Abstract

Despite a long-term trend towards reduction, the gender gap in employment keeps standing in Southern Europe. Numerous potential causes have been individuated, such as the household configuration, the human capital of the women, or the institutions that regulate the labour market. Less is know about the role of the locality. This paper explores what covariates influence women's access to labour markets, and whether it is unevenly distributed across different countries and regions in the Southern Europe. The analysis is based on the dataset round 9 (2018) from the European Social Survey. We focus on the following countries available in the dataset: Cyprus, Italy, Spain and Portugal. Italy and Spain are further differentiated into vulnerable and affluent regions according to the regional GDP in 2018. We apply a regression model for the binary response that is the indicator of having been doing paid work for the last seven days of each individual in the sample. We adopt the Bayesian approach, in order to derive conclusions via a whole probability distribution, i.e., the posterior of all parameters, given data. The statistical goal is the selection of the most important covariates for access to labour market, focusing on gender differences. Our analysis finds out that the individual characteristics are mediated by household composition. Even though a higher education increases women's

employment, the presence of children and having an employed partner reduce such involvement. Moreover, a larger gender gap is detected in vulnerable regions rather than in affluent ones, especially in Italy.

Keywords: Bayesian approach, covariate selection, gender gap, labour market, regression models.

1 Introduction

Women's labour market access is an important societal, political and economical issue. In fact, despite a consistent steady growth that took place in the European countries since the beginning of the '80s, contemporary labour markets are still characterised by gender inequalities in access to employment. However, women's disadvantage do not distribute evenly between countries, and, furthermore, even within countries there are strong territorial disparities that shape women's capacity to access employment. The Southern Europe is the region that shows the persistence of the strongest inequalities for accessing employment between genders. If we look at the EIGE inequality index in the domain of access to work¹, we see that three out of four countries that traditionally are included in the Southern European model are well below the European average (81,3) and countries like France (83,7) or Germany (84,2): Spain (80,2), Greece (72,7) and Italy (69,1). The only exception to this rule is Portugal, with 88,2.

Women's difficult access in the labour market depends on cultural reasons [1], but also on the specific configuration that welfare state assumed in the Southern European countries [2]. In particular, the Southern European model of social protection [3] has always promoted a male breadwinner model, in which women's labour has been considered a secondary (and expendable) contribution to the main income that was procured by men to their household [4]. In this model, women are traditionally assigned to care and domestic role, while the state do not intervene to support the unpaid work provided by women [5]. Despite the unfavourable societal and political context that explains the lag in gender inequalities in Southern Europe, the individual characteristics of women take a role as well. In fact, level of education, presence of children and family configuration affects the capacity of women of accessing labour market [6]; the recent crises [7, 8] increased the inequality within women, as women most likely lose their jobs when they were the low educated, with a migrant background or in presence of young children. In this paper, we aim at studying what are the individual characteristics that might affect women's labour market participation and to what extent being resident in one region or another another can shape the relationship between gender and access to employment.

We consider data from the European Social Survey and we focus on dataset round 9 (2018). The data come from interviews to respondents from Italy,

¹https://eige.europa.eu/gender-equality-index/2021/compare-countries/work/1/bar

Spain, Portugal and Cyprus, which are the only countries from South Europe in dataset round 9. We are interested in the probability that a respondent has been doing paid work for the last seven days (from the interview). The dataset collects further information, that we treat as covariates in a logistic regression model: gender, age, number of children, being immigrant, education level, if the respondent has a partner, and if the partner has a job. We have also included a dummy variables for each of the countries the respondents are from, having splitted Spain and Italy into two parts.

We consider the Bayesian approach to the model, since it automatically provided uncertainty quantification of the regression parameters. Posterior inference is computed though simulation methods easily obtained using probabilistic programming languages. The findings of the Bayesian logit model confirm that individual characteristics of women (e.g. education, migrant background) are mediated by household characteristics (e.g. having a partner, presence of children) in their influence of women's access to labour market. Moreover, women's access to labour market is unevenly distributed and depends on the different economic capacity of regions.

The remainder of this paper is structured as follows. Section 2 describes all the difficulties for women to access the labour market in Southern Europe, while Section 3 introduces the dataset we have analyzed and a preliminary exploratory analysis. In Section 4 we present the Bayesian logit model we apply to the data. Section 5 presents the posterior inference and the findings we get from this specific dataset. Section 6 concludes the paper with a discussion.

2 Women's Labour Market Access in Southern Europe

2.1 Women's dilemma between paid and unpaid work

The role of family in preventing women from labour market access has always been debated in feminist perspective on gendered labour market. From one side, authors (as Williams [9]) argued that it is the role of the gendered unbalance in unpaid work (that is, care and domestic work) that prevented women to be active in labour market as men do. On the other side, authors like Walby [10] sustained that the disadvantaged conditions of women's in the labour market exacerbated women's predominance in reproduction. The expression Work-Family role system is used to indicate the interconnections of family, care policies and labour market regulation [11]; it indicates the strong degree of interdependence between the possibility that women have of taking up employment and the organisation of the family. If it is difficult to decide what comes first (gender roles or labour market), it is nevertheless quite important to explore the relationships between the two.

