven, CT, (8)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (9)University of California, Los Angeles, Los Angeles, CA, (10)Center for Child Health, Behavior and Development, Seattle Children's Research Institute, Seattle, WA, (11)Yale Child Study Center, Yale Child Study Center, New Haven, CT

Background: Previous studies indicate that children with autism spectrum disorder (ASD) experience higher rates of anxiety disorders than typically developing (TD) peers, with roughly 40% of autistic youth having at least one co-occurring anxiety disorder (Mingins et al., 2021). Research using eye-tracking technology indicates that many children with ASD attend less to faces (Shic et al., 2022) and eyes (Unruh et al., 2016). Similarly, individuals with general and social anxieties may avoid fixations to the eye (Günther et al., 2021). However, the influence of anxiety symptomatology on visual attention to social stimuli in ASD is still unclear (Wei et al., 2023).

Objectives: The current study aimed to examine the relationship between social and generalized anxiety symptoms and visual attention to faces in children with and without ASD.

Methods: Participants included 395 children ages 6-11 (autistic=276, TD=119, $M_{age} = 8.37 \pm 1.65$ years, 74.43% male) that participated in the Autism Biomarkers Consortium for Clinical Trials (ABC-CT). Binocular eye-tracking data was collected at 500Hz using an SR Eyelink 1000 Plus.

Participants were presented with six photographs of children or of children and adults for 20 seconds each. Percent looking to faces was calculated as the number of valid gaze samples in a pre-defined region around the face content divided by the total number of onscreen gaze samples. To measure child anxiety symptoms, we utilized the anxiety subscales from the Childhood and Adolescent Symptom Inventory, 5th Edition (CASI-5) completed by caregivers. Multiple linear regressions were conducted to determine relationships between anxiety type and percent looking to faces by diagnostic group, covarying for age.

Results: Social anxiety significantly predicted percent looking to faces in the ASD group ($\beta = 0.004$, $p = .008$) such that increased social anxiety was associated with increased attention to faces. Similarly, child age was significantly predictive of increased looking to faces in the ASD group ($\beta = 0.003$, $p = .004$). The interaction between social anxiety and age in the ASD group was significant ($\beta = -0.00004$, $p = .011$) such that with increasing age, higher levels of social anxiety were associated with decreased attention to faces. General anxiety did not predict percent looking to faces in the ASD group controlling for age ($\beta = 0.003$, $p = .195$). No significant relationships between general ($\beta = 0.004$, $p = .546$) or social ($\beta = -0.0005$, $p = .945$) anxiety and percent looking to faces were found among the TD group.

Conclusions: Social anxiety yielded a significant influence on looking to faces in children with ASD but not non-autistic children. This relationship was related to age such that older children with social anxiety were less likely to look at faces; these results are consistent with previous findings that social anxiety relates to increased avoidance of faces in autistic children as they age (Chen et al., 2020). Group differences and relationships to social attention were not observed for general anxiety, suggesting specific relevance of social anxiety to social visual attention. Characterizing the distinct ways in which social anxiety influences social behavior in children with autism may inform development of supports for autistic individuals. For example, these data raise the possibility that treating anxiety might impact social differences in ASD.

442.327 The “Reading the Mind in Films” Task: A Pilot Study on Complex Emotion Recognition for the Italian Adaptation in Adults with and without Autism Spectrum Conditions

R. S. Scuotto¹, **S. Bonfanti²** and **P. Ricciardelli³**, (1)Psychology, Dept. Psychology, University of Milano - Bicocca, Milano, Italy, Milano, Milano, Italy, (2)Department of Psychology, University of Milano Bicocca, Milano, Milano, Italy, (3)Psychology, University of Milano-Bicocca, Milano, Italy

Background: Emotion recognition, particularly of complex emotions, is a cognitive challenge for individuals with Autism Spectrum Condition (ASC). The Reading the Mind in Film (RMF) task, designed to assess emotion and mental state recognition in naturalistic settings, has been adapted into few languages but lacks of an Italian version. This study adapts the RMF task for an Italian adult population and explores its effectiveness in differentiating emotion and mental state recognition abilities in adults with and without ASC.

Objectives: The main objectives are to (1) adapt and translate the RMF task for Italian adults, and (2) compare the performance of individuals with ASC to neurotypical adults in emotion and mental state recognition via this task.

