7 **Abstract** Knowledge of the in situ stress state of rock mass is fundamental
8 for engineering, geological and geophysical applications. In situ stress state de-
9 termination requires in principle the evaluation of the three principal stresses
10 and the related principal directions, but it is widely recognized in the liter-
11 ature that the maximum horizontal stress is the most difficult component to
12 accurately estimate. In the context of borehole methods, this paper proposes
13 a step-by-step analytical procedure to estimate some bounds to the maximum
14 horizontal stress, starting from a geomechanical description of the rock and
15 relying on information generally available in the engineering practice. The pro-
16 cedure is divided in substeps, each one requiring additional information about
17 the mechanical properties of the rock and on the geometrical properties of the
18 failed portion of rock: more information available implies a lower uncertainty

on in situ stress estimate. Furthermore, since the proposed procedure is analytical, it allows a complete and very easy implementation in a spreadsheet. The aim of the work is thus to provide a rigorous but simple analytical tool that can be used in engineering practice to estimate some bounds to the maximum horizontal in situ stress state. The approach is finally validated by means of both numerical simulations, performed with a sophisticated numerical tool, and experimental field data coming from the literature.

Keywords In situ stress · borehole · breakout failure · tensile failure · rock mechanics · analytical procedure

1 Introduction

Knowledge of in situ stress state is fundamental for the solution of many problems not only in the field of civil, mining and petroleum engineering, but also for geological and geophysical applications. For instance, stress concentration around underground openings is significantly affected by the in situ original stress state, and its knowledge is mandatory for any deformation and instability evaluation of tunnels and shafts. When dealing with oil and gas applications (e.g. borehole excavations, sand production management and stimulation interventions), the knowledge of the stress state and its variation is required before and during reservoir depletion, as well as to predict the distribution and the propagation of cracks as a consequence of hydraulic fracturing jobs.

In situ stress state evaluation implies the determination of six independent quantities, namely the components of the Cauchy second order tensor with respect to a given coordinate system. However, it is most common in engineering practice to determine the three principal stresses and to identify the related principal directions. The initial stress state of horizontal and homogeneous soil layers, which are commonly originated by deposition, is generally evaluated by assuming that the vertical and the horizontal directions are principal ones: the vertical stress is considered coincident with the overburden, while the horizontal one is evaluated by means of the K_0 concept (Jaky, 1944, Schmidt, 1966). When the geometric configuration is more complex, numerical simulations of the deposition process are usually performed by increasing the unit weight of the material. When dealing with rock formations at large depths, the problem of identifying the initial stress state is much more complicated, being the result of many processes and mechanisms, involving tectonic, gravity and residual stresses. At a smaller scale, the in situ state of stress is also locally influenced by the presence of cavities and discontinuities. Uncertainties related to the exact geological history, the constitutive laws and the detailed structure of the rock mass imply that no numerical computations can be performed to reliably simulate the whole geological history and thus to estimate the in situ stress field (Zang and Stephansson, 2010). Nowadays, it is widely accepted in the engineering practice that the in situ stress state can be estimated by means of techniques that disturb the rock itself, evaluating the induced mechanical

response, which in turn depends on the initial stress state itself.

According to Amadei and Stephansson (1997), classical crustal in-situ measurement techniques require either a well bore (e.g. breakout analysis, hydrofrac) or core materials (e.g. overcoring, strain relief). Despite coring methods are widely used techniques for stress measurement in the engineering practice, they suffer of some limitations related to the maximum depth allowed and to the small volume involved. Borehole methods applicability is vice versa limited just by the maximum borehole depth. Zoback et al (2003) evidenced the advantages and the reliability of borehole methods to determine both stress magnitude and orientation in deep wells, highlighting the role of a sound geomechanical model of the subsurface and of wellbore imaging devices, like ultrasonic viewers and electrical imaging tools, to yield detailed information about wellbore failure.

The classical strategy that is employed to characterize the stress field (see, e.g. Zoback et al, 2003 and Zoback, 2007) is based on the following steps: i) The vertical equilibrium, i.e. integrating density logs, enables the determination of the vertical stress; ii) Wellbore and recent geologic observations as well as earthquake focal mechanisms allow the determination of the principal stresses directions; iii) The analysis of hydraulic fracturing and leak-off tests (see, e.g. Zoback and Healy (1992) and Haimson et al (2009)) permits the estimation of the minimum principal stress; iv) Direct measurements or a cautious estimation from geophysical logs or seismic data are used to determine pore pressure magnitude. Generally, it is assumed that the vertical stress is principal: as a consequence, the two other principal directions lie in the horizontal plane. This assumption is widely accepted for non-active regions from the tectonics point of view, or for regions where the tectonical stress has already relaxed. In fact, according to Bell (2003), the free surfaces of sedimentary basins are generally horizontal, implying that the principal stress directions can be considered vertical and horizontal. From this picture, it is evident that most difficult component to estimate is the maximum horizontal principal stress. Some bounds to the maximum horizontal stress can be provided by the application of the Anderson faulting theory together with Mohr-Coulomb failure. For any given depth of a rock mass, some limiting values of the difference between the maximum and the minimum principal stresses can be argued, relying on the assumption that the stresses in the earth crust cannot exceed the frictional strength of pre-existing faults. Of course, this argument is valid at a broad scale and, locally, exceptions can exist. Furthermore, an estimate of fault friction angle is needed. Applications are shown in Moos and Zoback (1990), Wiprut and Zoback (2000) and Zoback et al (2003). Shear failure data registered on circular well bores, induced by excavation and pressurization processes, provide other bounds to the maximum horizontal principal stress. Such bounds derive from the shear strength of the material. As a matter of fact, when a well bore is drilled, some material is removed from the original rock mass: the exhumed material is no more able to carry the stress, that is

transferred to rock around the well. This process implies a stress concentration in the rock surrounding the well. According to the linear elasticity theory, this stress redistribution amplifies the difference between the virgin principal stresses and thus the maximum shear stress in the rock mass. The so-called *breakout* failure is in fact the consequence of the increase in shear stress on the borehole wall due to the excavation-induced increase of the hoop stress around the wall. Breakout failure can also provide information about the principal stress directions: when either the borehole and the principal stress are vertical, the azimuth of breakout failures coincides with the minimum horizontal stress direction. The reliability of breakout data as a tool to estimate the in situ stress state is justified also by the possibility of having multiple determination of stress in single well and by the possibility to check for regional consistency among numerous wells. Breakout failures have been exploited to determine some limiting values of the maximum horizontal principal stress in Leeman (1964), Bell and Gough (1979), Zoback et al (1986). A relevant role in breakout failure analysis is provided by the failure criterion used to describe rock behaviour: Moos and Zoback (1990) provided solutions by considering a Galileo-Rankine criterion for the compressive strength of the rock, characterized by a constant value, while Vernik and Zoback (1992) provided estimates via the Weibols and Cook (1968) strain energy failure criterion. Zoback et al (1985) exploited the elastic Kirsch solution and Mohr-Coulomb failure criterion to highlight the role of breakout shape and inelastic deformation around the borehole, as later evidenced by Barton et al (1988), Aadnoy et al (2013) and Della Vecchia et al (2014). Important information about the magnitude and the orientation of the horizontal maximum principal stress can be also obtained by drilling induced tensile fractures: these fractures form on the wall of the borehole with an azimuth coincident with the direction of the maximum horizontal stress, when one principal stress is locally tensile.

According to this picture, it is evident that the estimate of in situ rock stress state for engineering purposes suffers, as any other geomechanical application, of a relevant problem: due to the complex stress-strain behavior of rocks, sophisticated theoretical and numerical tools are in principle needed to obtain reliable predictions. The applicability of such models is, however, limited by the effort needed in their calibration and in their numerical implementation, which is generally unaffordable for common engineering applications. In order to overcome this seeming insurmountable dichotomy between reliable predictions and applicability for engineering purposes, this paper presents a step-by-step analytical procedure to estimate the in situ maximum horizontal stress exploiting borehole failure data. The procedure is divided in sub-steps, each sub-step implying an increasing degree of detail about the knowledge of the mechanical properties of the materials involved and on the geometrical properties of the failed portions of rocks. Of course, the larger the quantity of information available, the lower the uncertainty on the estimated stress: the bounds identified by the application of the procedure plays the same role of the classical error bars that are often presented in the literature about in-situ

stress state. It is worth underlying that the procedure is purely analytical: it is thought to be implemented in a simple spreadsheet and no programming or dedicated software are required. In order for the procedure to be analytical, some simplification are necessarily introduced: for example, the role of temperature changes is neglected, as well as the role of possible not axisymmetric distribution of pore pressure near the well. Remarkably, all the parameters required are easy to determine: in the proposed version of the procedure the rock will be characterized in terms of uniaxial strength and friction angle, while the only information needed from the field is the orientation of the faults (if any) and the size of the breakout failure (if any). The procedure has been successfully validated basing on both numerical analyses and case histories from the literature. Numerical analysis has been performed by means of a Finite Element approach, capable of simulating the mechanical behaviour of the rock surrounding the borehole by means of a brittle damage constitutive model for geological media recently proposed in De Bellis et al (2016, 2017). The model in fact proved able to simulate the mechanical behaviour of both sedimentary and crystalline rocks, both in the pre- and the post-peak stages, showing to be particularly suitable for materials characterized by a brittle behavior. The approximation provided by the simplified analytical solution to the results obtained by means of such a sophisticated numerical tool is excellent, at least for breakout opening lower than 90° , proving that the procedure is able to provide reliable results also for non-circular and collapsed boreholes. Appreciable agreement has been also obtained by applying the procedure to in situ experimental data presented in the literature.