This debate started already in the '70s, with the neoclassical theory of Gary Becker [12] who sustained that the most rational choice for an household is to have one member specialised in paid activities and one member that

3

specialised in the unpaid activities necessary for reproduction. In his economic perspective, the most efficient equilibrium is given when the first were men and the second were women: men are usually paid more on labour markets, while women are *naturally* inclined to care, so they are more efficient in doing unpaid work. The fact that this household organization exacerbates gender inequality between men and women is not at all considered an issue in this theoretical perspective. A second important intervention was proposed by Hakim [13] with her theory of preferences. She focuses on analysing differences among women and puts forward two main ideal-types of women confronting the *Work-Family role system*: the first group called *the grateful slaves* are women who prefer family over work commitment and the second one *the self-made women* have on the contrary a preference for work. She measures in a later work [14] that the two groups weight 20% each, while about 60% of women have mixed preferences - that explained the variability in women's labour market access in real labour markets.

Hakim's intervention gave ground to fierce reactions, especially among feminist scholars. She was accused of blaming the victim [15], instead of pointing at the real constraints that women faced when trying to access the labour market: a gendered distribution of unpaid work, culturally grounded in the European societies [1] and a systems of institutions that locked women into their role of mothers [16].

In the cultural perspective, gender norms prescribe the "correct" number of working hours for women: institutions are shaped over the gendered norms and reproduce inequalities that have their roots in the way in which societies assign roles to genders [1]. In the institutional perspective, the reconciliation of work commitments outside of the home with family duties is strongly influenced by services available that effectively allow women to work. Women are thus structurally compelled to work less than men because labour markets are incompatible with unpaid work and welfare state do not always offer the sufficient support for externalizing care outside families [15, 17].

Since family workloads are particularly significant when there are small children or elderly family members to look after, comparative studies reveal the importance of the availability of public childcare services and of parental leave, if female employment is to be facilitated [5, 18, 19]. Many studies of the development of the welfare state from a gender perspective have shown, however, that the way in which childcare and elderly care becomes the responsibility of the State, varies enormously from one country to another [20]. In this regard, Naldini and Saraceno [21] utilise the concepts of *defamilisation* to describe the various degrees to which different welfare regimes pursue the redefinition of gender relations. To be more precise, the term *defamilisation* refers to the capillary presence of those services that release women in particular from the task of looking after dependant family members (e.g. young children), and thus increase their chances of pursuing a career which would otherwise be seriously threatened by the problem of reconciling work and family commitments. The term *supported familialism*, on the other hand, means the existence of periods of leave, parental allowances and monetary transfers, which permit a person to interrupt working in order to look after a family member, thanks to the financial aid provided. In the absence of either types of policy, then *familialism by default* is the term used [5], which necessarily implies the family shouldering all responsibility for providing such care.

Geographically speaking, countries that defamilialise are Scandinavian and Northern countries: in Scandinavian, the externalisation occurs thanks to the involvement of the State as provider of services; in countries such as UK or Ireland, it occurs through private service paid on the market. The supported familialism characterised Continental Europe, with countries like France, Germany or Austria that extensively support families with monetary transfers and services in their reproductive role. Lastly, Southern European countries are characterised by the lack of support to families, with women entrapped in the *double shift* of being workers and mothers [22].

2.2 The specificity of the Southern Europe

The Southern European Welfare model has been proposed by Maurizio Ferrera in 1996. The original formulation of the welfare regime theory made by Esping Andersen [23] included Southern Europe in the regime of Conservative countries. However, scholars like Ferrera were unsatisfied with this classification, as these countries distinguished for several characteristics from the Conservative group. In fact, even if it is true that labour market policies are organised on a Bismarckian model of assurance like France or Germany [24], Southern Europe has a limited intervention in social care and family policies that completely distinguish these countries from Continental ones [22, 25]. Although following the social investment turn in European policies an increased attention to the childcare service has been taking place also in the South, still the provisions of childcare lags behind Continental and Northern Europe [26]. It thus configures a situation in which there are a scarcity of publicly provided alternatives to family care, while the monetary transfers to families with needy members are low.

The limited intervention of the state, defined by Chiara Saraceno the unsupported familialism [27], implies that the unpaid work is considered by the Work-Family role system as mainly a responsibility of families while the State intervene only when households are not able to comply their role. As a consequence, countries in Southern Europe have a limited provisions of care service, which jeopardise women's involvement in labour markets as they are usually the main provider of care work within families. In addition, the model of family that it is assumed by family policy is a model in which men are the primary earner, while women income is a complement to men's one [4]. The male breadwinner model is persistent, and it is quite far from the dual earner-dual carer model that lies behind the process of defamilisation [21].

As such, empirical evidence has demonstrated the importance of household composition in determining the likelihood of women's involvement in labour market [7]. Together with education and the presence of children, having a

partner become fundamental in order to predict women's access to labour market [28]. As childcare services are provided mostly at local level, we assist in Southern Europe to an uneven distribution of services not only between countries but also within countries. The strong territorial disparities in the provisions of services depends on the economic capacity of the regions and, even if the direction of causality is unclear, is strongly associated with women's access to labour market [29]. Especially in the bigger countries like Spain or Italy, geography shapes women's labour market access as much as individual characteristics, such as education.