Methods: We adapted the 22 film clips available from the Autism Research Centre (University of Cambridge), by translating the scripts of the clips into Italian. The correctness of the translation was verified using the back-translation method. Professional voice actors performed the dubbing of the clips. The meticulous audio editing ensured synchronization while maintaining the original emotional tone matching the mental state of the films' characters. We included 44 participants (20 male, 22 female), divided into the ASC group (N = 22; F=11 ; M=10) and the neurotypical control group (N = 22; ; F=11 ; M=10). The ASC adults were all attending a post-diploma filmmaking course. Participants completed the Autism-Spectrum Quotient (AQ) and two mental state recognition tasks: the Italian adaptation of RMF and the Italian version of Reading the Mind in the Eyes Test (RMET).

Results: The control group's performance was consistent with findings from the original RMF study, confirming the validity and reliability of the Italian translation and dubbing process. The dubbing process accurately conveyed emotions, matching the original study by Golan and colleagues (2006). The congruence in response accuracy validates the rigorous translation process. However, no significant performance differences were observed between the ASC and the control group, which may be due to the experience of the ASC group with films, gained from their filmmaking training.

Conclusions: These results suggest that specialized training in visual media, such as filmmaking, might affect emotion and mental state recognition performance in adults with ASC. Further research is needed to assess how visual expertise influences social cognitive abilities in individuals with ASC.

442.328 Understanding Autistic Adults' Social Motivation

K. M. Baro and **A. Nadig**, McGill University, Montreal, QC, Canada

Background: Social motivation (SM), or the mechanisms that drive individuals to orient to and take part in the social world, seems key to understanding and explaining Autistic social experiences. Chevalier et al. (2012) offered the first, widely accepted, hypothesis of SM in Autism. They hypothesized that Autistics have reduced SM compared to neurotypicals according to observations of reductions of social orienting, seeking and liking and social maintaining behaviors. As highlighted by Jaswal and Akhtar (2019), reports of Autistic lived experience have challenged Chevallier et al (2012)'s diminished SM hypothesis of Autism by highlighting evidence of Autistic interest and engagement in the social world. In addition, Jaswal and Akhtar point out that characteristics of Autism such as sensory sensitivities may interfere with Autistic Adults SM manifesting in expected (neurotypical) ways. No research has looked at how Autistic Adults themselves characterize their SM, furthering a deficit-based, neurotypical-focused understanding of Autism.

Objectives: The objective of this study is to gather and analyze the valuable perspectives of Autistic Adults on their SM to increase our understanding of their SM.

Methods: The first author, an Autistic Master's student, has conducted interviews with 12 Autistic Adults without Intellectual Disability on how they think, feel and act in relation to their SM. Participants took part online or in-person and were recruited from across Canada. The interviews, lasting a maximum of 2 hours, were in French or in English. The semi-structured interview protocol was based on 8 themes (Social Opportunities, Social Interest, Meaning of Relationships, Value of Social Support, Perception of Self in the Social World, Social Initiative Taking, Social Flexibility, and Motivation to Conform Socially) elaborated from existing SM measures (Gong et al., 2020; LLerena et al., 2013; Elias & White, 2020; Phillips et al., 2019). This protocol was reviewed and updated based on feedback from the first four participants, as recommended by Castillo-Montoya (2016).

Results: The first author will analyze the interviews following Braun and Clarke (2006)'s six-phase Reflexive Thematic Analysis guidelines. Thus far, four interviews have been transcribed with initial coding completed. The 8 a priori themes are present and represented in these transcripts, with additional codes surfacing in the transcripts as well. Final themes will be elaborated to reflect significant codes from all twelve interviews by February 2025.

Conclusions: The interviewed Autistic Adults have provided detailed and rich responses with respect to their own SM. It is anticipated that the full analysis of this data will constitute a novel contribution in understanding Autistic SM (specifically what influences it) and, more generally, the social experiences of Autistic Adults as explained by themselves.

442.329 Visual Attention in Autism: The Role of Social Anxiety and Facial Context in Gaze Patterns

L. M. Robinson¹, **A. Naples²** and **J. McPartland³**, (1)McPartland Lab - Yale Child Study Center, Yale School of Medicine, New Haven, CT, (2)Yale Child Study Center, Yale University School of Medicine, New Haven, CT, (3)Yale Child Study Center, Yale Child Study Center, New Haven, CT

Background: Distinct patterns of eye contact are a well-documented feature of autism, with autistic individuals often describing direct eye contact as aversive, overstimulating, or distracting. These experiences may contribute to diminished eye contact during interpersonal interactions. In contrast to non-autistic individuals, prior research suggests that autistic individuals do not display an inadvertent attentional bias to look towards eyes, even when explicitly instructed not to. However, factors driving differences in eye contact remain unknown, and key potential contributors, such as social anxiety, have not been adequately studied. In the present study, we utilize eye-tracking data to investigate differences in gaze trajectory in response to direct eye cues, aiming to better understand the role of anxiety in modulating gaze behavior in autistic adults.

