Abstract

Wind tunnel tests of a heavy-class helicopter model were carried out to evaluate the effectiveness of several components optimised for drag reduction by CFD analysis. The optimised components included different hub-cap configurations, a fairing for blade attachments and the sponsons. Moreover, the effects of vortex generators positioned on the back-ramp were investigated. The optimisation effect was evaluated by comparison of the drag measurements carried out for both the original and the optimised helicopter configurations. The comprehensive experimental campaign involved the use of different measurement techniques. Indeed, pressure measurements and stereo particle image velocimetry surveys were performed to achieve a physical insight about the results of loads measurements. The test activity confirms the achievement of an overall reduction of about 6% of the original model drag at cruise attitude.

Keywords: Drag reduction, Helicopter, Wind Tunnel, Particle Image Velocimetry.

Nomenclature

C_D	drag coefficient
C_{Dc}	drag coefficient measured for the original upright model with rotating hub at cruise angle of attack
C_p	pressure coefficient
DAER	Dipartimento di Scienze e Tecnologie Aerospaziali
FS	Full Scale
H_{VG}	VG height
L_{VG}	VG chord length
LGV	Politecnico di Milano large wind tunnel
Ma	Mach number
p	Kulite pressure signal [Pa]
$\|p\|$	pressure signal spectral magnitude [Pa]
PIV	Particle Image Velocimetry
POLIMI	Politecnico di Milano
Re	Reynolds number
RMS	root mean square
ROD	ROtorcraft drag Reduction
$\|U\|$	velocity magnitude [m/s]
U_∞	free-stream velocity [m/s]
VG	Vortex Generator
X	stream-wise coordinate [m]
Y	span-wise coordinate [m]
Z	vertical coordinate [m]
u	stream-wise velocity component [m/s]
v	span-wise velocity component [m/s]
w	vertical velocity component [m/s]
α	angle of attack [deg]
α_{VG}	VG pitch angle [deg]
δ	boundary layer displacement thickness
μ	advance ratio
ψ	azimuthal blade angle [deg]
ω	rotor hub rotational speed [RPM]

1   Introduction

The recent expansion of helicopter use has made the problem of environmental impact particularly important. Therefore, the will to reduce fuel consumption spurred research activities on the optimisation of helicopter shape for drag reduction. In fact, in the late 80's and early 90's particular effort was spent in US to test different hub and pylon fairing configurations for helicopter drag reduction. Comprehensive experimental test activities showed that a consistent reduction of the total helicopter drag can be obtained by combining a small circular-arc hub fairing with a nontapered pylon fairing in an integrated configuration [1].

Recently, the attention of the rotorcraft research community was oriented to the investigation of active/passive flow control devices for the suppression of the recirculating flow region over the fuselage back-ramp. For instance, active flow-separation control was the topic of different comprehensive activities combining computational and experimental effort to study drag reduction on a generic rotorcraft fuselage. In particular, in the recent years, ONERA and NASA collaborated to the investigation of the effectiveness of air-jet blowing devices over the back-ramp region using independent experimental platforms and different flow solvers [2, 3]. The experimental activities conducted in these frameworks demonstrated that a significant drag reduction could be obtained over a wide range of angles of attack through the use of different flow control strategies. Similar results were found in the numerical/experimental study by Ben-Hamou *et al.* [4] aimed to investigate the effect on drag reduction produced by piezo-fluidic actuators situated at the back-ramp lower corner of a generic transport helicopter fuselage.

The aerodynamic optimisation of helicopter components became a research topic introduced in the work plan of the GRC (Green RotorCraft) project in the frame of Clean Sky programme. The Clean Sky JTI (Joint Technology Initiative) was launched in 2008 as a Public-Private Partnership between the European Commission and industry with the mission to develop technologies that increase the environmental performance of air transport. In particular, in the past years, within the frame of the ADHeRO project [5], comprehensive wind tunnel tests and numerical simulations were carried out to investigate the effects of shape modifications and passive flow control devices on drag reduction of a light weight utility helicopter. Moreover, within the frame of CARD project [6], an experimental activity was carried out on a helicopter model of the same class to investigate innovative hub-fairing and beanie configurations for drag reduction.

The GRC2 Consortium decided to focus the investigation on drag reduction also for a heavy-weight class helicopter, considering the same geometry tested during the GOAHEAD project, funded by EU's Sixth Framework Programme for Research (FP6). In that framework, this helicopter model was the

object of a comprehensive experimental campaign with the aim to build an experimental database for a complete rotorcraft configuration [7]. The database was then used to validate state-of-the-art CFD solvers developed for the study of rotorcraft aerodynamic problems [8]. The results of the experimental and numerical studies enabled an improvement in the understanding of the complex flow field related to a complete helicopter configuration [9], providing a more detailed insight into the interactional aerodynamics features of rotorcraft (i.e. dynamic stall [10], tail-shake, pitch-up [11]) and their effects on the helicopter performance for different operating flight conditions.