2 Steps involved in the procedure: methodology

The procedure to estimate the maximum horizontal stress detailed below involves four sub-steps: Step 1 is based on Anderson faulting theory, and just a broad estimate of the friction angle of the faults is required. Step 2 is based on the application of the Kirsch elastic solution for the redistribution of stresses around a borehole in plane strain conditions: depending on the azimuth and the far-field stress state, the maximum and minimum principal stress on the borehole wall coincides with different stress components, i.e. radial, hoop or vertical. Stress distribution around the hole according to the Kirsch solution, together with simple visual information obtained along borehole depth about the orientation of drilling-induced failure, allows a refinement of the bounds of the far field stress obtained in Step 1. It is worth noting that Step 2 does not require any information about strength properties of the material at the borehole scale, being based on an elastic solution. Step 3 takes advantage on both the information about the presence of tensile and breakout failures on borehole wall and the knowledge of rock failure criterion, further reducing the bounds identified in Step 2. Finally, if also the size of the borehole breakout is known, Step 4 will provide a unique value of the maximum horizontal stress.

196 In the following, S_v represents the total principal vertical virgin stress,
 197 S_H the total maximum horizontal virgin stress and S_h the total minimum
 198 horizontal virgin stress. According to the Introduction, S_v and S_h are assumed
 199 to be known in terms of both magnitude and direction. When dealing with
 200 the mechanical behaviour of rocks, the stress to be used in the failure criteria
 201 are effective stress, indicated as S'_v , S'_h and S'_H for the vertical and the two
 202 horizontal stress directions, respectively. The effective stress tensor, in general
 203 indicated as σ'_{ij} is evaluated according to the poroelastic theory proposed by
 204 Biot as

$$\sigma'_{ij} = \sigma_{ij} - \alpha p_w \delta_{ij} \quad (1)$$

205 where σ_{ij} is the total Cauchy stress tensor, p_w is the pore fluid pressure, α the
 206 Biot coefficient and δ_{ij} is the Kronecker delta. Experimental and theoretical
 207 evidences (e.g. Boutéca and Guéguen, 1999) prove that, even for the same
 208 material, α is not a constant, but it depends on the phenomenon that has
 209 to be modeled. A large amount of experimental evidence related to sedimentary
 210 rocks (Vincké et al. (1998), Espinoza et al. (2015), Sulem and Ouffroukh
 211 (2006), Han et al. (2018)) shows that reproducing the elastic behaviour usually
 212 requires α to be smaller than one, while reproducing failure generally requires
 213 α to be equal to one. Since all the following steps deal with failure condi-
 214 tions, in the following, $\alpha = 1$ is assumed and the rock is always considered as
 215 saturated.

216 2.1 Step 1: limits on the stress state from the tectonic regime

217 The idea of using the Anderson (1951) faulting theory to estimate some broad
 218 limits on the in situ stress state relies on the assumption that brittle frac-
 219 ture evidenced at the laboratory scale appears to be reproduced also in na-
 220 ture by geological structures (Zang and Stephansson, 2010): faults thus result
 221 from brittle failure, according to the Mohr-Coulomb failure criterion. Following
 222 Anderson, tectonic stress near the Earth crust can be classified into normal,
 223 strike-slip and reverse, depending on the relative combination of the principal
 stresses (Table 1).

Regime	S_1	S_2	S_3
Normal NF	S_v	S_H	S_h
Strike-slip SS	S_H	S_v	S_h
Reverse RF	S_H	S_h	S_v

Table 1 Principal stresses in the different tectonic regimes

224 At each depth, the Anderson faulting theory defines some relations between
 225 the values of stresses, according to the strength criterion of the material. Let
 226 us assume that the Mohr-Coulomb failure criterion holds in the form
 227

$$\sigma'_1 = C + N_\phi \sigma'_3 \quad (2)$$

228 being σ'_1 and σ'_3 the maximum and minimum principal effective stress, respec-
 229 tively, C the uniaxial compressive strength and N_ϕ a parameter dependent on
 230 the friction angle ϕ' , i.e. $N_\phi = (1 + \sin \phi') / (1 - \sin \phi')$.

231 For any tectonic regime, a relation between some of the in situ principal
 232 stresses can be identified, corresponding to the fulfilment of Equation 1:

233 – Normal fault (NF) $S'_v > S'_H > S'_h$

$$\frac{\sigma'_1}{\sigma'_3} = \frac{S'_v}{S'_h} = \frac{C}{S'_h} + N_\phi \quad (3)$$

234 – Strike-slip fault (SS) $S'_H > S'_v > S'_h$

$$\frac{\sigma'_1}{\sigma'_3} = \frac{S'_H}{S'_h} = \frac{C}{S'_h} + N_\phi \quad (4)$$

235 – Reverse fault (RF) $S'_H > S'_h > S'_v$

$$\frac{\sigma'_1}{\sigma'_3} = \frac{S'_H}{S'_v} = \frac{C}{S'_v} + N_\phi \quad (5)$$

236 For a given depth (and thus a given overburden stress) and pore pressure,
 237 the equations above identify a region in the horizontal stresses plane: the in
 238 situ stress state of the material, that cannot support a shear stress greater
 239 than the one identified by the failure criterion, must lay inside the region or
 240 on its boundaries. For detailed information about this procedure see Zoback
 241 et al. [43] and Moos and Zoback [25].

242 This first step of the procedure needs just a broad estimate of the strength
 243 parameters of the material involved: as it has been shown from laboratory
 244 studies on a large variety of rock samples and from in situ experiments in
 245 different fault regimes, the friction coefficient generally ranges between 0.6
 246 and 1.0 (i.e. ϕ' between 30° and 45°). In this case just literature data of
 247 friction angle for the studied litotypes can be used, being not known a priori
 248 if the major role in terms of failure is provided by the faults or by the core
 249 material. As for the value of the uniaxial strength, it is worth evidencing that
 250 in petroleum engineering applications the role of C in drawing stress polygons
 251 is generally neglected.

252 In the following, each step of the procedure is applied to a well documented
 253 case study from the literature, i.e. a 2-km-deep research borehole (Hole-B)
 254 drilled in the context of the drilling project investigating the Chelungpu Fault
 255 (Taiwan). Information about material properties and in situ stress state can be
 256 found in different studies present in the literature (e.g. Wu et al., 2007, Hung
 257 et al., 2007, Lin et al., 2009, Haimson et al., 2009); leak-off tests allowed the
 258 determination of the variation of the minimum horizontal principal stress S'_h
 259 with depth, while from the interpretation of *formation microscanner* FMS
 260 results breakout widths have been estimated for depths between 940 m and
 261 1310 m. Figure 1 shows the stress state limits that can be identified for a depth
 262 of 1000 m, where the rock mass is characterized by a a far-field minimum

263 horizontal principal stress equal to $S'_h = 10.8$ MPa and a far-field vertical
 264 effective stress $S'_v = 14.7$ MPa: S'_H is limited by a lower bound $S'_H = S'_h = 10.8$
 265 MPa and by an upper bound $S'_H = 39.8$ MPa, corresponding to a stress
 266 anisotropy $S'_H/S'_h = 3.7$ deriving from the limit corresponding to the strike-
 267 slip regime. Values of $\phi' = 35^\circ$ and saturated density $\rho_{sat} = 2.5$ g/cm³ have
 268 been used, according to Haimson & Rudnicki (2009) and Wang (2011). Pore
 269 pressure has been assumed to be hydrostatic.

Fig. 1 Admissible stress polygon and limits from tectonic regimes for the Chelungpu fault site.