In conclusion, based on the theory that we have reviewed regarding the *Work-Family role system* in Southern Europe we might elaborate the following hypothesis in relation to the determinants of women's access to labour market:

- I We expect that individual characteristics of women (e.g. education, migrant background) are mediated by household characteristics (e.g. having a partner, presence of children) in their influence of women's access to labour market. Having a working partner and the presence of children reduce the likelihood that women work.
- II Women's access to labour market is unevenly distributed and depends on the different economic capacity of regions. We assume that richer regions not only offers more employment opportunities, but they are also more capable to offer care services for working women.

3 Data description and exploratory analysis

In this section we give a description of the data we focus on to for later inference (in Section 5). In particular, Section 3.1 describes the dataset and variables used for analysis and Section 3.2 presents the exploratory data analysis which summarizes the main data characteristics by using statistical visualization tools.

3.1 Description of the dataset

The European Social Survey (ESS) is an academically driven crossnational survey that collects information in more than thirty European nations since its establishment in 2001. In this paper we focus on dataset round 9 (2018) provided by the ESS; data can be downloaded at https://www.europeansocialsurvey.org/data/round-index.html.

The dataset, as for similar round, is the result of hour-long face-to-face interview for respondents aged 15 and over, resident within private households from twenty-seven European countries. The interview includes questions on various core topics: social trust, political interest and participation, sociopolitical orientation, social exclusion, etc. This results in a large number (557) of covariates for each respondent. Note that we will not use the whole dataset for analysis, since there are irrelevant covariates with respect to the main research question. We have organized the dataset as follows.

- (a) We consider only those respondents aged between 25 and 55 years old, since most people aged under 25 years old might be students and those aged over 55 might have retired yet or will be in a few years.
- (b) We restrict the analysis to data from countries of South Europe, where the gender gap on economic participation and opportunity is larger than in North Europe [30]. However not all South European countries participate the survey. We have data from Cyprus, Italy, Portugal and Spain. This will be the definition of South Europe in the rest of the paper. However, we have excluded respondents from two Spanish regions, the enclaves of Ciudad Autónoma de Ceuta and Ciudad Autónoma de Melilla, as their economical situation is very different from other Spanish regions.
 - We include the following variables in the dataset we focus in this paper:
 - age: respondent's age in years.
 - *child*: number of children (son, daughter, step or adopted or foster child) under 14 years old of the respondent and living in the same household. We consider only children below 14 years old in this variable since it is well-known that they need more attention from parents, as they develop competencies, interests, sense of confidence and of autonomy during these vears [31].
 - *region*: region of the country of the respondent.
 - *country*: country of residence of the respondent. Instead of considering only the four countries in the dataset (Cyprus, Italy, Portugal and Spain), we have considered two groups for both Italy and Spain. Specifically, we have grouped Italian and Spanish regions into two levels, that is affluent and vulnerable, according to regional GDP per capita in 2018, since there exists huge difference in terms of economic development between regions of these two countries [32]. More specifically, we have calculated the median regional GDP per capita for Italy and Spain separately in 2018: the value equals 23200 \in for Spain and 31700 \in for Italy. The regions whose GDP per capita is lower than the median are considered vulnerable regions, otherwise affluent ones. See Appendix A for the associated classification. We use the covariate *country* in the rest of the paper, but the levels it assume are affluent Italy, vulnerable Italy, affluent Spain, vulnerable Spain, Cyprus and Portugal.
 - *citizen*: respondent's citizenship status which can be autochthonous or immigrant. A respondent is autochthonous if he/she is born in country and has the citizenship of country, otherwise he/she is immigrant. The variable *citizen* equals 1 if the respondent is autochthonous and 0 otherwise.
 - *education*: respondent's highest education level with three ordered levels. Education = 1 means up to lower secondary education or less; Education = 2 corresponds to upper secondary education or post-secondary or shortcycle tertiary; Education = 3 indicates other higher education levels.
 - *qender*: respondent's gender.

7

- *partner*: status of respondent's partner, a categorical covariate with 4 levels. A respondent may live without a partner (*no partner*) or with an unemployed partner (*inactive partner*) or with a partner who looks actively for job (*partner looking for job*) or with a partner who has been doing paid work for the last seven days (*working partner*).
- pdwrk: this variable is equal to 1 if respondent performed at least one hour of paid work during the last seven days, 0 otherwise (definition by Eurostat²). This is the response variable in the model. In the rest of the paper we denominate as *probability of employment* the probability that pdwrk is equal to 1.

The dataset downloaded from the ESS website is richer of information, though full of missing values. Based on experts' knowledge, we have initially included information on religion, sexual orientation and personal opinions, in addition to the covariates listed above. We considered only records with nonmissing values of age and satisfying the points (a) and (b), which resulted in reducing the number of subjects from more than 47,000 to 2908. Then subjects with missing values among the larger set of selected covariates were further excluded; this results into a dataset from 2488 subjects. However, since too many non-informative covariates may influence the quality of the statistical inference we produce under our model, we have fitted preliminary frequentist lasso regression [33, 34] in a rather black-box fashion. This method automatically selects a subset of covariates that are most significant for the response. In our case, information on religion, sexual orientation and personal opinions were discarded as being non-significant.