The present work describes the wind tunnel tests carried out in the frame of the Clean Sky ROD project, funded by EU's Seventh Framework Programme for Research (FP7). The main goal of the activity was to evaluate the effectiveness of the CFD-based shape optimisation performed by the GRC2 consortium on several components of the considered common platform helicopter. In particular, the attention of the optimisation was focused on the rotor hub, on the sponsons and on the back-ramp area. The rotor hub represents, indeed, the source of a conspicuous part of the helicopter drag (of the order of 40% of the total drag). Thus, different hub-cap configurations were investigated both by DLR's [12] and by ONERA's numerical groups. In particular, the latter group also investigated the shape of a fairing for blade attachments to be used together with the optimised hub-cap for a further reduction of the drag due to the rotor hub. Moreover, ONERA numerically investigated the use of vortex generators (VGs) positioned on the fuselage back-ramp area [13]. In fact, the pronounced upsweep of the after-body shape characterising the blunt fuselages is responsible for a recirculating region at the junction with the tail boom that yields penalties on helicopter drag.

The helicopter fuselage model used for the present activity was basically the same as that employed in the frame of GOAHEAD project wind tunnel tests [7]. However, for the present experimental campaign the model internal structure, the motorised horizontal stabilizer and the swash-plate were purposely re-designed and built. The tests were carried out in the large wind tunnel of Politecnico di Milano (LGV). The comprehensive experimental campaign included tests both with the original and the optimised helicopter configuration to evaluate the performance improvements by comparison.

During the wind tunnel campaign different measurement techniques were employed. In particular, in addition to the global aerodynamic loads measurement, two partial balances for rotor hub and the horizontal stabilizer were used during the test activity. Moreover, steady pressure measurements were performed at more than 300 points located on the fuselage and the horizontal stabilizer, while the back-ramp and the fin of the model were instrumented with fast-response pressure transducers to evaluate the typical unsteadiness of the flow field around these components. In addition, stereo PIV surveys were performed above the back-ramp region and in the area before the fin to investigate

respectively the effect of the VGs on the three-dimensional flow behaviour and the rotor wake patterns relative to the different hub-caps tested.

In section 2, the setup of the helicopter model and of the measurement techniques is described. Section 3 reports the main results of the wind tunnel activity. Final considerations and comments are given in section 4.

2 Experimental Setup

The tests were carried out in the large wind tunnel (LGV) of Politecnico di Milano (POLIMI). The LGV test section dimensions are 4 m × 3.84 m. The maximum wind velocity is 55 m/s and the turbulence intensity is less than 0.1%.

2.1 The helicopter model

The 1/4 scale helicopter model was setup starting from some pre-existing components. Indeed, the model fuselage, based on the NH90 geometry, was the one used for the GOAHEAD test activity [7], while the swash-plate, the internal structure and additional sponsons were purposely designed for the present test activity as well as the new motorised horizontal stabiliser [14]. The new layout of the helicopter model is shown in Fig. 1.

Figure 1: Layout of the helicopter model.

Since the main goal of the experiments was drag measurement of the fuselage and rotor-hub, the helicopter model did not include the complete main rotor but only the rotor hub equipped with blade stubs. The span-wise extent of the blade stubs is equal to 30% of the rotor radius. Three electric

actuators acting on the swash-plate were used to set the collective and cyclic pitch of the blade stubs. The rotor was driven by a brushless motor with a 5:1 gear-drive. The 1/rev of the master blade was measured using a Hall Effect sensor mounted on the rotor shaft. An internal metal-structure was designed and built to interface the model with the LGV pylon in both upright and upside-down configurations (see Fig. 2). The pylon head controlled by a hydraulic system allowed the model angle of attack to be set. The sideslip angle of the model was set by means of a turn-table positioned on the test-section floor. The experimental study of the optimised solutions involving the lower part of the fuselage (i.e. VGs and sponsons) was carried out with the model in upside-down configuration to avoid the pylon interference. Moreover, tests with a dummy pylon were also carried out with this model configuration for the evaluation of the corrections due to the supporting pylon interference.

(a) Upright configuration

(b) Upside-down configuration

Figure 2: Original model configurations in the LGV test section.