270 2.2 Step 2: limits on the stress state from failure orientation

271 The estimate of the bounds on the value of the maximum horizontal stress
 272 identified at Step 1 can be refined by means of a visual inspection of borehole
 273 failure, performed, e.g., by ultrasonic televiewers. It is well known that a cir-
 274 cular hole in a isotropic linear elastic material induces a perturbation in the
 275 stress field, which can be computed according to the Kirsch solution. In the
 276 following, a is the internal radius of the circular hole, subjected to a uniform
 277 internal pressure p_i , r is the radial coordinate, i.e. the distance from borehole
 278 center that varies between a and ∞ , and θ , positive counterclockwise, is the
 279 angle between the radius considered and the direction of the maximum hori-
 280 zontal stress (see figure 2). Another useful variable is the so-called net pressure
 281 p_{net} , defined as the difference between p_i and the pressure of the pore fluid,
 282 p_w : $p_{net} = p_i - p_w$. The Kirsch solution, developed in plain strain conditions,
 283 reads (see, e.g. Jaeger [21]):

Fig. 2 Radial coordinates for the circular hole

$$\begin{aligned}
 \sigma'_r &= \frac{1}{2}(S'_H + S'_h) \left[1 - \left(\frac{a}{r}\right)^2 \right] + p_{\text{net}} \left(\frac{a}{r}\right)^2 + \frac{1}{2}(S'_H - S'_h) \left[1 - 4\left(\frac{a}{r}\right)^2 + 3\left(\frac{a}{r}\right)^4 \right] \cos 2\theta, \\
 \sigma'_\theta &= \frac{1}{2}(S'_H + S'_h) \left[1 + \left(\frac{a}{r}\right)^2 \right] - p_{\text{net}} \left(\frac{a}{r}\right)^2 - \frac{1}{2}(S'_H - S'_h) \left[1 + 3\left(\frac{a}{r}\right)^4 \right] \cos 2\theta, \\
 \tau_{r\theta} &= -\frac{1}{2}(S'_H - S'_h) \left[1 + 2\left(\frac{a}{r}\right)^2 - 3\left(\frac{a}{r}\right)^4 \right] \sin 2\theta,
 \end{aligned} \tag{6}$$

284 where σ'_θ , σ'_r and $\tau_{r\theta}$ are the effective hoop, radial and shear stress, respectively
 285 and S'_H and S'_h are maximum and the minimum horizontal effective far-field
 286 stresses.

287 Under the assumption of drilling operations performed in plane strain condi-
 288 tions in the vertical direction, the principal stresses on borehole wall ($r = a$)
 289 and $\theta = 0$ can be expressed, according to the Kirsch solution, as

$$\begin{aligned}
 \sigma'_r &= p_{\text{net}} \\
 \sigma'_\theta &= 3S'_h - S'_H - p_{\text{net}}, \\
 \sigma'_z &= S'_v + \Delta\sigma'_z = S'_v + 2\nu(S'_h - S'_H).
 \end{aligned} \tag{7}$$

290 In accordance with the elastic solution introduced, the increment $\Delta\sigma'_z$ due
 291 to borehole excavation follows from the assumption of null vertical strain in-
 292 crement ($\Delta\varepsilon_z = 0$). The increments of radial and hoop stress can finally be
 293 calculated as $\Delta\sigma'_r = p_{\text{net}} - S'_h$ and $\Delta\sigma'_\theta = \sigma'_\theta - S'_H = 2'S_H - S'_h - p_{\text{net}}$, so that
 294 $\Delta\sigma'_z = 2\nu(S'_H - S'_h)$ (being ν the Poisson coefficient of the rock).

295 If the stress components are divided by the minimum effective far-field
 296 horizontal stress S'_h , the role of the far-field stress anisotropy ratio S'_H/S'_h is
 297 highlighted:

$$\begin{aligned}
\frac{\sigma'_r}{S'_h} &= \frac{p_{net}}{S'_h} \\
\frac{\sigma'_\theta}{S'_h} &= 3 - \frac{S'_H}{S'_h} - \frac{p_{net}}{S'_h} \\
\frac{\sigma'_z}{S'_h} &= \frac{S'_v}{S'_h} + 2\nu \left(1 - \frac{S'_H}{S'_h} \right).
\end{aligned} \tag{8}$$

Equations (8) represent three lines in the σ'/S'_h vs. S'_H/S'_h plane, that can be easily drawn when the relevant information about S'_v , S'_h and p_{net} are known: for example, plotting the three lines allows the visualization of the maximum, the intermediate and the minimum principal stresses on borehole wall for $\theta = 0$, i.e. when tensile failure is anticipated.

Figure 3(a) shows an example of the evolution of the stress state in $\theta = 0$ as a function of the horizontal anisotropy ratio for $S'_v = 14.7$ MPa and $p_{net} = 0$ MPa. The maximum stress anisotropy considered in the example is the one identified in Step 1, i.e. $S'_H/S'_h \leq 3.7$ (see section 2.1). It is evident that for low values of S'_H/S'_h , the minimum principal stress is the radial one, while for high values of S'_H/S'_h , the hoop stress becomes the minimum one. If a visual information about tensile failure is provided, it is possible to determine what is the direction of the minimum principal stress: vertical fractures are generally obtained if the hoop stress is minimum, horizontal fractures if the vertical stress is minimum, concentric fractures if the radial stress is minimum (see, e.g Zang and Stefansson, 2010). Once the minimum principal stress is identified, the relevant zone according to Equation (8) can be identified, and thus a further limitation in stress anisotropy is obtained. According to the example, in the presence of vertical fractures σ'_θ has to be the minimum principal stress, and so $3 \leq S'_H/S'_h \leq 3.7$; if concentric fractures are detected, σ'_r is the minimum principal stress, so that $1 \leq S'_H/S'_h \leq 3$. The limiting anisotropies separating the different tensile failure orientation can be plotted in the stress polygon, as shown in Figure 4, where the line $S'_H = 3 \cdot S'_h$ divides vertical and concentric fractures.

The same logical path can be applied on the borehole wall in $\theta = \pi/2$, when shear failure is anticipated: also in this case the failure pattern is dependent on which components are the maximum and the minimum ones. In this case the principal effective stresses on borehole wall ($r = a$) reads:

$$\begin{aligned}
\sigma'_r &= p_{net} \\
\sigma'_\theta &= 3S'_H - S'_h - p_{net} \\
\sigma'_z &= S'_v + 2\nu(S'_H - S'_h),
\end{aligned} \tag{9}$$

Fig. 3 Relation between normalized principal components as a function of horizontal stress anisotropy S'_H/S'_h ($S'_v = 14.7$ MPa, $\nu = 0.34$, $p_{net} = 0$).

Fig. 4 Identification of the regions where the different tensile failure orientations can potentially take place.

327 and in non dimensional form

$$\begin{aligned}
 \frac{\sigma'_r}{S'_h} &= \frac{p_{net}}{S'_h} \\
 \frac{\sigma'_{\theta}}{S'_h} &= 3 \frac{S'_H}{S'_h} - 1 - \frac{p_{net}}{S'_h} \\
 \frac{\sigma'_z}{S'_h} &= \frac{S'_v}{S'_h} + 2\nu \left(\frac{S'_H}{S'_h} - 1 \right).
 \end{aligned} \tag{10}$$

328 Figure 3(b) shows the evolution of the stress components in $\theta = \pi/2$ as
 329 a function of the horizontal anisotropy ratio and it clearly illustrates that in
 330 this specific case for all the admissible anisotropy ratios the radial effective
 331 stress is always the minimum principal stress and the hoop stress is always
 332 the maximum principal stress ($\sigma'_r < \sigma'_z < \sigma'_{\theta}$). In this specific case, such an
 333 information cannot provide any further refinement of S'_H bounds, because just

334 a type of breakout failure is predicted. If viceversa also the lines predicted by
 335 (10) would cross themselves, then the same logic of Figure 3(a) can be followed:
 336 depending on failure pattern in the breakout zone, the relevant region in term
 337 of stress anisotropy could be identified.

338 2.3 Step 3: limits on the stress state from rock failure criterion

339 According to Equation 6, under the assumption of plane strain conditions
 340 during drilling operations, the complete effective state of stress can be written
 341 on borehole wall ($r = a$), allowing to determine, once the strength parameters
 342 of the materials are known, if failure conditions are met. According to the
 343 literature, the evolution of the effective hoop stress on the borehole wall can
 344 be considered as a proxy to determine which zones of the borehole can be
 345 subjected to shear failure and which ones to tensile failures. Writing σ'_θ as a
 346 function of θ in $r = a$ leads to the expression

$$\sigma'_\theta(a, \theta) = (S'_H + S'_h) - p_{\text{net}} - 2(S'_H - S'_h) \cos 2\theta, \quad (11)$$

347 that shows that the minimum value $3S'_h - S'_H - p_{\text{net}}$ is achieved for $\theta = 0$ or
 348 $\theta = \pi$, while the maximum one, $3S'_H - S'_h - p_{\text{net}}$, for $\theta = \pi/2$, or $\theta = 3/2\pi$.