Objectives: To investigate attentional differences in disengagement from eyes relative to other facial features and their association with individual differences in anxiety between autistic (ASD) and neurotypical (NT) adults.

Methods: Participants were 67 adults (34 ASD [confirmed with ADOS-2], 33 NT) ages 18-39 ($M=27.2$, $SD=5.64$). Participants completed an eye tracking task in which a fixation cross was presented on a screen preceding a face over a gray background. Fixation cross locations (FCLs) were placed such that, when the face appeared, participant gaze was directed to a facial feature (nose, mouth, left eye, or right eye). Data were collected at 500 Hz using a SR EyeLink 1000 Plus remote eye tracker. Attentional disengagement was operationalized as the latency to look more than 2 degrees of visual angle away from the facial feature. Attentional disengagement time was calculated within participants and across trials for each FCL, while anxiety features were assessed using the Liebowitz Social Anxiety Scale (LSAS).

Results: A mixed-effects model revealed that diagnostic group ($F(1,66)=0.09$, $p=.762$) and LSAS total score ($F(1,68)=0.62$, $p=.432$) were not associated with changes in attentional disengagement, while FCL was associated with changes in attention such that people looked away from mouths faster than they did from eye regions ($F(3,190)=7.19$, $p<.001$). Additionally, a significant three-way interaction was observed between FCL, diagnostic group, and LSAS score ($F(3,192)=4.59$, $p=.004$) indicating that disengagement from facial features varied across groups as a function of anxiety. Increased anxiety was associated with longer looking to the left-eye in the NT group ($r=0.37$, $p=.029$) but not in ASD ($r=-0.07$, $p=.67$), whereas this pattern was not identified in the right eye.

Conclusions: We identified that all participants disengaged more rapidly from socially uninformative facial regions, such as the mouth, compared to the eyes. In the ASD group, social anxiety differentially predicted disengagement from uninformative face regions. These findings did not support a baseline difference in visual attention to the eyes in autistic individuals but suggested that increased anxiety delayed attentional disengagement; this may suggest that anxiety heightens attention to emotionally salient information contained in the eyes. Ongoing analyses will explore how sensory and social characteristics relate to attentional disengagement and whether increased anxiety is associated with a bias toward looking to the eyes when attention is initially directed elsewhere.

442.330 R/AutismInWomen As a Site of Social Support for the Unique Needs of Autistic Women

K. Chapman and X. Page, Computer Science, Brigham Young University, Provo, UT

Background: Prior work indicates that women on the autism spectrum are more likely to experience negative mental health and loneliness than the general population (Lee, 2019; Lai, 2019; Newell, 2023; South, 2020; South, 2021; Twenge, 2020; Sedgwick, 2020). This has been attributed to an increased likelihood of masking, under-diagnosis, and misdiagnosis of autism in females (Miller, 2021; Fede, 2023; Haney, 2016). Research suggests pseudo-anonymous forums can be a vehicle for accessing social support (De Choudhury, 2014) and thus we study whether and how autistic females are using such forums. We focus on communities related to autism on a commonly used pseudo-anonymous platform, Reddit (Gottfried, 2024). The two largest communities are the subreddits r/autism (for anyone on the autism spectrum) and r/AutismInWomen (for women on the autism spectrum).

Objectives: We seek to compare disclosure content and behaviors between a general autism support forum (r/autism) and a forum specifically to support autistic women (r/AutismInWomen) to understand and compare the role of each in supporting autistic women.

Methods: In order to collect posts from the most active Reddit users, we examined users who had posts on the “Hot list”, a list which features the most popular posts on a subreddit at any given moment. On April 13, 2024 we gathered the top 1000 “Hot list” responses from both r/autism and r/AutismInWomen using the Reddit developer API. We then extracted the list of users who had made these posts (1,726 users). We narrowed our list of users to those who have previously posted in both subreddits (192 users). This allows us to make comparisons of what a given individual decided to share on which subreddit. We then collected all the posts which they had made in the two communities. For posts on both forums, the first author utilized inductive coding to analyze the posts and perform a content analysis (McDonald, 2019). Then an individual level analysis was performed to compare the content users chose to post on each of the subreddits. Posts from 50 users (381 posts total, 7.62 posts per user on average) were analyzed. The remainder of users’ posts will be analyzed prior to the conference.