The model was equipped with three strain gauge balances. The main balance was a six-component RUAG 192-6L installed on the head of the supporting strut (see Fig. 1). From the calibration report delivered by the balance manufacturer, a maximum error of the order of 0.6% of the helicopter original geometry drag in cruise condition (C_{Dc}) is declared for the load class corresponding to the load conditions measured in the present test campaign. It must be considered that this maximum error is evaluated taking into account also load configurations quite different from the ones measured in this campaign. Thus, taking also into account that the *in situ* checks carried out by means of calibrated weights showed much lower errors, an accuracy of the order of 0.5% of the helicopter original geometry drag in cruise condition can be reasonably and precautionary assumed. A second six-component RUAG 196-6D strain-gauge balance was used to measure the partial aerodynamic loads

acting on the rotor hub (see the installation layout in Fig. 1). Moreover, the horizontal stabilizer was instrumented with a two-component strain-gauge balance to measure the vertical component of the aerodynamic load and the rolling moment.

More than three-hundred static pressure taps distributed on the model fuselage (not on the sponsons) and on the horizontal stabilizer were connected to 8 pressure scanners (1 PSI FS, accuracy 0.1% FS) embedded inside the model. Unsteady pressure measurements were carried out on the back-ramp and the fin of the model instrumented with twenty XCS-093 Kulite miniature fast-response pressure transducers (2 PSI FS, accuracy 0.1% FS). Pressure (steady and unsteady) and loads measurements were carried out simultaneously for an acquisition time of 10 s for each model attitude. The acquisition frequency of unsteady pressure transducers was 10 kHz. The pressure taps position on the model for both the steady and unsteady measurements is illustrated in Fig. 3, showing also the X-Y-Z reference system employed in this work. In particular, the $X - Z$ plane is located on the model mid-span plane and the origin of the reference system is positioned on the fuselage nose. More details about the test rig can be found in Gibertini et al. [15].

Figure 3: Layout of the pressure taps distribution on the model.

The helicopter components optimised for drag reduction were designed by POLIMI starting from the shapes computed by ONERA's and DLR's numerical simulations. The improvements of the performance produced by the optimised components were evaluated by comparison with the drag measurements carried out with the original configuration components.

Figure 4 shows the layout of the different hub-caps tested during the wind tunnel activity. In
particular, Fig. 4(a) shows the original hub-cap of the helicopter model. The first optimised hub-cap and the set of optimised fairings for blade stubs attachments provided by ONERA (respectively called small hub-cap and stubs fairings from now on) are shown in Fig. 4(b). A second optimised hub-cap was designed starting from the external shape of a full hub fairing optimised by DLR described in the work by Khier [12]. However, the tested hub-cap (called large hub-cap from now on) presents a large open underside suitable for the mounting on the rotor hub that was not considered in the CFD optimisation by DLR (see Fig. 4(c)).

(a) Original hub-cap

(b) Small hub-cap + stubs fairings

(c) Large hub-cap

Figure 4: Layout of the hub-caps tested in wind tunnel.

The CFD-based optmisation activity was also dedicated to the sponsons. In particular, Fig. 5 shows the layout of the original and the new set of sponsons optimised by DLR's computation tested in the wind tunnel (called new sponsons from now on).

The experimental activity included tests of VG arrays positioned on the helicopter back-ramp area. In particular, the four most promising sets of 2×8 co- and counter-rotating VGs resulting from the CFD optimisation [13] were considered for the wind tunnel tests. The size and the pitch angle with respect to the local velocity field of the optimised VG configurations are reported in Tab. 1, where the chord length and the height of the VG are given with respect to the computed boundary layer

displacement thickness (δ).

The VGs were cut from a 1 mm thick PVC sheet and glued on a thin strip made of the same material (0.5 mm thickness and 30 mm chord). The tests were performed with the VG arrays attached on the model slightly downstream of the fuselage upsweep, representing the best position indicated by the CFD activity to obtain the highest drag reduction. The layout of the co- and counter-rotating VG arrays positioned on the fuselage model is shown in Fig. 6.

Table 2 summarizes the model configurations tested during the wind tunnel campaign.

2.2 Stereo PIV setup

Two different areas of investigation were investigated by stereo PIV surveys during the wind tunnel activity. With the model in upside-down configuration, the aim of the survey was the investigation of the effect of the VGs in the area of the junction between the fuselage back-ramp and the tail boom. With the model in upright configuration, PIV surveys were carried out in the area just ahead of the model fin to investigate the patterns of the rotor wake with the different hub-caps tested. The PIV system was set up to measure the three velocity components on longitudinal X-Z plane windows at different span-wise locations of the model. This technique enabled to reconstruct the average three-dimensional flow field over a volume of interest, as performed in the work by Zanotti *et al.* [16]. A set

Figure 7: PIV measurement volumes on the back ramp and ahead of the fin, dimensions in mm.