349 If the elastic and strength parameters of the material, as well as the values
 350 of S_v , S_h , p_{net} and p_w , are known from previous determinations, it is possible
 351 to obtain some bounds for S_H depending on the occurrence of compression or
 352 tensile failure at the borehole wall.

353 2.3.1 Using breakout failure to estimate maximum horizontal stress S_H 354 bounds

355 When a breakout failure occurs, Step 3 of the procedure allows the determi-
 356 nation of a lower bound for the maximum horizontal stress S_H^{min} . This step
 357 relies on the assumption that, as soon as breakout failure starts to develop, it
 358 involves just a single point of the borehole wall, rather than a finite volume of
 359 rock. Breakout failure generally starts at an azimuth $\theta = \pi/2$, i.e. where σ'_θ is
 360 locally the maximum principal stress. Equation (10) shows the dependence of
 361 the principal stresses on the the far-field (virgin) stresses in $\theta = \pi/2$.

362 Because both the principal effective stresses on the borehole wall σ'_θ and
 363 σ'_z depend on the only unknown of the problem S'_H , from the mathematical
 364 point of view the problem reduces to finding S'_H such that

$$f_C(\sigma'_z(S'_H), \sigma'_r, \sigma'_\theta(S'_H)) = f_C(S'_H) = 0, \quad (12)$$

365 where $f_C(\sigma'_{ij}) = 0$ is a suitable shear failure criterion of the material. The
 366 methodology is intended to work for any failure criterion, and analytical solu-
 367 tions can be found for several failure criteria, e.g. Mohr-Coulomb, Hoek-Brown
 368 and Mogi-Coulomb (Hashemi et al, 2014, 2015). For the sake of simplicity, in

the following just the Mohr-Coulomb (MC) criterion will be considered, being its parameters the easiest to determine.

The Mohr-Coulomb failure criterion can be expressed in terms of maximum and minimum principal effective stresses (σ'_1 and σ'_3 respectively) as:

$$\sigma'_1 = C + N_\phi \sigma'_3. \quad (13)$$

where C is the uniaxial compression strength and $N_\phi = \frac{1 + \sin \phi'}{1 - \sin \phi'}$, being ϕ' the internal friction angle. For $\theta = \pi/2$, where breakout failure are anticipated, the maximum principal stress is generally σ'_θ . For the minimum principal stress two cases are possible, i.e. $\sigma'_3 = \sigma'_r$ and $\sigma'_3 = \sigma'_z$:

– If the minimum principal stress is σ'_r , the value of S'_H corresponding to failure (for given S'_v and S'_h) is

$$S'_H{}^{MC} = \frac{1}{3} [S'_h + (1 + N_\phi)p_{\text{net}} + C] \quad \text{if } \sigma'_3 = \sigma'_r, \quad (14)$$

– If the minimum principal stress is σ'_z , it follows that

$$S'_H{}^{MC} = \frac{C + N_\phi S'_v + S'_h(1 - 2\nu N_\phi) + p_{\text{net}}}{3 - 2\nu N_\phi} \quad \text{if } \sigma'_3 = \sigma'_z. \quad (15)$$

If breakout failure occurs, $S'_H{}^{MC}$ has to be considered as a lower bound for S'_H , because in order to have failure, a value of $S'_H \geq S'_H{}^{MC}$ is needed. Viceversa, if breakout failure does not occur, then $S'_H{}^{MC}$ has to be considered an upper bound for S'_H .

Figure 5(a) shows the line expressed by equation 14 taking $C = 79.5$ MPa and $\phi' = 35^\circ$, representing a bound for the maximum horizontal stress S'_H , thus identifying two possible domains for S'_H according to the detection of breakout failures. Due to the presence of shear failures in the considered borehole section, it can be stated that S'_H has to be greater than $S'_H > 30.1$ MPa (therefore $S'_H/S'_h > 2.8$) for the specified S'_h value. Step 3 of the procedure, accounting for breakout failure, is shown in Figure 5(b): the admissible stress state has to fall between the limits deriving from Anderson faulting theory (Step 1) and from the detection of breakout.

2.3.2 Using tensile failure to estimate maximum horizontal stress S_H bounds

Also when a tensile failure occurs, Step 3 of the procedure allows the determination of a lower bound for the maximum horizontal stress $S'_H{}^{\text{min}}$, which is in general different from the one estimated for breakout failure. Also for tensile failure, the step relies on the assumption that, as soon as failure starts to develop, it involves just a single point of the borehole wall, rather than a finite volume of rock. Tensile failure in general starts at an azimuth $\theta = 0$, i.e. where σ'_θ is locally the minimum principal stress. Equation (8) shows the dependence of the principal stresses on the the far-field (virgin) stresses in $\theta = 0$.

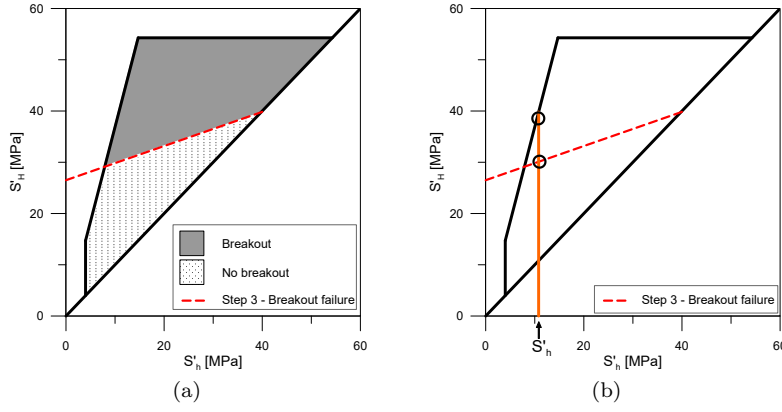

Fig. 5 Stress polygon with the dashed red line identifying the lower bounds for S'_H in order to have breakout failures according to the Mohr-Coulomb failure criterion.

402 Also in this case the principal effective stresses σ'_θ and σ'_z depends on the
 403 unknown S'_H , that can be found by imposing

$$f_T(\sigma'_z(S'_H), \sigma'_r, \sigma'_\theta(S'_H)) = f_T(S'_H) = 0, \quad (16)$$

404 where $f_T(\sigma'_{ij}) = 0$ is the chosen tensile failure criterion for the rock. Also in
 405 this case, the methodology is intended to work for any failure criterion. For the
 406 sake of simplicity, in the following part just the Galileo-Rankine (G) criterion
 407 will be considered, because it requires just one parameter to determine, i.e the
 408 tensile strength S_T .

409 The Galileo failure criterion depends only on the minimum principal stress
 410 (σ'_3), so that

$$\sigma'_3 = S_T. \quad (17)$$

411 For $\theta = 0$, where tensile failures are anticipated, the minimum principal
 412 stress is σ'_θ . The value of S'_H corresponding to failure (for given S'_h) is

$$S'^G_H = 3S'_h - S_T - p_{net}. \quad (18)$$

413 In the case that tensile failure occurs, S'^G_H has to be considered as a lower
 414 bound for S'_H , i.e. in order to have failure, a value of $S'_H \geq S'^G_H$ is needed.
 415 Viceversa, if tensile failure does not occur, then S'^G_H has to be considered an
 416 upper bound for S'_H .

417 Figure 6(a) shows the line expressed by equation 18, representing an upper
 418 bound for the maximum horizontal stress S'_H , since no tensile fractures have
 419 been registered in the section taken as example. Two possible domains for
 420 S'_H are identified according to the detection of tensile failures. A value $S_T =$
 421 5.4 MPa, as reported by Haimson & Rudnicki (2009), has been considered.
 422 Combining this information with that derived in 2.3.1, it can be stated that
 423 S'_H ranges between 30.1 MPa (Fig. 6(b)) and 37.8 MPa (corresponding to $2.8 <$
 424 $S'_H/S'_h < 3.5$) for the specified S'_h value.

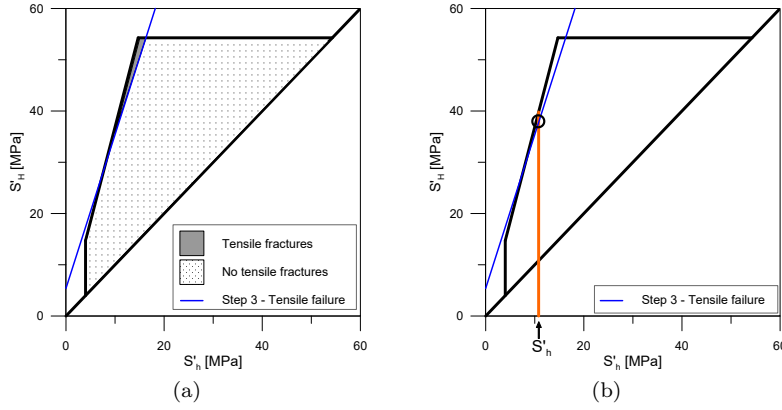

Fig. 6 Stress polygon with the blue dashed line identifying the lower bounds for S'_H in order to have tensile failures according to the Galileo strength criterion.