The final dataset we consider for the Bayesian statistical analysis in this paper has the following characteristics: the sample size is n = 2488 (this is the number of respondents in the dataset), 8 independent variables (covariates, itemized above), and one dependent variable (pdwrk). The empirical sizes of the respondents in the four countries are $n_C = 293$ for Cyprus, $n_P = 437$ for Portugal, $n_{Iv} = 338$ for vulnerable Italian regions, $n_{Ia} = 478$ for affluent Italian regions, $n_{Sv} = 248$ for vulnerable Spanish regions and $n_{Sa} = 271$ for affluent Spanish regions, with $n_C + n_P + n_{Iv} + n_{Ia} + n_{Sv} + n_{Sa} = n$. We refer to this data as SE (South Europe) labour market dataset.

3.2 Exploratory data analysis

We start from reporting summary statistics for the response pdwrk and of the only numerical covariates, age and child. See Table 1.

Figure 1 shows the empirical frequencies of the categorical variables introduced in the previous section. Note that the numeric variable *child* has been discretized with levels 0, 1, 2, 3+. Figure 1 shows that only 2.1% of respondents live with more than three children. As far as *citizen* is concerned, the

 $^{^{2}} https://ec.europa.eu/eurostat/statistics-explained/index.php?title=Glossary:Employed_person_-LFS$

9

Table 1 Empirical mean and standarddeviation of the response, age and child.

Variable	Mean	Standard deviation
pdwrk age	76% 41.55	0.009
child	0.57	0.82

dataset is clearly strongly unbalanced, since only 16% of respondents are immigrants. Other rounds of this type of data, referring to years close to 2018, show the same unbalancedness. Differently from *citizen*, *gender* is balanced.

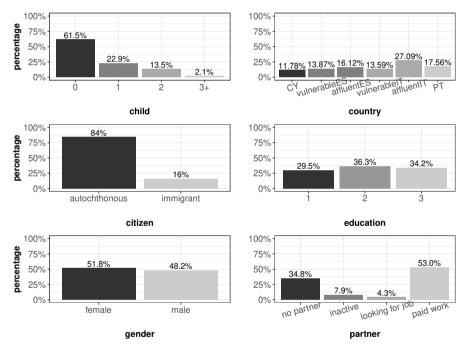

Fig. 1 Empirical frequencies of the categorical covariates in the dataset.

In order to build the model for the posterior analysis, we analyze potential relationships among the covariates. Figure 2 shows boxplots of *age* and *child* (the only numeric covariates in the sample) with respect to categorical covariates such as *citizen*, *education*, *partenr*, factorized by gender. From Figure 2, we see that respondents with high education level are younger, which might reflect the improvement of the education level in European countries during these last decades [35]. Moreover, the empirical distribution of *age* is shifted towards higher values for those respondents living with an inactive partner, especially for women; this could account for women with older partners who may have already retired. Respondents living without a partner and female

respondents with an inactive partner have no child. Here we can observe a remarkable gender difference: the distribution of *child* is shifted toward higher values for men with an inactive partner than for women in the same condition.

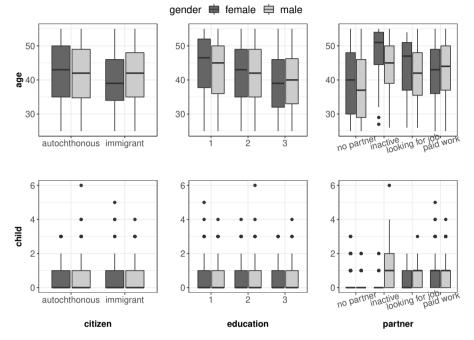

Fig. 2 Boxplots of *age* and *child* for each level of the categories of *citizen*, *education* and *partner*, factorized by gender.

To understand the dependency between categorical variables (except for *country* and *region*), we have performed chi-squared tests of independence; the associated *p*-values are reported in Figure 3. Of course, as a rule of thumb, the smaller is the *p*-value of test in Figure 3, the stronger is the evidence against independence and the darker is the color we have used in the figure.

It is clear that dependence is detected between *partner* on one side and each of *child* or *citizen* or *education* or *gender* on the other; see also the plots at the bottom row of Figure 2. Similarly, there is empirical evidence of dependence between *child* and *citizen*. This is a well-known phenomenon, that immigrants tend to have a larger number of children [36].

Moreover, interactions between age and education, age and partner can be seen from Figure 2.

4 Bayesian modeling of the impact of covariates

This section specifies the model we use in Section 5 for posterior inference on the SE labour market dataset, that is a Bayesian lasso regression model.

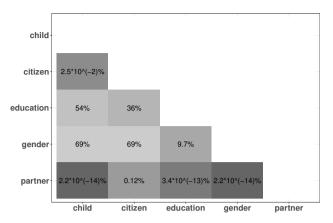

Fig. 3 p-values of chi-squared tests between each pair of categorical variables. The smaller is the p-value, the stronger is the evidence against independence and the darker is the color.

We also include a brief description of the probabilistic programming language, Stan, that is able to build an appropriate Markov Chain Monte Carlo algorithm, to approximate the full posterior distribution.