of 100 image pairs was acquired for each measurement plane. The PIV measurements were carried out over a total number of 53 longitudinal planes for the surveys over the back-ramp region (5 mm spacing in span-wise direction) and over 27 longitudinal planes for the surveys ahead the fin (10 mm spacing in span-wise direction). In the latter case, the choice of a lower number of PIV planes was dictated by the will to obtain a compromise between a reliable spatial resolution of the measurement and a duration of the survey suitable to avoid a prolonged stress of the rotating system. Thus, the span-wise dimension of the measurement volume for the surveys carried out with both model configurations was equal to 260 mm centered on the model mid-span section. The dimensions of the longitudinal measurement windows were respectively 365 mm × 185 mm for the surveys in the back-ramp region and 157 mm × 310 mm for those ahead of the fin. The location of the measurement volumes with respect to the fuselage model is shown in Fig. 7.

The PIV instrumentation consisted of a Litron NANO-L-200-15 Nd:Yag double pulsed laser with a 200 mJ output energy and a wavelength of 532 nm, and two Imperx ICL-B1921M CCD cameras with a 12 bit, 1952×1112 pixel array. The laser was mounted on the ceiling of the wind tunnel test section and was moved in span-wise direction by a single-axis traversing system. The CCD cameras were also moved in span-wise direction by means of two linear guides with high-accuracy in position. The guides were positioned on a metallic strut attached on the side wall of the test section enabling rotation of the cameras around the pitching axis of the model. With this solution, the image views were easily aligned with respect to the model angle of attack selected for the PIV survey. The cameras were equipped with a Nikkor 50 mm lens mounted on tilting mountings to achieve the Scheimpflug condition. The camera separation angle was set to $40°$ to obtain a correct optical access to the measurement area. During the PIV test run, the laser and the cameras were moved simultaneously in the span-wise direction to obtain a correct focusing of the laser sheet with the image plane for each longitudinal measurement plane. The stereo PIV system layout inside the LGV test section is shown in Fig. 8.

Phase-locked PIV measurements were possible for the surveys in upright configuration with the rotating hub using the 1/rev signal measured by the Hall Effect sensor mounted on the rotor shaft. In particular, for these tests the images acquisition was carried out at $\psi = 0°$ corresponding to the azimuthal position of the master blade stub aligned with the fuselage mid-span plane.

The image-pairs analysis was carried out by the PIVview 3C software [20], developed by PIVTEC. The multigrid interrogation method [19] was used starting from a 96 pixels $\times$ 96 pixel to a 32 pixel $\times$ 32 pixel interrogation window. The accuracy of the present PIV measurement can be estimated considering a maximum displacement error of 0.1 px [17]. Thus, taking into account the employed pulse-separation time and the optical magnification [18], the maximum in-plane velocity components error is about 1% of the maximum in-plane velocity component. Due to the stereoscopic optical set-up, a slightly higher error can be estimated for the out-of-plane velocity component.

3 Results

The main results of the comprehensive experimental campaign carried out with the model in both upright and upside-down configurations are outlined in the present section. The tests were performed with a wind tunnel free-stream velocity $U_\infty = 50$ m/s ($Ma = 0.15$). For the upright tests, the rotational speed of the rotor hub was set to $\omega = 710$ RPM ($\mu = 0.32$ based on the blade tip velocity of the entire scaled rotor and on the free-stream wind tunnel velocity). All the presented data are corrected considering wind tunnel effects. In particular, the wind tunnel data was corrected for the horizontal buoyancy in the test section, the supporting pylon
Figure 8: Layout of the PIV instrumentation in the LGV test section.

3.1 Upside-down configuration tests

As previously stated, the performance of the VG array on the back-ramp and of the optimised sponsons were evaluated with the model in upside-down configuration to avoid the interference of the strut wake. The effect produced by VGs and optimised sponsons are presented in this section adding their drag contribution measured during the tests in upside-down configuration to the baseline fuselage drag measured in upright configuration. This choice allowed to consider the proper contribution of these components to the helicopter fuselage drag corrected for wind tunnel effects (particularly for pylon interference). In fact, as the measurements in upright configuration indicated that the VGs and the new sponsons effects were clearly influenced by the strut wake, the results of the tests performed with the optimised hub are also reported in Sec. 3.2.1 considering the additional drag differences measured for these components in the upside-down configuration tests.

3.1.1 Loads measurements

First of all, in order to evaluate the VG layout providing the best drag reduction, the four selected arrays of VGs were tested at the cruise angle of attack of the actual helicopter ($\alpha = -1.8°$) with the model equipped with the original sponsons (next called baseline fuselage). The effects of the different VGs and new sponsons are presented in Fig. 9 and 10, where, as mentioned earlier, their drag contributions measured in upside-down configuration were added to the baseline fuselage drag measured in upright configuration.