2.4 Step 4: accounting for breakout size

In order to further reduce the uncertainties related to the determination of S'_H , an analytical solution was provided in Della Vecchia et al (2014), by exploiting also the information about the breakout width. Step 4 thus not only need the knowledge of the parameters characterizing the rock failure criterion, but also detailed outputs from dipmeters or borehole viewers during well loggings. According to Barton et al. (1998), the angle α_b subtending the breakout zone from the center of the hole is introduced. The same information in terms of azimuth is given by θ_b ($\theta_b = \pi/2 - \alpha_b/2$), which measures the angle between the radius passing from the extremity of the breakout zone and the direction of the S_H . The proposal of Della Vecchia et al (2014) is based on the assumption that the experimental breakout size measured at the borehole wall coincides with the size of the yield zone that would originate in the same conditions if the material is elastic perfectly plastic. Accordingly, the principal effective stresses on borehole wall in $\theta = \theta_b$ can be expressed as

$$\begin{aligned}\sigma'_\theta &= S'_H + S'_h - p_{\text{net}} - 2(S'_H - S'_h) \cos 2\theta_b, \\ \sigma'_z &= S'_v + \Delta\sigma'_z, \\ \sigma'_r &= p_{\text{net}}.\end{aligned}\quad (19)$$

Also in this case, the increment $\Delta\sigma'_z$ has been estimated assuming plane strain conditions in the vertical direction, i.e. $\Delta\varepsilon_z = 0$. Assuming that in $\theta = \theta_b$ both the elastic solution ((6)), and the Mohr-Coulomb yield condition ((13)) are fulfilled, i.e. the material is prone to yield, the effective stress distribution obtained depends both on the size of the yielded zone and on the chosen yield function. As for the elastic case, in $\theta = \theta_b$ the hoop stress σ'_θ is the maximum principal stress, while the minimum one is not known a priori: also in this case

Fig. 7 Stress polygon with green dotted line identifying the value of S'_H at $\theta_b = 68^\circ$ (eq. 20).

447 two possibilities must be taken into account. If the minimum principal stress
448 is σ'_r , then

$$S'_H = \frac{C - S'_h(1 + 2 \cos 2\theta_b) + (1 + N_\phi)p_{\text{net}}}{1 - 2 \cos 2\theta_b}, \quad \sigma'_3 = \sigma'_r. \quad (20)$$

449 If the minimum principal stress is σ'_z , then:

$$S'_H = \frac{C + N_\phi S'_v + S'_h[-1 - 2 \cos 2\theta_b(1 - \nu N_\phi)] + p_{\text{net}}}{1 + 2 \cos 2\theta_b(\nu N_\phi - 1)}, \quad \sigma'_3 = \sigma'_z. \quad (21)$$

450 If the breakout size is known, a unique value of the maximum horizontal
451 stress S_H can be determined. In the example, σ'_r is taken as the minimum
452 principal stress, assuming the principal components in $\theta = \theta_b$ to have the
453 same relations as those in $\theta = \pi/2$. Equation 20, plotted in Figure 7, identifies
454 a single value of S'_H for each minimum horizontal stress S'_h : it is evident that
455 the stress states with a known breakout width are larger than the stresses
456 deriving only from breakout failure starting at $\theta = \pi/2$. For the S'_h value at
457 1000 m depth, equal to 10.8 MPa, the maximum horizontal stress S'_H takes the
458 value of 34.8 MPa (corresponding to $S'_H/S'_h = 3.2$); this value falls between
459 the limits obtained in Step 3.

460 Table 2 summarises the bounds for S'_H obtained using the proposed ap-
461 proach for the Chelungpu site at 1000 m. It is evident that the greater the
462 detail of the analysis and the larger the information available, the lower the
463 uncertainty of S'_H estimate.

464 3 Numerical validation of the procedure

465 The procedure proposed is characterized by a continuous refinement of the
466 bounds in which the real value of S'_H should lie. If information on the me-
467 chanical properties of the material and the size of the breakout failures is

Step	$S'_H{}^{min}$ [MPa]	$S'_H{}^{max}$ [MPa]	Information needed
1	10.8	39.8	Broad estimate of ϕ'
2	Data not available	Data not available	Visual information of failures
3	30.1	37.8	C, ϕ', S_T
4	34.8	34.8	$C, \phi',$ breakout width

Table 2 Bounds for S'_H for each step using the proposed procedure for Chelungpu-Hole B at 1000 m

468 available, then Step 4 allows the determination of a unique value of S'_H . As
469 a consequence, a relevant issue is provided by the reliability of Equations 20
470 and 21. In Della Vecchia et al. (2014), FEM simulations were performed to
471 check if the analytical equations proposed were consistent with the mechanical
472 behaviour of an elastic-perfectly plastic material at the borehole scale.
473 However, rocks hardly behave as perfectly plastic materials, often showing a
474 brittle stress-strain response under stress paths that lead the material to fail-
475 ure: stress redistribution due to material failure and the consequent induced
476 anisotropy cannot be accounted for when perfect plasticity is assumed. In order
477 to validate step 4 of the procedure with reference to issues related to the
478 loss of circularity of the hole, the outcome of equations 20 and 21 has been
479 compared with the results of numerical simulations performed by considering
480 the complex stress-strain behaviour of the rock, including the possibility of
481 brittle failure. In particular, borehole excavation has been simulated via the
482 Finite Element Method, assuming the stress-strain relation to be described by
483 the brittle-damage constitutive model presented in De Bellis et al (2016, 2017).
484 The model is based on an explicit kinematic description of rock behaviour by
485 means of connected patterns of parallel equi-spaced faults that exist at the
486 material level: this micro-mechanical description guarantees that the rock un-
487 dergoes compatible deformations and remains in static equilibrium down to
488 the micro-mechanical level. Each family of faults is characterized by a spacing
489 L and a unit normal \mathbf{N} to the plane of the faults. In the following, for the
490 sake simplicity, it is assumed that just one family of fault can develop in the
491 material. The deformation of the rock is due to the contribution of both the
492 deforming homogenous rock matrix, $\boldsymbol{\varepsilon}^m$, and the opening faults, $\boldsymbol{\varepsilon}^f$, according
493 to:

$$\boldsymbol{\varepsilon} = \boldsymbol{\varepsilon}^m + \boldsymbol{\varepsilon}^f = \boldsymbol{\varepsilon}^m + \frac{1}{2L}(\boldsymbol{\Delta} \otimes \mathbf{N} + \mathbf{N} \otimes \boldsymbol{\Delta}) \quad (22)$$

494 being $\boldsymbol{\Delta}$ the displacement jump of the faults (i.e. the relative displacement of
495 the two sides of the fault) and \otimes the dyadic product.

496 Remarkably, the fracture pattern predicted by the model follows from
497 a thermodynamically consistent approach. Fault inception, orientation and
498 spacing are evaluated under the assumption that an incremental work of de-
499 formation exists, capable of accounting for both the reversible and dissipative
500 behaviour of the rock. Assuming that the material state at the representative
501 elementary volume level at time t_n is known, a numerical solution strategy is

502 employed to calculate incrementally the fault pattern and the effective stress
 503 at time $t_{n+1} = t_n + \Delta t$ for a given total deformation $\boldsymbol{\varepsilon}_{n+1}$. The incremental
 504 work of deformation $E_n(\boldsymbol{\varepsilon}_n, \boldsymbol{\Delta}, q)$ over the time interval Δt is defined as the
 505 sum of elastic, cohesive and frictional contributions:

$$E_n(\boldsymbol{\varepsilon}_n, \boldsymbol{\Delta}, q) = W^m(\boldsymbol{\varepsilon}_m) + \frac{1}{L}\Phi(\boldsymbol{\Delta}, q) + \frac{\Delta t}{L}\psi^*\left(\frac{\boldsymbol{\Delta} - \boldsymbol{\Delta}_n}{\Delta t}, \boldsymbol{\varepsilon}, \boldsymbol{\Delta}\right), \quad (23)$$