Generalized linear models (GLM) were introduced by Nelder and Wedderburn [37] by extending ordinary regression models to non-normal response distributions. The logistic regression model, an example of GLMs, is widely used for modeling the relationship between the binary response variable and a set of explanatory variables. Since our reponse variables Y_1, Y_2, \ldots, Y_n (indicator of paid work for the survey respondents) are binary, we fit the following model with logit link function:

$$Y_i | \pi_i \stackrel{\text{ind}}{\sim} Be(\pi_i), \quad i = 1, \dots, n \tag{1}$$

where the logit link is given by

$$\operatorname{logit}(\pi_i) = \boldsymbol{x}_i^t \boldsymbol{\beta}.$$
 (2)

In (2), $\boldsymbol{x}_i = (1, x_{i1}, \dots, x_{ip})$ is a (p+1)-dimensional vector of covariates for $i = 1, \dots, n$, while $\boldsymbol{\beta}$ is a (p+1)-dimensional coefficient vector. The model is completed with the following prior distribution:

$$\beta_j | \lambda \stackrel{iid}{\sim} Laplace(0, 1/\lambda), \quad j = 0, \dots, p$$
 (3)

$$\lambda^2 \sim Gamma(a_\lambda, b_\lambda), \quad a_\lambda > 0, b_\lambda > 0.$$
 (4)

This model represents a Bayesian counterpart of the lasso (least absolute shrinkage and selection operator) method introduced by Tibshirani [33]. The (frequentist) lasso method is a well-known regularization approach for generalized linear models. It shrinks some coefficients and sets others to 0, so performs automatically a subset selection by imposing a penalty term on the objective

function. This penalty term is given by L_1 -norm of the coefficient vector $\boldsymbol{\beta}$ multiplied by a parameter $\lambda \geq 0$, that expresses the amount of shrinkage. The larger is λ , the larger is the penalization on the magnitude of coefficients.

The choice of β which minimizes the lasso penalty as described above corresponds to the Bayes posterior mode of β when the regression coefficients β_j 's are a priori distributed as in (3). As suggested by Park and Casella [34], one can specify a diffuse hyperprior distribution for λ like in (4). This prior allows to perform automatically the variable selection. This means that some coefficients get shrunk to exactly zero as they are not significant for the model.

For our application, we select the variables in Table 2 as covariate x_i in (2). They have been selected according to two criteria: (i) based on the preliminary analysis described in Section 3.2, and (ii) as those variables that are the most significant according to the full Bayesian models, i.e., including all variables and their two-way and three-way combinations. Specifically, this means that we have run our model (1)-(4) including all the covariates described in Section 3.1 and all two-way and three-way combinations for few iterations, and have discarded all the two-way and three-way combinations that were clearly not significative. This results in all the combinations of variables listed in Table 2.

Covariate	Type	Covariate	Type
age	numeric	child	numeric
citizen	binary	education	categorical
country	categorical	gender	binary
partner	categorical	-	-
age∙child	numeric	age·citizen	numeric
age·gender	categorical	child.education	categorical
child.gender	categorical	citizen·education	categorical
citizen·gender	categorical	education.gender	categorical
partner.age	numeric	partner.gender	categorical
age·child·education	numeric	age·child·gender	numeric
education · partner · age	numeric	education.partner.child	numeric
education.partner.gender	categorical	child.gender.education	numeric

Table 2 Independent variables and their combinations included in our statistical model.

Note that all numerical variables have been standardized and categorical variables were transformed into dummies by using the Python function **dmatrix** from the **patsy** package [38]. For example, the covariate *gender* is equal to 1 for female respondent and 0 otherwise. Hence the corresponding regression parameter expresses the algebraic increment on the logit of the success probability in case that the respondent is female. The reference value, represented by the intercept term, corresponds to the logit of the success probability of a native man coming from Cyprus, with education level 1 and without a partner.

All the inference in the Bayesian approach is based on the posterior distribution, i.e., the conditional distribution of (β, λ) , given data y_1, \ldots, y_n and covariates x_1, \ldots, x_n . In general, the posterior distribution is not available in closed analytic form; typical approximations are based on a class of simulation methods known as Markov Chain Monte Carlo (MCMC) [39]. However, MCMC methods can be extremely demanding from the computational point of view and the design of efficient MCMC algorithms is not a simple task. Thanks to the growth of computer processing power and the development of different accurate software products, probabilistic programming languages, which are able to generate MCMC samples in a black-box fashion given the specification of a Bayesian model, Bayesian statistics has become more popular in recent years. Suitable probabilistic programming languages for MCMC methods are JAGS [40] and Stan [41, 42]. The default go-to software is Stan [43], which automatically generates samples from the target distribution, the posterior, using Hamiltonian Monte Carlo (HMC) and No-U-Turn Sampler (NUTS) that provide high-quality chain [44]. There is also an R interface, i.e. the package *rstan* [45], that we use to call the Stan sampler.

5 Posterior inference on the SE labour market dataset

In this section we report posterior inference, such as posterior means and credibility intervals of parameters, for the model described in Section 4 and applied on our dataset presented in Section 3.1. In this work, we fix $a_{\lambda} = 1$ and $b_{\lambda} = 0.1$; see (4). We have run a single chain by Stan for the model described in Section 4. The first 5,000 iterations have been discarded as burn-in and the last 5,000 have been saved for the analysis. First, Section 5.1 reports the inference, while in Section 5.2 we report associated findings and comments.

5.1 Posterior means and 95% credible intervals

Figures 4 and 5 report posterior means and posterior 95% credibility intervals (CI) of each regression parameter. See also Table B2 and Table B3 (in Appendix B) which provide explicit numerical values of the posterior means and posterior 95% intervals of each parameter. As a selection criteria for covariates, we consider hard selection, that is if 0 is contained in the posterior 95% credibility intervals, then the corresponding covariate is not significative and can be removed from the model. We have signed in black all intervals which do not contain 0, while the rest are in light grey. However, to help readability of the plots, we have signed in black also those intervals that do not overlap the zero significantly, i.e. we consider the corresponding covariate to be significant enough. Figure 4 refers to the estimates of regression parameters corresponding to the linear terms and the two-way interactions, while Figure 5 concerns estimates of parameters of three-way interactions.