Figure 9: Effect on measured drag of the different arrays of VGs at $\alpha = -1.8°$ for the original fuselage configuration with original sponsons: the indicated percentage drag differences are calculated with respect to the drag coefficient C_{Dc} measured at cruise angle of attack for the original model in upright configuration with original sponsons and rotating hub.

The VG study showed that the the higher drag reduction at cruise attitude is provided by the smaller counter-rotating VG array (see Fig. 9). This measured value of drag reduction (1.9%) is comparable to the one measured by Breitsamter *et al.* [5] for a light-class helicopter model. Indeed, in the latter work a maximum drag reduction of 1.5% of the total helicopter drag was found using straight strakes and two pairs of VGs positioned slightly upstream of the back-ramp, with dimensions and inclination relative to the incoming flow very close to the best VG configuration tested in the present experiments. The drag reduction value (of the order of 2%) obtained at cruise attitude using such passive devices, requiring very simple modification to existing helicopters, can be considered a useful result leading to a non-negligible benefit in terms of fuel saving. In fact, recent literature has
Figure 10: Effect on drag of the best VG array and new sponsons measured for α-sweep tests, $Ma = 0.15$.

shown that slightly higher values of drag reduction (an average of 10% of the baseline fuselage drag only) can be obtained by employing active flow control strategies as air-jet blowing actuators positioned at back-ramp region [3, 4]. However, it must noticed that this latter solution would produce apparent drawbacks on existing helicopters related to installation, power requirements and maintenance of such active actuators.

The overall performance of the best VG array and the new sponsons are shown in Fig. 10 in the range of angles of attack between $-6° \leq \alpha \leq 6°$.

The α-sweep test results comparison shows that the small counter-rotating VG produce a benefit in terms of drag reduction also for angles of attack close to cruise attitude. In particular, the VGs are more efficient close to zero incidence. On the other hand, a decrease of the VG performance is observed for angles of attack smaller than the cruise incidence. By adding the optimised sponsons, a further drag reduction is observed for negative angles of attack of the model while the measured drag is slightly increased with respect to the baseline configuration with VGs. In particular, at cruise angle of attack the optimised sponsons produces a further decrease of 0.9% of the drag measured in upright configuration for the original model with rotating hub.

3.1.2 Velocity and pressure measurements

The best VG configuration was object of a detailed experimental investigation including pressure measurements and PIV surveys to achieve an insight about the flow physics related to the use of such devices.