Results: We found that users disclose different types of content in the two forums. Specifically, when seeking instrumental support users will share information in both subreddits. When discussing more sensitive topics such as mental health or seeking emotional support, users would post in one or the other subreddit. When sharing topics which may have unique contexts to autistic women (i.e., masking and diagnosis) users would primarily post only in r/AutismInWomen - one user shared “I want to unmask but I’m worried that I will face even more infantilization.” Further details of the findings will be shared at the conference.

Conclusions: Autistic females are consistently understudied and under-served. As offline support is often unavailable for this population, many turn to online forums such as Reddit. This study takes a first step in understanding the mechanism of support on Reddit for this population.

442.331 Examining the Effects of Generative-AI Chatbots on Autistic Young Adults

K. Chapman¹, G. D. Smith² and X. Page¹, (1)Computer Science, Brigham Young University, Provo, UT, (2)Brigham Young University, Provo, UT

Background: Generative AI-based chatbots have emerged as an effective tool for advertisers (Arsenijevic, 2019). Many widely available chatbots, such as MetaAI, use human-like characters in their interface. While there has been limited research on the effect of these chatbots on autistic individuals, research in a broader context has shown that autistic individuals are more likely to anthropomorphize non-human actors. This can lead to feelings of guilt when doing something the individual perceives to upset the actor (White, 2019; Clutterbuck, 2022). Coupled with an increased likelihood of autistic adults having lower financial literacy (Galizzi, 2023), chatbot advertisements have the potential to be harmful for this population.

Objectives: To understand the effects of generative-AI based chatbots on perceived preferences for autistic young adults with substantial support needs and low support needs.

Methods: We developed an experimental survey where participants were asked to rank a series of consumer products (e.g., chocolate bar types, fast food), in order of most to least favorite. Participants then viewed a chatbot interaction, where the chatbot shared the opposite opinions about the products (i.e., whatever the participant ranked as their favorite, the chatbot would state it disliked; whatever the participant ranked as their least favorite, the chatbot would state it liked). After viewing the interaction, participants were asked to once again rank the items. We tested whether the most favorite item's ranking had decreased and the least favorite increased.

We deployed this survey with three groups: neurotypical individuals, autistic adults with substantial support needs (autisticS) and autistic adults with low support needs (autisticL). We then ran tested for ranking differences before and after viewing the chatbot interaction using the Wilcoxon Signed Rank test. The Mann-Whitney U test was used to probe on between-group differences.

Results: For autisticS, the least favorite ($z=3.95$, $p=0.0000$) and most favorite ($z=-2.81$, $p=0.0080$) item rankings changed significantly. For autisticL, the least favorite item ranking ($z=3.15$, $p=0.0020$) and most favorite item ranking ($z=-2.64$, $p=0.0156$) also changed significantly. For the general population, only the least favorite item ranking ($z=4.15$, $p=0.0000$) changed significantly. We also found that these changes were significantly greater for autisticS than the general population ($z=-2.75$, $p=0.0079$; $z=2.55$, $p=0.0101$). AutisticL was not statistically different from the general population ($z=1.74$, $p=0.1255$; $z=1.59$, $p=0.1136$). AutisticS had a significantly bigger change than AutisticL only for least favorite ($z=3.84$, $p=0.0001$).

Conclusions: This work shows that chatbots have a greater influence on autistic adults with substantial support needs, leaving them more vulnerable. This work underscores the need to include this population in research.

Poster Session

May 3rd, 2025, 12:30 PM - 1:30 PM - Hall 4A

443.332 Social Media Safety Literacy for Emerging Adults: A Rule-Based Curriculum

K. Chapman¹, **K. Klabacka²**, **T. P. Gabrielsen¹** and **X. Page¹**, (1)Computer Science, Brigham Young University, Provo, UT, (2)Brigham Young University, Provo, UT, (3)Counseling Psychology and Special Education, Brigham Young University, Provo, UT

Background: Social Media has shown to provide many benefits including social capital, accessing resources, and professional development (Gillespie-Lynch et al. 2014). Recent work reveals how social media can enormously benefit those on the autism spectrum by allowing them to make social connections, but also points to how autistic social media users interpret social media features literally, leading to social, psychological, and physical harms (Page et al. 2022).