From the left panel of Figure 4, we see that covariates such as *child*, *region*, *country*, *education*, *gender* and *partner* are significant to explain the success probability, that is the probability of employment. Note that, since the posterior distributions of the regression parameters associated to *gender*[*female*]

Springer Nature 2021 LATEX template

14 Gender inequalities at work in Southern Europe

and *country/vulnerableIT* are concentrated on negative values, being a woman coming from *vulnerable* Italian regions decreases the probability of employment. This confirms that there is difference between regions within Spain and Italy: the probability of being employed in *vulnerable* Italian regions is smaller, but it is higher in *affluent* Italian and *affluent* Spanish regions, given the same value of all other covariates. Living with an inactive partner or having children less than 14 years old increases the probability of employment. Living with an employed partner increase the success probability as the posterior distribution of the regression coefficient of *partner/paid work* is concentrated on the positive values. However, this is not true for women: the negative values assumed by the regression parameter assumed when we include the interaction between being a female respondent and having a working partner, i.e., partner/paid work]-gender/female, demonstrate the negative impact of having an employed partner on the employment probability for women; see the right panel of Figure 4. From the plot on the left of Figure 4 it is evident that a higher education level increases the probability of being employed. Being an immigrant with medium education level decreases the success probability as shown by the plot on the right, probably due to the problem of recognition of education obtained in other countries for immigrants.

From the right panel of Figure 5, we observe other interesting interactions that involve the education level, such as $education \cdot partner \cdot age$ and $education \cdot partner \cdot child$. A higher age can increase the probability of employment for respondents with education level 2 or 3 and without a partner. Having more children less than 14 years old decreases such probability for respondents with education level 1 or 2 and living with an employed partner.

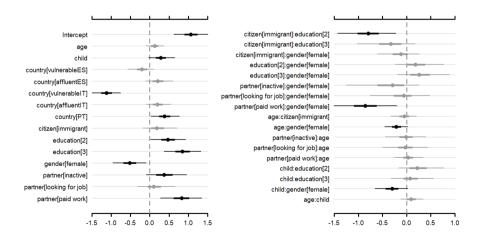

Fig. 4 Marginal posterior credible intervals for regression parameters; the points represent posterior means, the thicker segments are 50% CIs and the thinner ones are 95% CIs. Black intervals denote that the corresponding covariate is significative, i.e., the intervals do not contain 0.

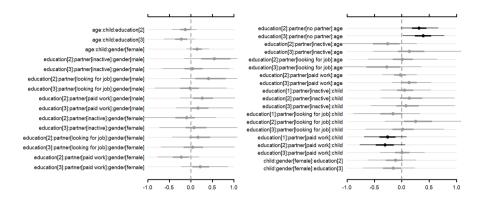

Fig. 5 Marginal posterior credible intervals for regression parameters; the points represent posterior means, the thicker segments are 50% CIs and the thinner ones are 95% CIs. Black intervals denote that the corresponding covariate is significative, i.e., the intervals do not contain 0.

5.2 Profiling respondents

In this section we focus on respondents with particular characteristics and calculate the associated probability of employment, to better understand how those significant covariates (described in Section 5.1) influence the labour participation, possibly across different countries. The resulting plots do not show anything new with respect to the inference displayed in Figures 4 and 5, but they may help in understanding the gender gap in SE labour market.

First, let us consider as *reference* respondents two interviewed people with the following characteristics: not immigrant, having 1 child, with education level 2 and living with an employed partner. We denote these subjects as *female* and *male reference respondents*. Figure 6 shows the posterior medians (continuous lines) of the success probability for each value of *age* for the male and female reference respondents across different countries, while the dashed lines are the posterior 95% credibility bands. It is evident that there is significant difference between genders: the success probability for female reference respondents is always lower than that for male respondent. A larger discrepancy can be observed in the vulnerable regions rather than in the affluent ones.

Another signicant covariate is *child* and we show the success probabilities, as a function of this covariate, for two *reference* respondents with the following characteristics: not immigrant, 42 years old (empirical median of *age*), with education level 2 and living with an employed partner. Figure 7 shows the success probability with 95% posterior credible bands in dashed lines for the female and male reference respondents as a function of the number of children. As a result, as number of children increases, women are more excluded by the labour market, especially in *vulnerable* Italian regions, while men are more