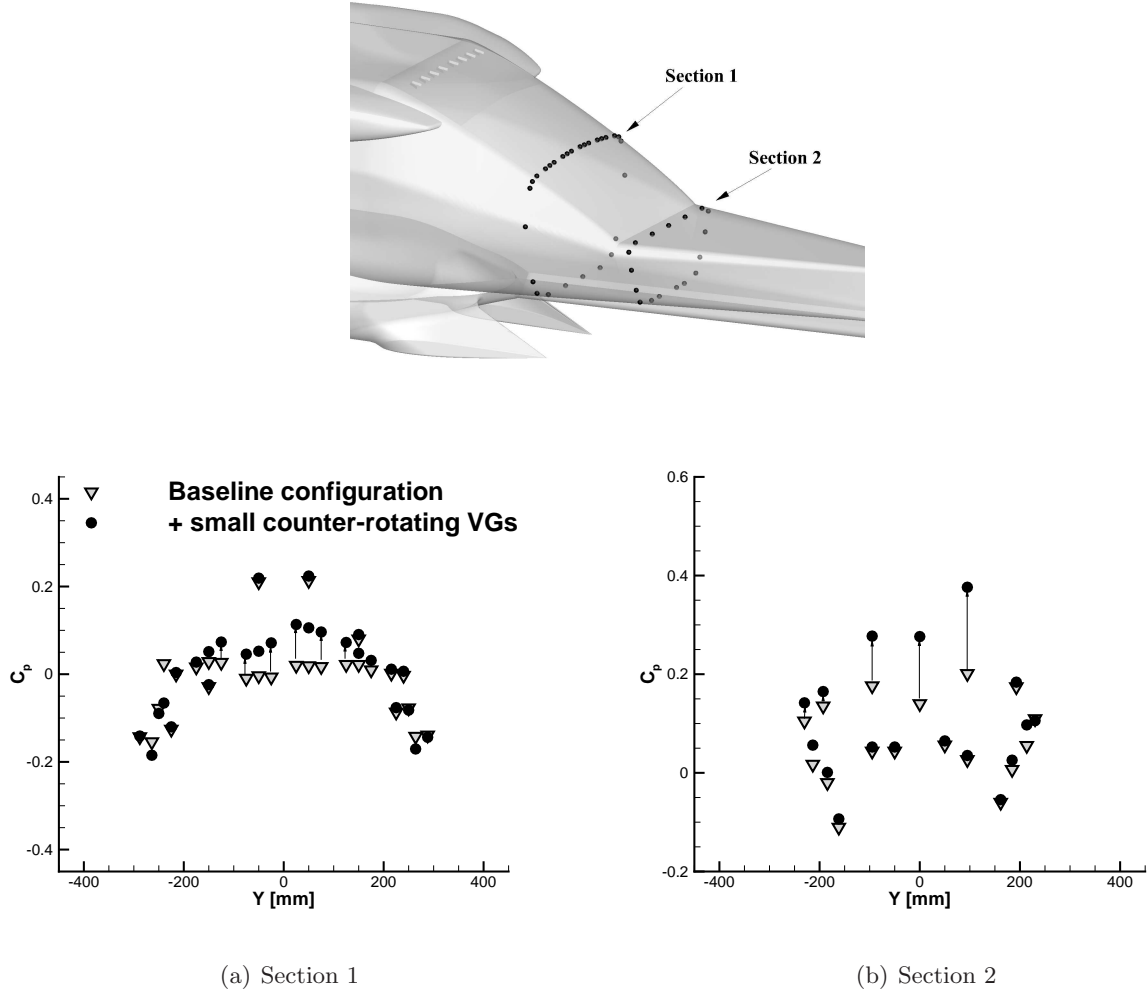

(a) Section 1

(b) Section 2

Figure 11: Effect of the best VG array on C_p distribution at selected fuselage sections for the tests in upside-down configuration, $\alpha = -1.8°$, $Ma = 0.15$.

The average pressure coefficient (C_p) distributions measured over two selected sections downstream of the best VG array is compared in Fig. 11 with the ones measured for the baseline fuselage configuration. On both the considered instrumented sections an apparent increase of pressure on the back-ramp surface is observed when the VG array is mounted on the model, as indicated by the upward oriented arrows. These steady pressure measurements confirm that the VGs are responsible for limiting the suction effect responsible for pressure drag rise. Moreover, re-energising the boundary layer, VGs are

suitable to prevent or limit the flow separation on the back-ramp region. This effect is confirmed by the PIV survey results obtained with and without the best VG array.

The comparison of the averaged non-dimensional stream-wise velocity component u/U_∞ measured on a longitudinal and on different span-wise planes extracted from the measurement volume is reported in Fig. 12. For the baseline fuselage configuration, the flow close to the ramp is characterised by a large flow separation. The extent of the three-dimensional separated flow is highlighted by the back-flow region evaluated on $X - Z$ and $Y - Z$ planes. On the other hand, the back-flow region in the PIV volume of investigation vanishes when the model is equipped with the VG array and the flow field shows an attached behaviour close to the back-ramp. A similar effect due to the VG solution on the flow field over the back-ramp region was also described by Breitsamter *et al.* [5] where cross-flow PIV surveys depicted a reduction of the area of the mean axial velocity deficit located in upper central back-ramp section.

(a) Baseline configuration
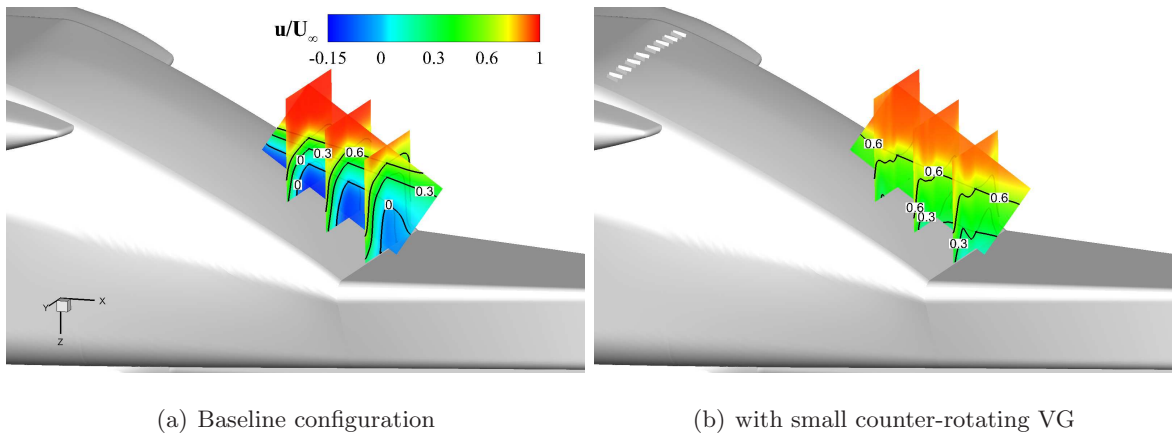

(b) with small counter-rotating VG

Figure 12: Effect of the best VG array on the velocity field in the back-ramp region: PIV results for the tests in upside-down configuration at $\alpha = -1.8°$, $Ma = 0.15$.