506 where W^m is the elastic strain energy density per unit volume of the matrix,
 507 Φ is the cohesive energy density per unit surface of the faults, the term includ-
 508 ing ψ^* represent the frictional dissipation in Δt and q is an internal variable
 509 describing the state of the faults. The cohesive energy $\Phi(\boldsymbol{\Delta}, q)$ has been de-
 510 fined assuming a linear decreasing cohesive law, according to De Bellis et al
 511 (2016, 2017). Just two parameters are thus needed to describe the cohesive
 512 behaviour: the tensile strength S_T and the critical energy release rate G_c . The
 513 tensile strength S_T corresponds to the maximum attainable effective traction
 514 on the faults, while G_c is the area enclosed by the cohesive law. According to
 515 standard cohesive theory, a critical opening displacement $\Delta_c = 2G_c/S_T$ can
 516 be defined: for opening larger than the critical one, cohesive forces vanishes.
 517 Irreversibility is introduced in the damage law by means of the scalar internal
 518 variable q , corresponding to the maximum opening attained by the fault. Upon
 519 unloading, the cohesive behaviour of the fault is supposed to be linear elastic
 520 up the origin. Frictional dissipation processes are finally accounted for via the
 521 introduction of a dual dissipation potential per unit fault area ψ^* . According
 522 to the Coulomb friction model, it reads:

$$\psi^* = \mu \max\{0, (\boldsymbol{\sigma}'\mathbf{N}) \cdot \mathbf{N}\} |\dot{\boldsymbol{\Delta}}|, \quad (24)$$

523 where $\mu = \tan(\phi')$ is the friction coefficient, $(\boldsymbol{\sigma}'\mathbf{N}) \cdot \mathbf{N}$ is normal component of
 524 the traction vector on fault plane and $|\dot{\boldsymbol{\Delta}}|$ the norm of the displacement jump
 525 rate. The model thus accounts for two types of material failure: in tension
 526 (according to the Galileo-Rankine criterion) and in shear (according to the
 527 Mohr-Coulomb criterion). The solution of the incremental problem is obtained
 528 by the minimization of the incremental work of deformation, subjected to the
 529 constrains provided by the impenetrability of the closed faults (i.e. $\Delta_N \geq 0$)
 530 and the irreversibility of damage (i.e. $\Delta q \geq 0$). The minimization process
 531 finally provides the solution in terms of fault spacing and orientation: further
 532 details on the model equations and the numerical solution strategy can be
 533 found in De Bellis et al. (2016). From the practical point of view, just 6 material
 534 parameters are needed:

- 535 – The Young modulus E and the Poisson ratio ν , describing the elastic be-
 536 haviour of the homogeneous matrix, i.e. the behaviour of the material in
 537 the pre-failure stage;
- 538 – The friction angle ϕ' and the tensile strength S_T , describing the failure
 539 properties of the rock according to the Mohr-Coulomb failure criterion;
- 540 – The critical energy release rate G_c ;

– A scale parameter L_0/Δ_c .

The model proved able to reproduce the triaxial response of different type of rock, both in the pre- and post-peak stages, as shown in De Bellis et al (2016, 2017) and Della Vecchia et al (2016).

In the context of the determination of the in-situ stress state, numerical simulations with the advanced model have been performed with the aim of providing a validation of the simplified analytical model presented in Step 4. The excavation of a vertical borehole within a horizontally bedded rock formation has been simulated via the Finite Element method, starting from a computational domain that includes a 1 m thick, 40 m wide horizontal square layer perpendicular to the borehole axis. The finite element mesh consists of 8,010 nodes and 36,086 tetrahedral elements. The simulation of the excavation is achieved numerically by removing (or deactivating) the elements that fall at the interior of a cylindrical cavity, whose radius takes the value $a = 1$ m. The model is able to predict the evolution of stress concentration around the borehole, together with the development of shear-induced failures, in correspondence to the maximum deviatoric stress, and tensile fractures. In the context of this paper, Figure 8 shows the elements (red spheres) characterized by the presence of shear induced fractures for two different stress anisotropy ratios S'_H/S'_h , equal to 4.0 and 4.5, for the Chelungpu example. The material parameters used are listed in Table 3. As expected, the higher the anisotropy ratio in the horizontal plane, the larger the amplitude of the failed zone. By a visual evaluation of the amplitude of the failed zone, the relationship between θ_b and S'_H can be estimated, according to the advanced constitutive model proposed. It is worth noting that, due to the stress redistribution induced by the failed elements, the numerical model has the built-in capability in accounting for the variation in borehole shape (i.e. ovalization) induce by breakout failures.

E	ν	μ	S_T	G_c	L_0/Δ_c

$13.7 \cdot 10^9$	0.35	0.7	29,800	0.005	1

Table 3 Material parameters introduced in the numerical simulations for Chelungpu-B

Simulations have been carried out by varying the value of S'_H at a constant S'_h , measuring the resulting breakout amplitude, if any. Results of the simulation in terms of breakout amplitude for different S'_H values are indicated with black points in Figure 9 for the Chelungpu site, while the continuous line represents the outcome of the simplified analytical procedure (Equation 20). Despite the strong assumptions at the basis of the analytical procedure, the accordance between the two prediction is remarkably good, at least for breakout amplitudes not exceeding 90° . It is worth noting that, for parameter

Fig. 8 Evolution of the zones subjected to shear failures at varying far-field stress anisotropies

578 calibration, real data coming from the relevant literature have been used: how-
 579 ever, available information is generally limited to friction angle and uniaxial
 580 compressive strength, which can be related to the tensile strength according
 581 to the Mohr-Coulomb failure criterion. As for the elastic parameters, E and
 582 ν , typical values for any kind of rock can be easily found in the literature.
 583 The remaining parameters are more complex to determine: in order to avoid
 584 to consider them as variables that can be used a posteriori to fit the analytical
 585 equation, sensitivity analyses have been performed in order to highlight their
 586 role for the problem at hand: as shown in Scelsi (2017), the evolution of θ_b
 587 with the far-field stress is not significantly influenced by G_c and L_0/Δ_c . Values
 588 of these parameters have just been taken from the literature (e.g. De Bellis et
 589 al. (2016, 2017), Della Vecchia et al. (2016)), without any significant influence
 590 on the numerical validation.

591 **4 Experimental and numerical validation of case histories from the** 592 **literature**

593 In this section, a further numerical and experimental validation of the proposed
 594 simplified procedure is presented, basing on two case histories presented in the
 595 literature.

596 4.1 Basel 1 enhanced geothermal system

597 In 2006 a 5-km-deep borehole has been drilled under the Swiss city of Basel
 598 with the aim of developing an "Enhanced Geothermal System" EGS for a
 599 geothermal power plant. The orientation of the maximum horizontal princi-
 600 pal stress has been determined from the observations of failures derived from
 601 ultrasonic televiewer images in 2two vertical boreholes. In the granite, tensile

Fig. 9 Chelungpu, Hole-B (1000 m depth); comparison between the simplified analytical model and numerical results.

602 fractures are present in intermittent way, while breakout are present almost
 603 continually, except for the first 100 m where they are sparse. The mean orientation
 604 of S_H from tensile and breakout failures is $N143^\circ E \pm 14^\circ$. Information
 605 about material properties and in situ stress state can be found in different
 606 studies presented in the literature (e.g. Valley and Evans, 2015, Haring et
 607 al., 2008). The profile of the breakout width is also available along the whole
 608 depth of borehole Basel-1. In the following, the stress state at 4,632 m will be
 609 analysed, where the measurement of S_h is available ($S'_h = 74.4$ MPa). Rock
 610 properties and the known effective stress state, taken from Valley & Evans
 611 (2015), are listed in Table 4.

Property	Value
S'_v [MPa]	69.6
S'_h [MPa]	28.9
ϕ' [°]	44
C [MPa]	167
θ_b [°]	≈ 60

Table 4 Data used in the study of Basel-1 at 4.632 km depth (Valley & Evans, 2015).

612 The analytical procedure have been applied according to the following
 613 steps:

- 614 – Step 1: limits on the stress state from the tectonic regime
- 615 The polygon of the admissible stress states in the plane $S'_H - S'_h$ is rep-
 616 resented considering all faulting regimes. Figure 10(a) allows to identify
 617 graphically the first limits on S'_H : this value has to be between $S'_h = 28.96$
 618 MPa by definition and 160.73 MPa ($S'_H/S'_h = 5.6$), i.e. limit deriving from

619 strike-slip regime. From the polygon it can be easily deduced that the tec-
 620 tonic regime can be either normal or strike-slip.

621 – Step 2: limits on the stress state from failure orientation

622 Principal stresses are computed using the relation defined by Equations (8)
 623 for $\theta = 0$ and from Eq. (10) at $\theta = \pi/2$. The components corresponding to
 624 the minimum, intermediate and maximum principal stress can be seen in
 625 Figure 11 for admissible tensional anisotropies S'_H/S'_h , i.e. $1 \leq S'_H/S'_h \leq$
 626 5.6. It can be observed that:

- 627 - $\sigma'_r < \sigma'_z < \sigma'_\theta$ in $\theta = \pi/2$ for all the values of S'_H/S'_h , apart from
 628 anisotropies $S'_H/S'_h < 1.2$ for which the vertical stress is greater than
 629 the hoop stress. The presence of visual observations of failure directions
 630 could thus allow a further refinement of S'_H bounds;
- 631 - in $\theta = 0$, since no tensile fractures are registered at the considered
 632 depth, the relation between stress components cannot be used to further
 633 limit the anisotropy S'_H/S'_h .