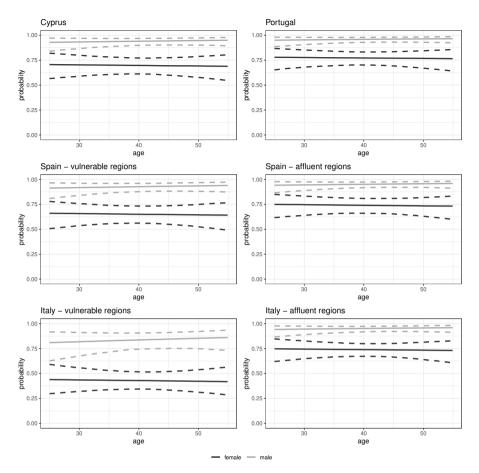

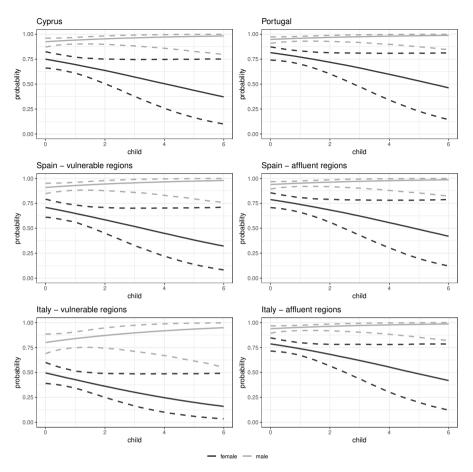

Fig. 6 Probability of been doing paid work in the last 7 days, as a function of *age* between 25 to 55 years old, with posterior 95% credible bands (dashed lines) for male and female reference respondents in different countries of Southern Europe.

likely to be employed. The gender differences becomes more evident with a higher number of children.

From Figure 4 (right) we have seen that one of the significative two-way combination is the interaction between *citizen* and *education*. Table 3 shows the posterior mean of the employment probability for a female/male reference respondent with different education level, citizenship and countries, given that both are 42 years old, have 1 child and live with an employed partner. If we condition to respondent coming from the same country, with the same citizenship status and the same education level, the success probability for any male reference respondent is always higher than that for the associated female respondent. While for the male reference respondents it is true that the higher the education level, the higher the probability of being employed, regardless of being *immigrant* or not, this is not true for female reference respondents.

Gender inequalities at work in Southern Europe 17

Fig. 7 Probability of been doing paid work for the last 7 days, as a function of *child* between 0 and 6, with posterior 95% credible bands (dashed lines) for male and female reference respondents in different countries of Southern Europe.

In fact, in *vulnerable* Italian or Spanish regions, female immigrants with education level 2 are more likely to be excluded from the labour market than those with education level 1. Moreover, the gender difference is particular evident in *vulnerable* Italian regions since the employment probability for female respondents is much lower than that for male respondents.

We now focus on significative three-way interactions pointed out by Figure 5 such as the association between *education*, *partner* and *age* and between *education*, *partner* and *child*. To visualize how the first combination affects the probability of being employed, we have computed such probability as a function of *age* for reference respondents who are not immigrant, have 1 child and live in *vulnerable* Italian regions. The plots are reported in Figure 8; in this case, the 95% posterior credible bands were not included in the figure

Country	Citizen	Education	Gender

 Table 3
 Posterior estimates of success probability for female and male reference

 respondents varying citizenship and education level.

to make the plots clearer. From Figure 8, it is evident that a higher education level increases the employment probability. In particular, education can bring radical changes to women living with an employed partner: female reference respondents with education level equal to 1 have always lower probability of being employed than others in the same condition but with different partner's status (the plot in the top right corner). However, if they are highly educated, i.e., with education level 3, they are more active on the labour market than those living without a partner or with an inactive partner (the plot in the bottom right corner). A larger gender discrepancy can be observed by comparing the success probability for male and female reference respondents with education level 1 (the plots on top): while male respondents with an employed partner are more active on the labour market with respect to other male respondents with different partner's status, female respondents with an employed partner have lower success probability than others. We observe also that ageing is a helpful factor for single respondents, in particularly for women with high education level: while the curve of the employment probability for single female reference respondents with education level 1 is almost flat as age varies, it is clearly increasing for women with education levels 2 or 3.

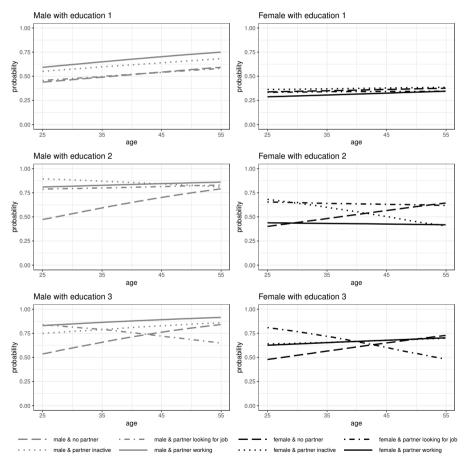

Fig. 8 Probability of been doing paid work in the last 7 days for male and female reference respondents varying age, partner's status and education level in *vulnerable* Italian regions.

To display the interaction between *education*, partner and child, Figure 9 reports the employment probability curves as a function of *child* for male and female respondents with any education level and any partner's status from vulneerable Italian regions (not immigrant, 42 years old). While the trend of the curves remains similar for male reference respondents with different education level or partner's status, it changes significant for female reference respondents. The probability of being employed decreases for women living with an employed partner as the number of children increases, especially if women have low education level. There exists a great difference between female reference respondents with education level 2, but characterized by different partner's status: in case that their partners are inactive or looking for job, they tend to become more active on the labour market with a higher number of children and their probability curves share similar tendencies with those of male reference respondents with education level 2, while they are more excluded by the labour market if living with an employed partner. Note also that the employment probability curves for women living with employed partner and with low education level (level 1 or 2) are quite similar, but they differ significantly from the curve for women highly educated, i.e., with education level 3.