The unsteadiness level of the flow field close to the back-ramp surface can be evaluated by the analysis of the unsteady pressure trasducers signals. Figure 13 show the comparison of the pressure signals root mean square (RMS) measured by two Kulite transducers located on the mid-span plane of the back-ramp downstream the VG array. A higher value of the pressure signals RMS is apparent for the baseline fuselage configuration with respect to the ones calculated with the small counter-rotating VG. Indeed, the amplitude of the pressure fluctuations is quite decreased when the VGs are present, as confirmed by the comparison of the same pressure signals spectrum shown in Fig. 14 and coherently with the quite regular behaviour of the flow observed by the PIV surveys over the back-ramp region.
Figure 13: Comparison of the Kulite pressure signals RMS measured on the fuselage back-ramp for the tests in upside-down configuration, $\alpha = -1.8°$, $Ma = 0.15$.

(a) Kulite 1

(b) Kulite 2

Figure 14: Comparison of the back-ramp Kulite pressure signals spectrum for the tests in upside-down configuration, $\alpha = -1.8°$, $Ma = 0.15$.

3.2 Upright configuration tests

The tests with the model in upright configuration were mainly addressed to evaluate the effects of the different solutions optimised to reduce the rotor hub drag. Figure 15 shows the helicopter model equipped with the different optimised rotor hub components in the LGV test section.

3.2.1 Loads measurements

An accurate estimate of the contribution to the aerodynamic performance was obtained by adding all the optimised components starting from the original to the final optimised configuration. As previously mentioned, in upright configuration the VGs and the new sponsons effects were clearly influenced by the strut wake. Thus, in the present section these measured spurious drag contributions were removed from the global measured drag and the drag differences evaluated for the VGs and the new sponsons in upside-down configuration were added to consider the proper effects of these components to the total drag of the optimised model.

(a) Small hub-cap + blade stub fairings   (b) Large hub-cap

Figure 15: The helicopter model with the optimised hub-caps in the LGV test section.

The comparison of the drag coefficients measured for the different rotor hub configurations at cruise attitude is shown in Fig. 16. In this figure, the contribution of the different optimised components are indicated in terms of percentage drag differences calculated with respect to the drag measured at cruise angle of attack for the original model configuration.

At cruise angle of attack the small hub-cap produces a higher drag reduction with respect to the large hub-cap. A slight drag decrease can be observed by adding the blade stub attachment fairings to the small hub-cap, while they produce a small decrease of the large hub-cap performance. Generally, the wind tunnel activity showed that, at cruise attitude, an overall maximum drag reduction of 6.1% with respect to the original configuration can be obtained by the optimised helicopter configuration equipped with the small hub-cap, the blade stub fairings, the new sponsons and the small counter-rotating VG array.

An interesting result was also the drag reduction obtained with the large hub-cap if compared with the wind tunnel data measured by Martin *et al.* [1]. In fact, these tests showed that a circular-arc hub fairing with diameter and thickness to rotor radius ratio similar to the large hub-cap tested in
Figure 16: Effect on measured drag of the different rotor hub configurations at $\alpha = -1.8°$ for the tests in upright configuration with rotating hub, $Ma = 0.15$, $\omega = 710$ RPM: the indicated percentage drag differences are calculated with respect to the C_D measured at cruise angle of attack in upright configuration for the original model with rotating hub.

the present experiment produces an increase of the total drag if tested with unfaired mast.

A more general overview of the performance of the optimised components can be deduced from the comparison of the drag measurements carried out in the α-sweep tests. The drag coefficient curves comparison in the range between $-6° \leq \alpha \leq 6°$ is shown in Fig. 17.

The model configuration with the small hub-cap and the new sponsons produces an apparent drag decrease with respect to the original model configuration in the whole range of angles of attack considered around the cruise attitude. The addition of the stub attachment fairings produces a further slight decrease of the model drag, in particular from the cruise attitude towards positive angles of attack. The model configuration with the large hub-cap shows worse performance with respect to the small hub-cap configuration in the whole considered range of incidences. However, for negative angles of attack a benefit with respect to the original model configuration is still apparent, while a performance decrease is observed for positive incidences. For the latter hub-cap configuration, the use of the stubs attachments fairings does not produce an appreciable increase of the performance in terms of drag reduction in the whole range of angles of attack considered.
Figure 17: Effect on measured drag of the different rotor hub configurations for α-sweep tests in upright configuration with rotating hub, $Ma = 0.15$, $\omega = 710$ RPM.