Objectives: Mitigate the harms that autistic young adults face on social media through an educational intervention.

Methods: We developed a social media literacy educational intervention with a team of multidisciplinary autism researchers. The materials were catered to autistic young adults and covered a range of topics including the social norms of social media, how to choose safer settings, how to identify fake profiles, how to classify connections into social groups, determining what types of information is safe to share with various audiences, and the differences between social media and reality. We utilized an algorithmic, rule-based pedagogy in the modules teaching participants how to make safe decisions. We then deployed the educational intervention to 15 participants at a local residential program for autistic young adults (ages 18-29) with substantial support needs - one student had intellectual disabilities. Immediately before and after each lesson, participants were given a knowledge assessment. Both knowledge assessments were identical, and participants were not told whether they had correctly answered the questions. We then used Wilcoxon Signed-Rank tests to determine whether there was a difference between their scores initially and after the intervention. We also qualitatively coded classroom utterances to understand the differences between students who had an above or below average change in learning effect.

Results: We found that there was a statistically significant improvement between the initial and post-intervention assessment score for several rule-based modules: social norms of social media, how to identify fake profiles, and classifying profiles into social groups. We also found that participants who had an above average improvement in score were the ones actively participating in class (both answering and asking questions).

Participants who had a more modest improvement in score were less verbally involved in class, occasionally bringing up unrelated information when there was a lull. The student with intellectual disability fell in this group of those who improved to a more modest degree. Finally, one student in the class had scores that decreased. This student was frequently verbally engaged, but their responses were tangential to the current topic.

Conclusions: This research suggests that algorithmic rule-based lessons can be effective in teaching autistic young adults about how to make safer decisions on social media. Furthermore, our work underlines how active involvement in a classroom setting can be an indicator of successful outcomes for this population.

4443.333 Investigating Alterations in the Limbic System in Preschoolers with Autism: A Diffusion Tensor Imaging Tractography Study

Background: It has been suggested that alterations in the limbic system are implicated in social-communicative as well as associated mental health features of Autism. However, evidence of differences in limbic tracts in autistic preschoolers is largely lacking. While previous studies have shown changes in white matter (WM) tracts in the limbic system in individuals with autism who are school-aged and older (e.g., Ameis et al., 2013; Ikuta et al., 2014), few studies examined white matter difference in the limbic system in younger children.

Objectives: The objectives of this study were to examine white matter differences in limbic tracts between autistic and typically developing preschoolers using Diffusion Tensor Imaging (DTI) Tractography, and to assess the association between white matter properties and strengths of autistic features as well as social adaptive behaviour respectively in the autism group.

Methods: To date, DTI data were acquired from 102 preschoolers participating in The Preschool Brain Imaging and Behaviour Project (PIP). In the preliminary analyses, we compared the first batch of the samples consisting of 25 autistic preschoolers (mean age: 44.6 months) and 44 typically developing (TD) preschoolers (mean age: 42.2 months). The cingulum and uncinate, as well as the two sub-divisions of the cingulum – the superior and temporal cingulum, were dissected using MegaTrack, an automated dissection methodology. Their tract volume and anisotropy (fractional anisotropy, FA; hindrance modulated orientational anisotropy, HMOA; and anisotropic power, AP) were quantified and the two groups were compared using one-way analysis of covariance. Strength of autistic features was measured using the Social Responsiveness Scale-2 and social adaptive behaviour was assessed with the Vineland Adaptive Behavior Scales-3. Their associations with tract volume and anisotropy were analysed using partial correlation analyses, controlling for age, sex and scanner type.

Results: Preliminary analyses showed no significant mean-group differences between the autistic and TD groups in any tracts. Similarly, there was no significant correlation between the white matter tracts and autistic features or level of social adaptive behaviour in any tracts.

Conclusions: To our awareness, this is one of the first preschool MRI studies examining white matter tracts in the limbic system in autistic preschoolers. While the sample size of preliminary analyses is similar to those in other MRI studies, our null-finding is inconclusive. This may indicate that preliminary analyses were under-powered to detect mean-group differences, that the limbic system is not affected in preschoolers with autism, or that heterogeneity of autism was a contributing factor. We will present data from the whole sample and use clustering approaches to detect potential subgroups with white matter differences in the limbic system.