We have repeated the same analysis for reference respondents living in other countries. However, the gender difference is more evident for respondents living in *vulnerable* Italian regions and this is the reason why we have focused on this case here.

6 Discussion and future work

In this article, we have analyzed the determinants of women's access to labour market in South Europe, focusing on Cyprus, Italy, Spain and Portugal. Our findings confirm that individual characteristics of women are mediated by household characteristics in their influence of women's involvement in labour market. On the one hand, education has a significant impact on the access to labour market for both genders, especially for women; the gender gap narrows among highly educated people. Whilst aging can be seen as a helpful factor for men being employed, this does not hold for women. On the another hand, the presence of children and having a partner, particularly having an employed partner, reduce the probability that women work.

The situation becomes more delicate and complicated when taking into account combinations of individual and household characteristics. The gender gap in terms of the access to labour market becomes negligible among highly educated people without partners. For these subjects, the probability of employment increases with ageing, regardless of genders. The presence of children has significant negative impact on the access to labour market for women with low or medium education level and having an employed partner. In these families, women usually provide family-related work, while men take the role of breadwinner due to limited provision of care service in Southern Europe.

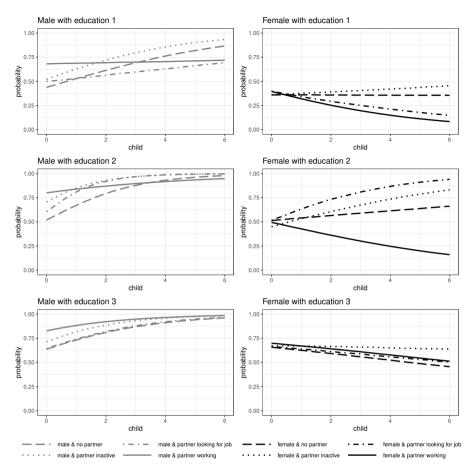

Fig. 9 Curve of the employment probability for male and female reference respondents varying number of children, partner's status and education level in *vulnerable* Italian regions.

Moreover, our findings confirm the uneven distribution of labour market access in South Europe, in accordance with the EIGE inequality index in the domain of access to work: among the Southern European countries included in our the SE labour market dataset, Portugal outperforms other countries in terms of access to labour market. This uneven distribution is strongly dependent on the economic capacity of regions or countries; there are sharp differences between vulnerable and affluent regions, especially in Italy. Moreover, our analysis points out the persistence of the gender inequality in South Europe, more evident in vulnerable Italian regions rather than in other regions. This can be traced back to the radical regional difference in Italy. An attempt to reduce such difference in the supply of early childcare services was made by the nationwide program, "Piano Straordinario per lo Sviluppo dei Servizi per la Prima Infanzia". However, the program effectiveness was nil in the Southern regions, but quite strong in other regions [46].

We also note that subjects with immigrant background and low education level are more likely to be employed than native-born subjects with low education. But the situation is reversed in case that subjects received middle or high education. Indeed, the competencies acquired by immigrants in their country of origin may be not suitable for labour market of the current country due to cultural or language barrier. Thus, access to highly qualified occupations for immigrants might be discouraged by such differences, while access to occupations that do not require specific skills, i.e. manual workers, is more straightforward. Moreover, the effect of education is not linear among immigrants: subjects with medium education level are less active on the labour market than those with low education level. Here one should consider the problem of recognition of education obtained in other countries and the mismatch between jobs and skills among immigrants [36].

In this work, we have assumed that the effect of being from a country (including the classification in Spain and Italy into two group each) is fixed. As future work, we could include this as random effects in generalised linear mixed-effects model, thus assuming a hierarchical model where groups might exchange a priori information as it is customary in these type of Bayesian models. See [47] for an approach of this type on a similar dataset.

Statements and Declarations

Funding

This article has received funding from the Spanish Ministry of Economy and Competitiveness. "Ramon y Cajal" Fellowship RYC2020-029833-I.

Competing Interests

The authors declare that there is no conflict of interest.

Appendix A List of affluent and vulnerable regions of Italy and Spain

As mentioned in Section 3.1, we have calculated the median regional GDP per capita for Italy and Spain separately in 2018: the value equals $23200 \notin$ for Spain and $31700 \notin$ for Italy. The regions whose GDP per capita is lower than the median are considered *vulnerable* regions, otherwise *affluent* ones. This classification procedure results in Table A1.

Appendix B Posterior means and 95% credibility intervals

Tables B2 and B3 report posterior means and marginal posterior 95% credible intervals for all regression parameters in model (1)-(4).

Country	Regions
Italy - affluent regions	Friuli Venezia Giulia, Emilia Romagna, Lazio, Liguria, Lombardia, Marche, Piemonte, Toscana, Trentino Alto Adige, Umbria, Veneto, Valle d'Aosta
Italy - vulnerable regions	Abruzzo,Basilicata, Calabria, Campania, Molise, Puglia, Sardegna, Sicilia
Spain - affluent regions	Aragón, Castilla y León, Cataluña, Cantabria, Comunidad de Madrid, Comunidad Foral de Navarra, Illes Baleares, Galicia, La Rioja, País Vasco
Spain - vulnerable regions	Andalucía, Canarias, Catilla-La Mancha, Comunidad Valenciana, Extremadura, Principado de Asturias, Región de Murcia

Table A1 List of regions classified as affluent or vunerable regions in Italy and Spain.