3.2.2 Velocity and pressure measurements

PIV surveys and unsteady pressure measurements results were carried out to investigate possible "tail-shake" effect with the different optimised hub-caps configurations. The comparison of the phase-averaged PIV results with the original and optimised hub-cap components at cruise angle of attack are illustrated in Fig. 18, showing the contours of the non-dimensional stream-wise velocity component on a longitudinal and span-wise plane extracted from the measurement volume. A quantitative evaluation on the extent of the rotor hub wake is obtained by the comparison of the stream-wise velocity component profiles extracted at model midspan on the span-wise measurement plane closest to the fin (see Fig. 19).

The PIV results analysis shows that the velocity deficit region measured for the original hub-cap configuration is confined in the lower part of the measurement volume close to the tail boom. Thus, in the present configuration, the rotor hub wake influences the lowest part of the fin only (see Fig. 18a). On the other hand, a wider velocity deficit region can be observed from the PIV results obtained with both the large and small optimised hub-caps. In particular, the area with the higher velocity deficit is more extended for the large hub-cap configuration (see Fig. 18b and c). This means that the optimised hub-caps do not deflect the wake enough to avoid collision with the fin. Moreover, the blade

Figure 18: Effect of the hub-caps on the rotor hub wake: phase averaged PIV results for the tests in upright configuration with rotating hub at $\alpha = -1.8°$, $Ma = 0.15$, $\omega = 710$ RPM, $\psi = 0°$.

stub attachment fairings do not produce appreciable effects on the rotor hub wake (see Fig. 18d).

The unsteady pressure measurements carried out on the fin provide interesting information about the unsteadiness of the rotor hub wake for the different hub-caps tested. Figure 20 shows the comparison of the pressure signals' RMS measured at cruise angle of attack by the Kulite transducers located on the port side of the fin. This side, corresponding to the upper side of the fin airfoils, is more sensitive to the instantaneous incidence variations.

In particular, the RMS of the pressure signals measured with the original hub-cap by the two highest Kulite transducers (KF1 and KF2) is lower with respect to the ones measured with both the

small and the large hub cap. The RMS value comparison shows that the flow impinging on the higher part of the fin presents the highest level of unsteadiness for the rotor hub configuration equipped with the large hub-cap. The spectrum of the KF1 transducer pressure signal confirms this feature. In fact,

the highest amplitude peak corresponding to the rotor 4-per-rev frequency is obtained for the signal measured with the large hub-cap configuration (see Fig. 21a). The measurements of the lower KF3 transducer show a similar level of pressure fluctuation for all three hub-cap configurations tested, as also confirmed by the spectra comparison shown in Fig. 21b. On the other hand, a higher value of the signal RMS for the original hub cap configuration can be observed from the lowest KF4 transducer measurements.

4   Conclusions

A comprehensive wind tunnel test campaign was performed in the POLIMI large wind tunnel to assess the effectiveness of helicopter components optimised by CFD for drag reduction. In particular, an heavy-class helicopter model was set up to be tested in both upright and upside-down configurations.

An accurate evaluation of the aerodynamic drag was carried out to evaluate the performance of different hub-caps, a set of blade stub attachment fairings and a new set of sponsons. Moreover, the use of different arrays of VGs located on the model back-ramp was investigated for the same purpose. Pressure measurements and stereo PIV survey enabled a detailed insight into the flow physics related to the use of the optimised components.

The wind tunnel tests carried out with the model in upright configuration with the rotating hub confirm the effectiveness of the optimised components showing an overall drag reduction of about 6% at cruise attitude with respect to the original model configuration. Moreover, stereo PIV surveys

enabled the evaluation of the wake patterns of the different rotor-hub configurations tested. The flow field surveys, combined with the unsteady pressure measurements on the fin, were also useful to investigate the performance of the optimised hub-caps on possible "tail-shake" effects.

The upside-down measurements confirms that the best performance in terms of drag reduction is obtained with an array of counter-rotating VG positioned on the fuselage back-ramp area slightly beyond the pronounced fuselage upsweep. PIV results clearly show that their action eliminated the recirculating region at the junction with the tail boom responsible for helicopter drag penalties. A drag reduction of the order of about 2% was found with the use of the best VG array. This can be considered a useful result as it produces the benefit of a non-negligible reduction of fuel consumption with a very simple modification to existing helicopters.