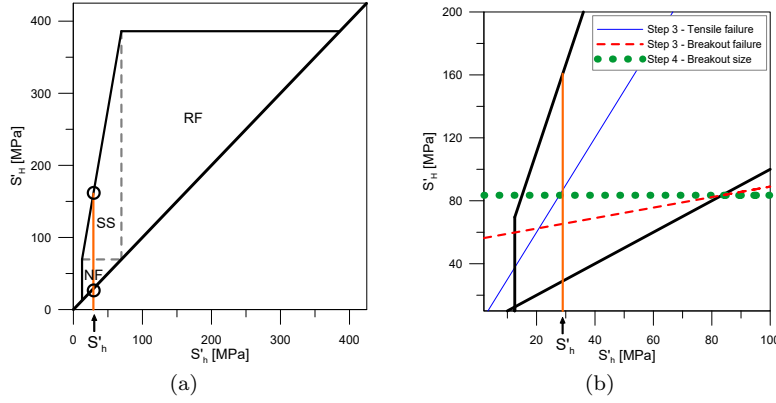

Fig. 10 (a) Admissible stress polygon. (b) Lines dividing stresses associated to different type of failures. The blue thin solid line represents tensile fractures, red dashed line the shear failures in $\theta = \pi/2$. The green dotted line indicates the value of S'_H at $\theta_b = 60^\circ$, according to Eq. 20.

634 – Step 3: limits on the stress state from rock failure criterion

635 Breakout failures have been registered in the section taken into account,
 636 while tensile fractures are absent. The Mohr-Coulomb failure criterion with
 637 tension cut-off is assumed to hold ($\phi' = 44^\circ$, $C = 167$ MPa, $S_T = 0$ MPa).
 638 The lines delimiting the presence or absence of fractures are drawn in
 639 the stress polygon (Figure 10(b)); the stress state has to lie below the
 640 line representing tensile fractures, and above the line delimiting breakout
 641 failures.

642 Considering the absence of tensile fractures, it can be stated that S'_H has to
 643 be smaller than 86.88 MPa; for shear failures in $\theta = \pi/2$ $S'_H > 65.32$ MPa.
 644 Therefore $2.3 < S'_H/S'_h < 3.0$.

Fig. 11 Visualization of the relation between normalized principal components as a function of S'_H/S'_h , limited between admissible values derived by tectonic limits; $\nu = 0.22$, $p_{net} = 0$.

645 – Step 4: accounting for breakout size
 646 Being the breakout angle approximately known ($\theta_b \approx 60^\circ$, corresponding
 647 to an amplitude $\alpha_b \approx 60^\circ$), a single value of the maximum horizontal *far-*
 648 *field* stress state can be determined. According to eq. 20, $S'_H \simeq 83.50$ MPa
 649 (corresponding to $S'_H/S'_h = 2.9$) and thus $S_H = 128.94$ MPa. This value
 650 falls between the limits obtained in Step 3.
 651 The tectonic regime is strike-slip, as it is clearly shown in Figure 10(b). The
 652 maximum horizontal stress ($S_H = 128.94$ MPa) differs of about 10 MPa
 653 from the value estimated by Valley & Evans (2015) with their empirical
 654 interpolation $S_H = 1.04z + 115$ MPa/km, which gives a result equal to
 655 119.82 MPa.

Step	$S'_H{}^{min}$ [MPa]	$S'_H{}^{max}$ [MPa]	Information needed
1	28.96	160.73	Broad estimate of ϕ'
2	Data not available	Data not available	Visual information of failures
3	65.32	86.88	C , ϕ' , S_T
4	83.50	83.50	C , ϕ' , breakout width

Table 5 Bounds for S'_H for each step using the proposed procedure for Basel-1 at 4632 m

656 Table 5 summarises the bounds for S'_H for each step of the proposed ap-
 657 proach for the Basel-1 borehole at 4632 m.
 658 The maximum horizontal stress obtained via the analytical procedure has been
 659 also validated by means of the numerical model described in Section 3. Mate-
 660 rial parameters are listed in Table 6, while the principal stress components S'_v
 661 and S'_h and the breakout width have been introduced in Table 4.
 662

E	ν	μ	S_T	G_c	L_0/Δ_c

$65 \cdot 10^6$	0.22	0.97	36700	0.005	1

Table 6 Material parameters introduced in the numerical simulations for Basel-1.

663 Different simulations have been carried out by varying S'_H between 29 MPa
664 (corresponding to $S'_H/S'_h = 1$) and 159 MPa (corresponding to $S'_H/S'_h = 5.5$),
665 measuring for each simulation the predicted breakout width. The obtained results
666 are plotted in Figure 12, together with the S'_H trend obtained at Step 4
667 via eq. 20. The numerical and analytical predictions are substantially essentially
668 coincident up to an anisotropy ratio $S'_H/S'_h = 4$ equal to 4 and to a
669 width $\alpha_b \approx 90^\circ$, the maximum relative error being lower than 15%.

Fig. 12 Basel-1; evaluation of S'_H through the Mohr-Coulomb failure criterion imposition in $\theta = \theta_b$ and results of simulations with brittle damage model.

670 4.2 Cajon Pass Scientific Research Borehole

671 At the Cajon Pass site (California) a scientific research borehole was conducted
672 between 1986 and 1987, reaching a depth of 3500 m. In the literature several
673 publications (Zoback & Healy (1992), Vernik & Nur (1992), Vernik & Zoback
674 (1992)) provide information regarding the material characteristics and the in
675 situ stress state; some minimum horizontal principal stress S_h measurements
676 and the amplitude of the breakout for depths between 907 m and 3486 m have
677 been obtained respectively via hydraulic fracturing and borehole televiewer.
678 In this case a depth of 2048 m has been considered, where an estimate of the
679 maximum horizontal stress S_H is available in Zoback & Healy (1992). Rock
680 properties and the known stress state are listed in Table 7.

Property	Value
S'_v [MPa]	32.15
S'_h [MPa]	19.81
ϕ' [°]	39
C [MPa]	132
T_0 [MPa]	13
θ_b [°]	≈ 73

Table 7 Data used in the study of Cajon Pass at 2.048 km depth.

681 The analytical procedure was applied according to the following steps:

- 682 – Step 1: limits on the stress state from the tectonic regime
683 The polygon of the admissible stress states in the plane $S'_H - S'_h$ is rep-
684 resented considering all faulting regimes. Figure 13(a) allows the graphi-
685 cal identification of the first limits on S'_H : this value has to be between
686 $S'_h = 19.81$ MPa by definition and 85.75 MPa ($S'_H/S'_h = 4.3$), i.e. limit
687 deriving from strike-slip regime. From the polygon it can be deduced that
688 the tectonic regime can be either normal or strike-slip.
- 689 – Step 2: limits on the stress state from failure orientation
690 Principal stresses are computed using the relation defined by Equations (8)
691 for $\theta = 0$ and from Eq. (10) at $\theta = \pi/2$. The components corresponding to
692 the minimum, intermediate and maximum principal stress can be seen in
693 Figure 14 for admissible tensional anisotropies S'_H/S'_h , i.e. $1 \leq S'_H/S'_h \leq$
694 4.3 . It can be observed that:
695 - $\sigma'_r < \sigma'_z < \sigma'_\theta$ in $\theta = \pi/2$ for all the values of S'_H/S'_h . The presence
696 of visual observations of failure directions could thus allow a further
697 refinement of S'_H bounds.
698 - in $\theta = 0$, since no tensile fractures are registered at the considered
699 depth, the relation between stress components cannot be used to further
700 limit the anisotropy S'_H/S'_h .
- 701 – Step 3: limits on the stress state from rock failure criterion
702 Breakout failures have been registered in the section taken into account,
703 while tensile fractures are absent. The Mohr-Coulomb failure criterion with
704 tension cut-off is assumed to hold ($\phi' = 39^\circ$, $C = 132$ MPa, $S_T = 0$ MPa).
705 The lines delimiting the presence or absence of fractures are inserted in
706 the stress polygon (Figure 13(b)); the stress state has to lie below the
707 line representing tensile fractures, and above the line delimiting breakout
708 failures.
709 Considering the absence of tensile fractures, it can be stated that S'_H has to
710 be smaller than 72.43 MPa; for shear failures in $\theta = \pi/2$ $S'_H > 50.60$ MPa.
711 Therefore $2.6 < S'_H/S'_h < 3.7$.
- 712 – Step 4: accounting for breakout size

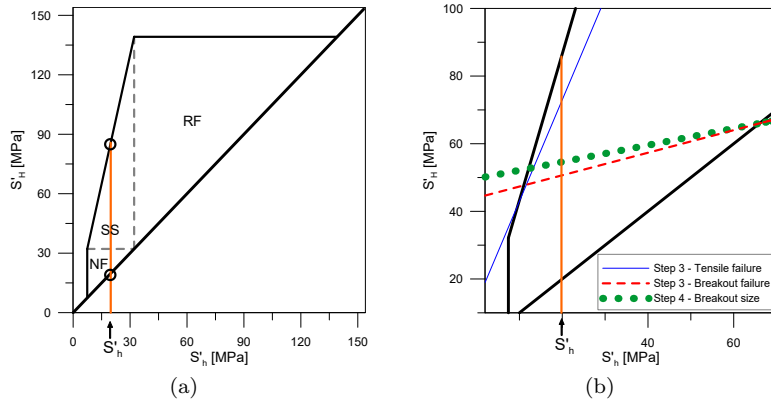

Fig. 13 (a) Admissible stress polygon. (b) Lines dividing stresses associated to different type of failures. The blue thin solid line represents tensile fractures, red dashed line the shear failures in $\theta = \pi/2$. The green dotted line indicates the value of S'_H at $\theta_b = 73^\circ$, according to Eq. 20.

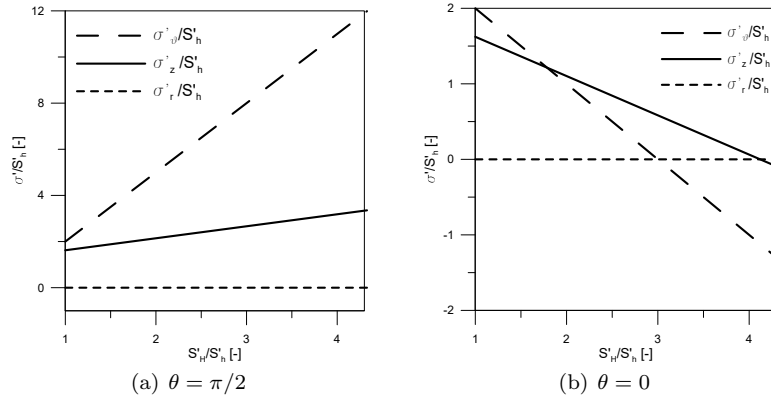

Fig. 14 Visualization of the relation between normalized principal components as a function of S'_H/S'_h , limited between admissible values derived by tectonic limits; $\nu = 0.26$, $p_{net} = 0$.

713 Being the breakout angle approximately known ($\theta_b \approx 73^\circ$, corresponding
 714 to an amplitude $\alpha_b \approx 34^\circ$), a single value of the maximum horizontal *far-*
 715 *field* stress state can be determined. According to eq. 20, $S'_H \simeq 54.56$ MPa
 716 (corresponding to $S'_H/S'_h = 2.8$) and thus $S_H = 74.7$ MPa. This value falls
 717 between the limits obtained in Step 3.

718 The tectonic regime is strike-slip, as it is clearly shown in Figure 13(b). The
 719 maximum horizontal stress ($S_H = 74.7$ MPa) differs of only 4.6 MPa from
 720 the value estimated from hydraulic fracturing data, equal to 79.3 MPa,
 721 reported in Zoback & Healy (1992).

722 Table 5 summarises the bounds for S'_H for each step of the proposed ap-
 723 proach for the Cajon Pass Borehole at 2048 m.

Step	$S'_H{}^{min}$ [MPa]	$S'_H{}^{max}$ [MPa]	Information needed
1	19.81	85.75	Broad estimate of ϕ'
2	Data not available	Data not available	Visual information of failures
3	50.60	72.43	C, ϕ', S_T
4	54.56	54.56	$C, \phi',$ breakout width

Table 8 Bounds for S'_H for each step using the proposed procedure for Cajon Pass Borehole at 2048 m

724 Material parameters are listed in Table 9, while the principal stress com-
725 ponents S'_v and S'_h and the breakout width have been introduced in Table 7.
726

E	ν	μ	S_T	G_c	L_0/Δ_c
[kPa]	[-]	[-]	[kPa]	[kN/m]	[-]
$90 \cdot 10^6$	0.26	0.8	39700	0.005	1

Table 9 Material parameters introduced in the numerical simulations for Cajon Pass Borehole at 2048 m depth.

727 Different simulations have been carried out by varying S'_H between 20 MPa
728 (corresponding to $S'_H/S'_h = 1$) and 109 MPa (corresponding to $S'_H/S'_h = 5.5$),
729 measuring for each simulation the predicted breakout width. The obtained re-
730 sults are plotted in Figure 15, where a comparison with the S'_H trend, obtained
731 via eq. 20, is shown.
732 Also in this case the numerical and analytical predictions are essentially co-
733 incident up to an anisotropy equal to 4 and to a width $\alpha_b \approx 90^\circ$, being the
734 maximum relative error lower than 3.5%.

735 5 Conclusion

736 Determination of in situ stress state is a preliminary activity necessary for any
737 application in the field of civil and reservoir engineering, as well as for geolog-
738 ical and geophysical applications. Among the different techniques proposed in
739 the literature to estimate in situ stress state in rock masses, borehole meth-
740 ods are certainly the most diffused. For these methods to be reliable, a sound
741 geomechanical model is needed, in order to address all the relevant characteris-
742 tics of rock mechanical response that influence the behaviour of the material
743 at the borehole scale. Unfortunately, refined models always requires a signifi-
744 cant number of parameters, which can hardly be known without a dedicated,
745 time consuming and expensive laboratory activity. In order to overcome such
746 limitations, this paper presented an analytical procedure to estimate in situ
747 stress state trying to combine a rigorous approach to the applicability of the

Fig. 15 Cajon Pass; evaluation of S'_H through the Mohr-Coulomb failure criterion imposition in $\theta = \theta_b$ and results of simulations with brittle damage model.

748 procedure in engineering practice. In particular, the procedure is intended to
 749 be applied following some clear steps, each one requiring some input paramet-
 750 ers and proving some bounds to the maximum horizontal stress, i.e. the most
 751 difficult stress component to determine. Step 1 stems from the application of
 752 the well-known Anderson faulting theory together with the Mohr-Coulomb
 753 failure criterion to provide some initial bounds to the stress state, exploit-
 754 ing information known at the reservoir scale, as already proposed in the literature.
 755 A refinement on in situ stress bounds is provided by Step 2, that just relies
 756 on visual information on failures at the borehole scale. In Authors' knowledge,
 757 this approach has never been proposed in the literature, and provides a sig-
 758 nificant reduction in stress bounds without the need of knowing rock failure
 759 parameters. Further refinement is provided by Step 3, which combine the in-
 760 formation of the possible presence of failures at the borehole scale with the
 761 information on the failure criterion of the rock. Finally, if also breakout failure
 762 amplitude is available, a unique value of the maximum horizontal stress can
 763 be estimated via Step 4. Remarkably, just three parameters to describe rock
 764 strength have been introduced: the friction angle, the uniaxial strength and
 765 the tensile resistance. As a further advantage of the procedure, no program-
 766 ming or use of dedicated software is needed: once the input data are known, just
 767 explicit algebraic equations are proposed.

768 The procedure has been then validated by means of both numerical analyses
 769 and some field data coming from the literature. Numerical analyses have
 770 been performed to check if the simplifications introduced in Step 4, involv-
 771 ing both the mechanical behaviour of the rock and the geometry of the failed
 772 borehole, are relevant. To this aim, numerical Finite Element analyses at the
 773 borehole scale have been performed, assuming a brittle damage behaviour of
 774 the rock. The constitutive model adopted in the simulations is able to well
 775 reproduce the behavior of different rocks under different stress levels, and
 776 in particular the expected post-peak brittle response. The model, based on

777 micro-mechanical considerations and on strong thermodynamical bases, pro-
 778 vides predictions that can be considered consistent with softening/hardening
 779 elasto-plasticity, yet in a framework more consistent with the failure processes
 780 in rocks. The outcomes of the numerical simulations have been compared with
 781 the Equations proposed in Step 4 in terms of borehole breakout dependence
 782 on stress anisotropy: the agreement between the two approaches is very good,
 783 at least for breakout amplitude lower than 90° , confirming that the assump-
 784 tion on which Step 4 relies are acceptable for the problem at hand. Finally,
 785 reasonable agreement has been obtained also between the predictions of the
 786 procedure with some data already present in the literature, where in situ stress
 787 estimate was performed by means of the combination of different techniques.
